We now return to our circular arc. Draw any square that contains the whole circle in its interior (Fig. 21.3). We project each point A_i onto the square, as indicated in the figure. That is, A_i' is the point where $\overrightarrow{DA_i}$ intersects the square. Then $A_{i-1}A_i < A_{i-1}'A_i'$. Therefore p_n is always less than $\Sigma_{i=1}^{n} A_{i-1}'A_i'$. Therefore p_n is always less than the perimeter of the square. Thus the perimeter of the square is the upper bound that we are looking for.

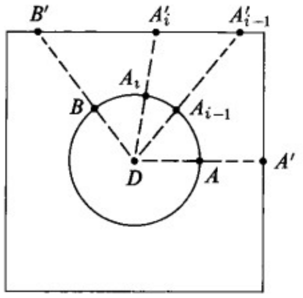

Figure 21.3

This justifies our definition

$$p = \sup P.$$

Of course a circle is not an arc. But we can define the circumference of a circle in an analogous way, by setting up an inscribed polygon with vertices

$$A_0, A_1, \ldots, A_{n-1}A_n = A_0.$$

We then let p_n be the perimeter

$$\sum_{i=1}^{n} A_{i-1}A_i,$$

we let P be the set of all such perimeters p_n, and we define the circumference as

$$p = \sup P.$$

21.2 The Existence of π

We now want to prove the existence of the number π. To do this, we need to show that the ratio of the circumference to the diameter is the same for all circles. This is a theorem about suprema, and to prove it, we need a preliminary result.

Let P be any bounded set of positive numbers, and let k be a positive number. Then kP denotes the set of all numbers of the form kp, where p belongs to P. For example, if

$$P = [0,1] = \{x \mid 0 \leqq x \leqq 1\},$$

and $k = 3$, then

$$kP = 3P = [0,3].$$

If $P = [1,2]$ and $k = \frac{2}{3}$, then $kP = [\frac{2}{3}, \frac{4}{3}]$; and so on.

This "multiplication" is associative. That is,

$$j(kP) = (jk)P,$$

because

$$\{jx \mid x \in kP\} = \{j(kp) \mid p \in P\} = \{(jk)p \mid p \in P\}.$$

Thus, for example, we always have

$$\frac{1}{k}(kP) = P.$$

LEMMA 1. If b is an upper bound of P, then kb is an upper bound of kP.

REASON. If $p \leqq b$, then $kp \leqq kb$.

LEMMA 2. If c is an upper bound of kP, then c/k is an upper bound of P.

PROOF. Since $P = (1/k)(kP)$, this follows from Lemma 1. ☐

These lemmas give us the following theorem.

■ ***THEOREM 1.*** $\sup(kP) = k \sup P$.

PROOF. Let $b = \sup P$. Then b is an upper bound of P. By Lemma 1, kb is an upper bound of kP.

Suppose that kP has an upper bound

$$c < kb.$$

Then c/k is an upper bound of P, by Lemma 2. This is impossible, because $c/k < b$, and b was the *least* upper bound of P. ☐

We can now prove the theorem which establishes the existence of π. What is needed is the following theorem.

■ ***THEOREM 2.*** Let C and C' be circles with radii r, r' and circumferences p, p'. Then

$$\frac{p}{2r} = \frac{p'}{2r'}.$$

That is, the ratio of the circumference to the diameter is the same for all circles. This common ratio is denoted by π.

PROOF. Suppose that the circles have the same center. (This involves no loss of generality.) In the figure, we indicate the ith side $\overline{A_{i-1}A_i}$ of a polygon inscribed in C. To each such polygon there corresponds a polygon inscribed in C', obtained by projection outward (or perhaps inward) from the common center D. We then have

$$\triangle DA_{i-1}A_i \sim \triangle DA'_{i-1}A'_i.$$

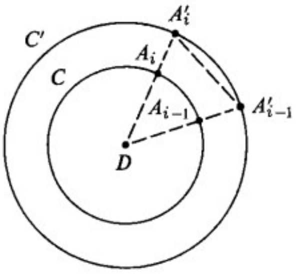

Figure 21.4

Therefore

$$\frac{A'_{i-1}A'_i}{A_{i-1}A_i} = \frac{DA'_i}{DA_i} = \frac{r'}{r}.$$

If the perimeters of our polygons are p_n and p'_n, then we have

$$p'_n = \frac{r'}{r} \cdot p_n.$$

Let

$$p = \sup P \quad \text{and} \quad p' = \sup P',$$

where $P = \{p_n\}$ and $P' = \{p'_n\}$, as usual. Then

$$P' = \frac{r'}{r} \cdot P.$$

Therefore, by the preceding theorem, using $k = r'/r$, we have

$$\sup P' = \frac{r'}{r} \sup P \quad \text{or} \quad p' = \frac{r'}{r} p \quad \text{or} \quad \frac{p'}{r'} = \frac{p}{r}.$$

Dividing both sides by 2, we get the equation called for in the theorem. ☐

An analogous theorem holds for circular arcs.

■ ***THEOREM 3.*** Let $\widehat{AB}$ and $\widehat{A'B'}$ be arcs of the same degree measure, in circles of radius r and r', respectively. Let the lengths of $\widehat{AB}$ and $\widehat{A'B'}$ be p and p'. Then

$$\frac{p}{r} = \frac{p'}{r'}.$$

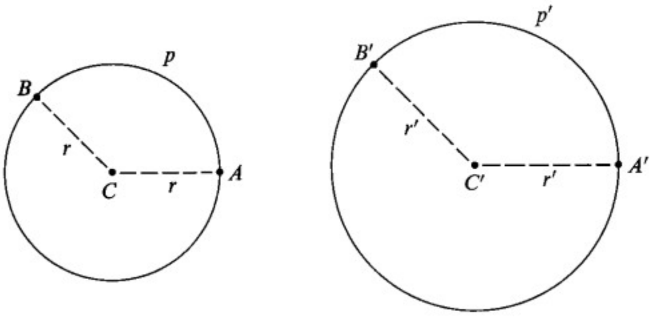

Figure 21.5

This ratio is called the *radian measure* of the arc $\widehat{AB}$. If $\widehat{AB}$ is a minor arc, then p/r is the *radian measure* of the angle $\angle BCA$. The theorem tells us that the radian measure really depends only on the angle, or on the degree measure of the arc, and is independent of the radius of the circle.

The proof is virtually identical with the proof of the preceding theorem.

21.3 Limits as the Mesh Approaches Zero

Given

$$p = \sup P,$$

we know that we can find numbers p_n in the set P, as close to $\sup P$ as we please. More precisely, if ε is any positive number, there is a p_n in P such that

$$p_n > p - \varepsilon.$$

This idea I have generalized and have reduced the expression to measures of the elements taken in pairs. On p. 109 is an important result which I regret does not appear with Chapter I (it should be read between §§ 20, 21), which states that the square of distances, that perpendicular distances and the sine and cosine of angles are reducible to the quotient of two polynomials in

(1) moduli of measures of two points, Ex. $|(ab)|$,
(2) measures of a point and line, Ex. $(a\beta)$,
(3) sines of measures of two lines, Ex. $\sin(\alpha\beta)$,
(4) cosines of measures of two lines, Ex. $\cos(\alpha\beta)$,
(5) measures of the join of two points and a point, Ex. $(\overline{ab}c)$,
(6) measures of the intersection of two lines and a line, Ex. $(\overline{\alpha\beta}\gamma)$.
(7) cosines of the join of two points and a line, Ex. $\cos(\overline{ab}\gamma)$.

9. Imaginary straight lines.

DEF. 4. *The locus of the double points (imaginary) of the overlapping involutions in which an overlapping involution pencil (real) is cut by real transversals is a pair of imaginary straight lines. Each part of this locus, which is continuous, constitutes an imaginary straight line.*

The two straight lines considered as a pair of straight lines are termed a pair of conjugate imaginary straight lines.

Hence it follows that an imaginary straight line is determined by an imaginary point, which is a double point of an involution, and a real point; the vertex of the involution pencil. The conjugate imaginary line is determined by the conjugate imaginary point, the other double point of the involution, and by the same real point, the vertex of the involution pencil. Hence two conjugate imaginary straight lines differ as to their determining elements only in the sign of the imaginary part. An imaginary line considered in reference to the involution pencil is spoken of as a double ray of the pencil.

From the definition it also follows that only one imaginary straight line passes through a given real and a given imaginary point.

The straight line joining the centre of an involution range to the vertex of the pencil is called the mean line of the two conjugate imaginary lines, which join its double points to the vertex of the pencil, This mean line is real. As there are an infinite number of involutions on the same base which have the same centre, there are an infinite number of pairs of imaginary straight lines through a given real point which have the same mean line.

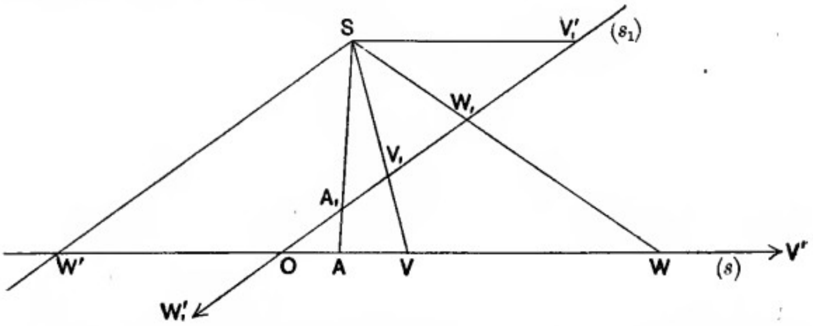
Hence given any real point L and any real straight line o through it, there are an infinite number of pairs of imaginary straight lines which pass through L and which have o as their mean line. Such a system of straight lines may be termed an imaginary system *centre L, mean line o.*

It also follows from the definition that every imaginary straight line passes through a real point, viz. the vertex of the involution pencil of which it is a double ray, and that a pair of conjugate imaginary straight lines intersect in a real point, viz. the vertex of the pencil of which they are the double rays.

10. *To determine the straight line which joins an imaginary point to a real point.*

Construct the involution of which the imaginary point is a double point. (1) If the real point lies on this straight line the required line is the real base of the involution. (2) If the real point does not lie on the base construct an involution pencil by joining pairs of real conjugate points of the involution to the real point. The required line is one of the imaginary double rays of this involution pencil.

To determine the point of intersection of a given imaginary straight line with a given real straight line.



Let the given imaginary straight line be determined as the connector of one of the imaginary double points E of an involution, centre V, constant $-K^2$, situated on a straight line s, with a real point S. Let s_1 be the given real straight line. Let V' and W_1' be the points at infinity on s and s_1 respectively and let ss_1 be O.

Construct V_1 and V_1' the projections of V and V' from S on s_1. Draw SW' parallel to s_1 to meet s in W'. Take W the conjugate of W' in the involution on s. Join W to S to meet s_1 in W_1. Then W_1 is the centre of the involution into which the involution on s is projected from S on s_1. Also $W_1V_1'.W_1V_1 = -M^2$, the constant of this involution on s_1.

Hence, if E be the double point of the involution on s remote from O, the point E_1 in which SE meets s_1 is at a distance $V_1'E_1$ from V_1' such that $V_1'E_1 = V_1'W_1 - \sqrt{W_1V_1 . W_1V_1'}$, the negative sign being given to the square root since $V_1'W_1$ is drawn in the opposite direction to VW.

The following relations hold between the lengths in the figure:

(*a*) $VW' . VW = -K^2, \qquad W_1V_1 . W_1V_1' = -M^2.$

(*b*) Since $(V'W'VW) = (V_1'W_1'V_1W_1)$ and V' and W_1' are at infinity,

$$\frac{VW}{W_1V_1} = \frac{VW'}{W_1V_1'} = \frac{W'W}{V_1'V_1},$$

and $$\frac{VW}{VW'} = \frac{W_1V_1}{W_1V_1'} = \frac{VW^2}{-K^2} = \frac{W_1V_1^2}{-M^2} = \frac{-K^2}{VW'^2} = \frac{-M^2}{W_1V_1'^2} = \lambda \text{ (suppose).}$$

(*c*) Since $$(V'W'OV) = (V_1'W_1'OV_1),$$
$$OW'.OV_1' = VW'.V_1V_1' = WW'.W_1V_1' = AW'.A_1V_1',$$

where A and A_1 are any pair of real points on s and s_1 collinear with S.

If a range composed wholly or partly of imaginary points be projected from a real point by imaginary and real straight lines upon any other real straight line so that a second range is formed on this straight line, the anharmonic ratios of any four corresponding points of these ranges are equal.

It will be proved that if, as in the preceding, V be the centre of the involution which determines an imaginary point E, and W_1 the centre of the involution which determines the corresponding point E_1, then $W'E.V_1'E_1 =$ a constant, where W' and V_1' are the points on the two bases which in a projection from S correspond to the points at infinity. It will also be shown that this constant is equal to the product of the distances of any pair of real corresponding points from W' and V_1' respectively. Hence since W' and V_1' are fixed points the theorem is true.

In the figure

$$\begin{aligned} W'E &= W'V + \sqrt{VW.VW'} & V_1'E_1 &= V_1'W_1 - \sqrt{W_1V_1.W_1V_1'} \\ &= W'V\left(1 - \sqrt{\frac{VW}{VW'}}\right) & &= V_1'W_1\left(1 + \sqrt{\frac{W_1V_1}{W_1V_1'}}\right) \\ &= W'V(1 - \sqrt{\lambda}), & &= V_1'W_1(1 + \sqrt{\lambda}). \end{aligned}$$

Therefore $$W'E.V_1'E_1 = W'V.V_1'W_1(1 - \lambda).$$

But $$1 - \lambda = 1 - \frac{W_1V_1}{W_1V_1'} = \frac{V_1V_1'}{W_1V_1'}.$$

Therefore $W'E.V_1'E_1 = W'V.V_1'V_1 = W'O.V_1'O = W'A.V_1'A_1$.

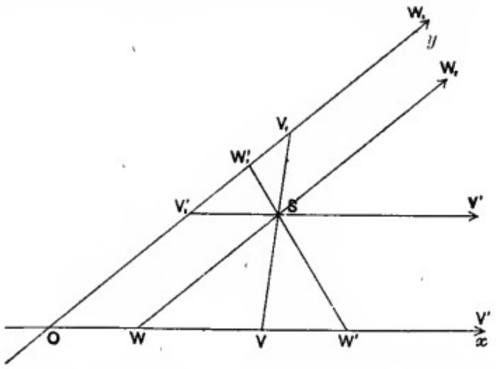
This theorem may be stated as follows:

If through any real point a system of real and of imaginary straight lines be drawn, these straight lines determine equianharmonic ranges on all real transversals.

It also follows that *projective ranges as defined in Art.* 6 *are also projective according to the usual conception.*

Analytical verification of Art. 10.

Let S be the vertex of the pencil and V the centre of the involution on OV. Take OV for axis of x and the given real line OV_1 for axis of y.



Let V' and W_1 be the points at infinity on the axes. Project these from S into V_1' and W. Let SV meet Oy in V_1.

Then V and V' are conjugate points of the involution on Ox, and therefore V_1 and V_1' are conjugate points of the involution on Oy.

Let W_1' be the centre of the involution on Oy.

Then W_1' and W_1 are conjugate points of the involution on Oy, and W and W' are conjugate points of the involution on Ox.

Since S is a given point, $OW\,(l)$ and $OV_1'\,(m)$ are given.

Also the constant of involution on $Ox\,(-b^2)$ is given and the point $V(a)$.

Hence $\quad OW'=a+\frac{b^2}{a-l}$, $\therefore\ OW_1'=\frac{m(b^2+a^2-al)}{b^2+(a-l)^2}$ and $OV_1=\frac{ma}{a-l}$.

Therefore $\quad V_1W_1'=\frac{-mlb^2}{(a-l)\{b^2+(a-l)^2\}}$ and $V_1'W_1'=\frac{ml(a-l)}{b^2+(a-l)^2}$.

Hence $-M^2$ the constant of the involution on Oy is $-\frac{m^2l^2b^2}{\{b^2+(a-l)^2\}^2}$.

Hence the distances of the double points of the two involutions from O are respectively $a+ib$, $a-ib$, and

$$\frac{m(b^2+a^2-al)}{b^2+(a-l)^2}+i\frac{mlb}{b^2+(a-l)^2},\quad \frac{m(b^2+a^2-al)}{b^2+(a-l)^2}-i\frac{mlb}{b^2+(a-l)^2}.$$

But the line joining $S\,(l,\,m)$ to $(a+ib,\,0)$ meets Oy in a point distant

$$\frac{m(a^2+b^2-al)-imbl}{(a-l)^2+b^2}$$

from O. This shows that the geometrical construction of Art. 10 agrees with the analytical conception of an imaginary straight line.

If E and E_1 be collinear double points

$$V_1'E_1 = ml\,\frac{(a-l)-ib}{b^2+(a-l)^2} \text{ and } WE = a-l+ib.$$

$\therefore$ $V_1'E_1 \,.\, WE = ml$, which is a constant for all involutions. This confirms the result of Art. 10.

11. *To determine the straight line connecting any two imaginary points.*

Construct the two involutions of which the two given imaginary points are each respectively a double point.

(1) If the two involutions have the same base this real line is the connector of the two imaginary points.

(2) If the two involutions have different bases, these involutions are in real perspective in two ways (Art. [60]) and in one of these perspectives the two given imaginary points are corresponding points. The required imaginary straight line is the connector of the centre of this perspective, which is real, with either of the two given imaginary points.

From this it follows that *only one straight line can be drawn to join two imaginary points and that it passes through a real point, viz., one of the centres of perspective of the involutions, and therefore no two imaginary straight lines can include a space.*

To determine the point of intersection of any two imaginary straight lines.

Construct the two involution pencils of which the two given imaginary straight lines are each respectively a double ray.

(1) If the two involution pencils have a common vertex, this vertex, which is real, is the point of intersection of the lines.

(2) If the two involution pencils have different vertices, these involutions are in real perspective in two ways (correlative of Art. [60]) and in one of these perspectives the two given imaginary lines are corresponding rays. The point of intersection of these lines is therefore a double point of the overlapping involution determined by the two involution pencils on one of their real axes of perspective.

Hence two imaginary straight lines intersect in only one point and this point lies on a real straight line, viz., one of the axes of perspective of the determining involutions.

12. Summary of properties of imaginary points and straight lines.

(1) *Every imaginary point contains one and only one real straight line.*	*Every imaginary straight line contains one and only one real point.*
This line is the base of the involution of which the imaginary point is a double point and it is the connector of the point and its conjugate imaginary point. There can be no other real straight line through the point for, if there were, the point would be a real point.	This point is the vertex of the involution pencil of which the imaginary line is a double ray and it is the point of intersection of the line and its conjugate imaginary line. There can be no other real point on the straight line for, if there were, the line would be a real straight line.
(2) *The connector of a pair of conjugate imaginary points is real.*	*The point of intersection of a pair of conjugate imaginary straight lines is real.*
(3) *Every real straight line, that contains an imaginary point, contains its conjugate.*	*Every real point, that contains an imaginary straight line, contains its conjugate.*
(4) *An imaginary straight line meets all real straight lines in imaginary points except those which pass through its one real point.*	*The only real points, the connectors of which to an imaginary point are real, are those which lie on the one real line through the point.*
(5) *The connector of a pair of imaginary points is real or imaginary; if real it contains the conjugates of both the points.*	*The intersection of a pair of imaginary lines is real or imaginary; if real it contains the conjugates of both the lines.*
(6) *A system of real and imaginary points on a real straight line is projected from a real point, not on the line, upon another real straight line, into a system in which real points correspond to real points and imaginary points to imaginary points.*	*A system of real and imaginary straight lines through a real point is cut by a real transversal in points which, when connected to another real point, give real straight lines corresponding to real straight lines and imaginary straight lines to imaginary straight lines.*
(7) *The connector of a pair of imaginary points and the connector of their conjugate imaginary points*	*The point of intersection of a pair of imaginary straight lines and the point of intersection of their con-*

are conjugate imaginary straight lines.

(8) *The imaginary double points of an involution are harmonic conjugates of every pair of conjugate points of the involution.*

(9) *If a pair of conjugate imaginary points coincide, they coincide in a real point.*

jugate imaginary lines are conjugate imaginary points.

The imaginary double rays of an involution pencil are harmonic conjugates of every pair of conjugate rays of the involution pencil.

If a pair of conjugate imaginary lines coincide, they coincide in a real line.

13. *In two projective pencils with real vertices, which have two pairs of real corresponding rays, all pairs of corresponding rays, real or imaginary, intersect on a straight line (real) if the ray joining the vertices of the pencils is a self-corresponding ray.*

Let S and S' be the vertices of the pencils. Then by Art. [34], the real pairs of self-corresponding rays intersect on a straight line s. Let an imaginary ray e of the first pencil meet s at E and the corresponding imaginary ray of the second pencil e' meet s at E'. Let the two pairs of real corresponding rays meet s in A, B and let SS' meet s in C.

Then $(ABCE) = (ABCE')$.

Therefore by Art. 5, E and E' coincide and e and e' meet on s.

Correlatively it may be proved that *if the point of intersection of the real bases of two projective ranges, which have two pairs of real corresponding elements, is a self-corresponding point, the connectors of all pairs of corresponding points of the ranges (real or imaginary) pass through a real point.*

If two imaginary lines are corresponding rays of two projective pencils with three pairs of corresponding real rays, the two imaginary straight lines of which they are conjugate imaginary lines are also corresponding rays of the pencils.

Let e and e' be the first pair of corresponding imaginary lines of the pencils. By Art. [37], displace the pencils so that they are in perspective. Then e and e' will intersect on s, the axis of perspective. The point ee' is then an imaginary point since the vertices of the pencils are the real points on e and e'. But s is a real straight line. Hence it passes through the conjugate imaginary point of ee'. Hence the connectors of this point to the vertices of the pencils, i.e., the conjugate imaginary lines of e and e', are corresponding rays of the pencils.

Correlatively it may be proved that *if two imaginary points are corresponding points of two projective ranges with three pairs of corresponding real points, their conjugate imaginary points are also corresponding points of the projective ranges.*

14. The triangle.

The different types of triangles which may occur are as follows, viz.:

(1) *Real Triangle.* A triangle consisting of three real vertices determining three real sides.	*Real Triangle.* A triangle consisting of three real lines determining three real vertices.
(2) *Semi-real Triangle.* A triangle consisting of one real vertex and two conjugate imaginary vertices (on a real line) determining a pair of conjugate imaginary lines (for two sides) and a real line for the third side (on which the pair of conjugate imaginary vertices are situated).	*Semi-real Triangle.* A triangle consisting of one real side and two conjugate imaginary sides (meeting in a real point) determining a pair of conjugate imaginary vertices (lying on the real side) and one real vertex (being the point of intersection of the pair of conjugate imaginary lines which form a pair of sides).
(3) *An imaginary Triangle,* type (*a*). A triangle consisting of one real vertex and two imaginary points situated on a real line determining one real side (on which the imaginary vertices are situated) and a pair of imaginary sides passing through the real vertex.	*An imaginary Triangle,* type (*a*). A triangle consisting of one real side and a pair of imaginary sides passing through a real point, determining one real vertex (through which the pair of imaginary sides pass) and a pair of imaginary vertices on the real side.
(4) *An imaginary Triangle,* type (*b*). A triangle consisting of a pair of conjugate imaginary vertices and a third imaginary vertex, determining one real side (joining the pair of conjugate imaginary vertices) and a pair of imaginary sides.	*An imaginary Triangle,* type (*b*). A triangle consisting of a pair of conjugate imaginary sides and a third imaginary side, determining one real vertex (being the point of intersection of the conjugate imaginary sides) and a pair of imaginary vertices.
(5) *An imaginary Triangle,* type (*c*). A triangle consisting of three imaginary vertices, determining three imaginary sides.	*An imaginary Triangle,* type (*c*). A triangle consisting of three imaginary sides, determining three imaginary vertices.

In all the above cases, except case (4), the triangle and that given by the correlative construction are of the same nature.

15. Extension of Menelaus' theorem.

I. *If an imaginary straight line meets one side of a real triangle in a real point and the other two sides in imaginary points, the product of the ratios of these points, with respect to the triangle, is unity.*

This may at once be deduced from Art. 10. For if a real straight line be drawn through S to meet s and s_1 in A and A_1, the triangle OAA_1 will be a real triangle and the imaginary straight line SEE_1 is a straight line which meets two of the sides in imaginary points E and E_1, and the third side in a real point S.

It follows from Art. 10 that

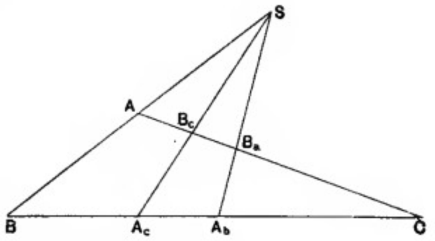
$$(OAEW') = (OA_1E_1\infty).$$

Therefore $$\frac{OE}{AE} : \frac{OW'}{AW'} = \frac{OE_1}{A_1E_1}.$$

But $\dfrac{OW'}{AW'} = \dfrac{A_1S}{AS}$, by similar triangles.

Therefore $$\frac{OE}{AE} \cdot \frac{AS}{A_1S} \cdot \frac{A_1E_1}{OE_1} = 1.$$

The theorem may also be proved independently as follows:



Take a real triangle ABC. Let A_b and A_c be the conjugate points of B and C in an involution (with imaginary double points) on BC.

Take any real point S on AB. From S project A_c and A_b into B_c and B_a.

Then the involution B, A_b, C, A_c is projected from S into A, B_a, C, B_c.

Let the ratios of A_c, A_b be a' and a and of B_c, B_a be b' and b. Then the ratios, x and y, of the double points of the involutions are given by

$$x^2 - 2xa' + aa' = 0$$

and $$y^2 - 2yb + bb' = 0. \qquad \text{(See Art. [61] Ex. (7).)}$$

If c be the ratio of S then

$$cab = 1 \text{ and } ca'b' = 1 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(1)$$

The double points are given by

$$(x - a')^2 = a'(a' - a)$$
$$(y - b)^2 = b(b - b'),$$
$$\therefore\ x = a' \pm \sqrt{a'(a' - a)},\ y = b \pm \sqrt{b(b - b')}.$$

But from (1) $$\frac{a}{a'}=\frac{b'}{b}=\frac{1}{ca'b}=\lambda \text{ suppose,}$$

$$\therefore x=a'\pm\sqrt{a'^2(1-\lambda)},\quad y=b\pm\sqrt{b^2(1-\lambda)}.$$

Let $$x_1=a'(1+\sqrt{1-\lambda}),\ y_1=b(1-\sqrt{1-\lambda});$$

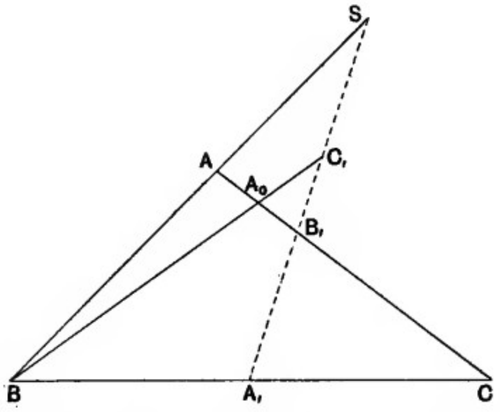
$$\therefore x_1y_1=a'b(1-1+\lambda)=a'b\lambda=\frac{a'b}{ca'b},$$

$$\therefore x_1y_1c=1.$$

Similarly if $$x_2=a'(1-\sqrt{1-\lambda}),\ y_2=b(1+\sqrt{1-\lambda}),$$

then $$x_2y_2c=1.$$

II. *If an imaginary straight line meets the sides of a real triangle in three imaginary points, then the product of the ratios of these points with respect to the triangle is unity.*



Take any real triangle ABC. Draw through B any real transversal to meet AC in A_0 and the imaginary line SB_1A_1 in C_1, where S is real.

Let the ratios of A_1, B_1, C_1 referred to the triangle A_0BC be x, y, z.

Let $$\frac{AS}{BS}=c.$$

Then from the triangle ABC

$$c\,.\,x\,.\,\frac{CB_1}{AB_1}=1 \text{ or } c\,.\,x\,.\,\frac{CB_1}{A_0B_1}\,.\,\frac{A_0B_1}{AB_1}=1 \text{ or } c\,.\,x\,.\,y\,.\,\frac{A_0B_1}{AB_1}=1,\ldots\text{(i)}$$

and from ABA_0

$$c\,.\,\frac{BC_1}{A_0C_1}\,.\,\frac{A_0B_1}{AB_1}=1 \text{ or } c\,.\,\frac{1}{z}\,.\,\frac{A_0B_1}{AB_1}=1.\ \ldots\ldots\ldots\ldots\text{(ii)}$$

Dividing the expressions (i) and (ii)

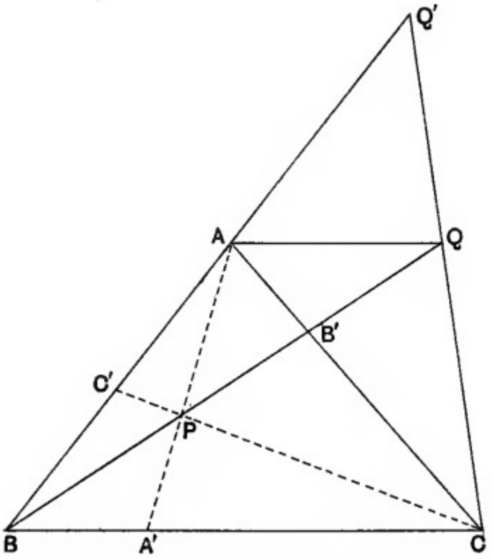
$$\frac{1}{xy}=z,$$

$$\therefore\quad xyz=1.$$

Hence the imaginary line $A_1B_1C_1$ meets the sides of the triangle of reference A_0BC in three points (imaginary) for which Menelaus' theorem holds.

16. Extension of Ceva's theorem.

I. *If the connector of any imaginary point to one of the vertices of a real triangle is real, the product of the ratios of the three points in which its connectors to the vertices meet the opposite sides of the triangle is* -1.



Let P be the imaginary point and let AP, BP, CP, meet the opposite sides of the triangle in A', B', C'. Let BPB' be real. Draw AQ parallel to BC to meet BB' in Q. Join CQ to meet AB in Q'.

Then $\quad (A\,.\,BB'PQ)=(BCA'\infty)$.

But $\quad (C\,.\,BB'PQ)=(BAC'Q')$.

Therefore $\quad (BCA'\infty)=(BAC'Q')$.

$$\therefore\quad \frac{BA'}{CA'}=\frac{BC'}{AC'}:\frac{BQ'}{AQ'}.$$

3. Hyperbolic Geometry

Suppose $w = f(z)$ is a conformal self-map of the open unit disk $\mathbb{D}$. From Pick's lemma we then have equality in (2.2),

$$\left|\frac{dw}{dz}\right| = \frac{1-|w|^2}{1-|z|^2}\,.$$

In differential form this becomes

$$\frac{|dw|}{1-|w|^2} = \frac{|dz|}{1-|z|^2}\,,$$

10. Show that any conformal self-map of the punctured complex plane $\{0 < |z| < \infty\}$ is either a multiplication $z \mapsto az$, or such a multiplication followed by the inversion $z \mapsto 1/z$.

11. Let $D = \mathbb{C} \backslash \{a_1, \dots, a_m\}$ be the complex plane with m punctures. Show that any conformal self-map of D is a fractional linear transformation that permutes $\{a_1, \dots, a_m, \infty\}$.

12. Determine the conformal self-maps of the following domains D: (a) $D = \mathbb{C} \backslash \{0, 1\}$, (b) $D = \mathbb{C} \backslash \{-1, 0, 1\}$, (c) $D = \mathbb{C} \backslash \{-1, 0, 2\}$.

13. Suppose $f(z)$ is an analytic function from the open unit disk $\mathbb{D}$ to itself that is not the identity map z. Show that $f(z)$ has at most one fixed point in $\mathbb{D}$. *Hint.* Make a change of variable with a conformal self-map of $\mathbb{D}$ to place the fixed point at 0.

14. Suppose $f(z)$ is an analytic function from the open unit disk $\mathbb{D}$ to itself that is not a conformal self-map, and denote by $f_n(z)$ the nth iterate of $f(z)$. Show that if $f(z)$ has a fixed point $z_0 \in \mathbb{D}$, then $f_n(z)$ converges to z_0 for each $z \in \mathbb{D}$. Show that for each $r < 1$, the convergence is uniform for $|z| \le r$. *Hint.* See Exercise 1.8.

15. We say that two conformal self-maps f and g of $\mathbb{D}$ are **conjugate** if there is a conformal self-map h of $\mathbb{D}$ such that $g = h \circ f \circ h^{-1}$. (See the exercises for Section II.7.) Let f be a conformal self-map of $\mathbb{D}$ that is not the identity map z. (a) Show that either f has two fixed points on $\partial\mathbb{D}$, counting multiplicity, or f has one fixed point in $\mathbb{D}$. (b) Show that f has a fixed point in $\mathbb{D}$ if and only if f is conjugate to a rotation $g(z) = e^{i\varphi}z$. (c) Show that rotations by different angles are not conjugate. (d) Show that f has two distinct fixed points on $\partial\mathbb{D}$ if and only if f is conjugate to $g(z) = (z - s)/(1 - sz)$ for some s satisfying $0 < s < 1$. (e) Show that g's for different s's are not conjugate. (f) Show that any two conformal self-maps of $\mathbb{D}$ with one fixed point on $\partial\mathbb{D}$ (of multiplicity two) are conjugate.

3. Hyperbolic Geometry

Suppose $w = f(z)$ is a conformal self-map of the open unit disk $\mathbb{D}$. From Pick's lemma we then have equality in (2.2),

$$\left|\frac{dw}{dz}\right| = \frac{1 - |w|^2}{1 - |z|^2}.$$

In differential form this becomes

$$\frac{|dw|}{1 - |w|^2} = \frac{|dz|}{1 - |z|^2},$$

which means that if γ is any smooth curve in $\mathbb{D}$, and $w = f(z)$ is a conformal self-map of $\mathbb{D}$, then

$$\int_{f\circ\gamma} \frac{|dw|}{1-|w|^2} \;=\; \int_\gamma \frac{|dz|}{1-|z|^2}\,. \tag{3.1}$$

Thus to obtain a length function that is invariant under conformal self-maps of $\mathbb{D}$, we are led to make the following definition. We define the **length of γ in the hyperbolic metric** by

$$\text{hyperbolic length of } \gamma \;=\; 2\int_\gamma \frac{|dz|}{1-|z|^2}\,. \tag{3.2}$$

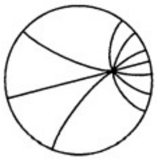
The factor 2 is a harmless factor, which is often omitted. (It adjusts the metric so that its curvature is -1.) The identity (3.1) shows that $f\circ\gamma$ has the same hyperbolic length as γ for any conformal self-map $f(z)$ of $\mathbb{D}$. Thus hyperbolic lengths are invariant under conformal self-maps of $\mathbb{D}$.

We define the **hyperbolic distance** $\rho(z_0, z_1)$ from z_0 to z_1 to be the infimum (greatest lower bound) of the hyperbolic lengths of all piecewise smooth curves in $\mathbb{D}$ from z_0 to z_1. Since conformal self-maps of $\mathbb{D}$ preserve the hyperbolic lengths of curves, they also preserve hyperbolic distances; that is, for any conformal self-map $w = f(z)$ of $\mathbb{D}$,

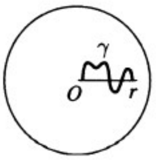
$$\rho(f(z_0), f(z_1)) \;=\; \rho(z_0, z_1), \qquad z_0, z_1 \in \mathbb{D}.$$

Theorem. *For any two distinct points z_0, z_1 in the open unit disk $\mathbb{D}$, there is a unique shortest curve in $\mathbb{D}$ from z_0 to z_1 in the hyperbolic metric, namely, the arc of the circle passing through z_0 and z_1 that is orthogonal to the unit circle.*

The paths of shortest hyperbolic length between points are called **hyperbolic geodesics**. The hyperbolic geodesics play the role that straight lines play in the Euclidean geometry of the plane. They satisfy all the axioms of Euclidean geometry except the parallel axiom (that through each point not on a given line there passes a unique straight line through the point and parallel to the given line).



hyperbolic geodesics



For a proof of the theorem, let $w = f(z)$ be a conformal self-map of $\mathbb{D}$ such that $f(z_0) = 0$. By multiplying by a unimodular constant, we can arrange that $f(z_1) = r > 0$. Since $f(z)$ preserves hyperbolic lengths, and since $f(z)$ maps circles orthogonal to the unit circle onto circles orthogonal to the unit circle, it suffices to show that the straight line segment from 0 to r is a unique path of shortest hyperbolic length from 0 to r. For this, let $\gamma(t) = x(t) + iy(t)$, $0 \leq t \leq 1$, be a piecewise smooth path in $\mathbb{D}$ from 0 to r. Then $\alpha(t) = \mathrm{Re}(\gamma(t)) = x(t)$ defines a path in $\mathbb{D}$ from 0 to r along the real axis, and

$$\int_\alpha \frac{|dz|}{1-|z|^2} = \int_0^1 \frac{|dx(t)|}{1-x(t)^2} \leq \int_0^1 \frac{|dx(t)|}{1-|\gamma(t)|^2} \leq \int_\gamma \frac{|dz|}{1-|z|^2}.$$

If $y(t) \neq 0$ for some t, then $|\gamma(t)| > |x(t)|$, and the first inequality above is strict. In this case, the path $\alpha(t)$ on the real axis is strictly shorter than the path $\gamma(t)$. Further, if $\alpha(t)$ is decreasing on some interval, we could reduce the integral by deleting a parameter interval over which $\alpha(t)$ starts and ends at the same value. We conclude that the integral is a minimum exactly when $\gamma(t)$ is real and nondecreasing, in which case the path is the straight line segment from 0 to r.

We turn now to an important reinterpretation of Pick's lemma.

Theorem. *Every analytic function $w = f(z)$ from the open unit disk $\mathbb{D}$ to itself is a contraction mapping with respect to the hyperbolic metric ρ,*

$$\rho(f(z_0), f(z_1)) \leq \rho(z_0, z_1), \qquad z_0, z_1 \in \mathbb{D}. \tag{3.3}$$

Further, there is strict inequality for all points $z_0, z_1 \in \mathbb{D}$, $z_0 \neq z_1$, unless $f(z)$ is a conformal self-map of $\mathbb{D}$, in which case there is equality for all $z_0, z_1 \in \mathbb{D}$.

To see this, let γ be the geodesic from z_0 to z_1. Then $f \circ \gamma$ is a curve from $f(z_0)$ to $f(z_1)$. Pick's lemma and the definition of the hyperbolic metric yield

$$\begin{aligned} \rho(f(z_0), f(z_1)) &\leq 2\int_{f\circ\gamma} \frac{|dw|}{1-|w|^2} = 2\int_\gamma \frac{|f'(z)|\,|dz|}{1-|f(z)|^2} \\ &\leq 2\int_\gamma \frac{|dz|}{1-|z|^2} = \rho(z_0, z_1). \end{aligned}$$

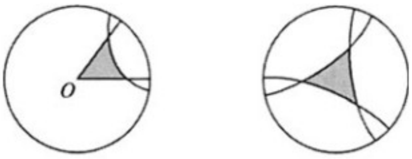
If $f(z)$ is not a conformal self-map of $\mathbb{D}$, there is strict inequality in Pick's lemma, and we obtain strict inequality in this estimate, hence in (3.3).

The hyperbolic distance from 0 to z can be computed explicitly. It is

$$\rho(0, z) = 2\int_0^{|z|} \frac{dt}{1-t^2} = \int_0^{|z|} \left[\frac{1}{1-t} + \frac{1}{1+t}\right] dt = \log\left(\frac{1+|z|}{1-|z|}\right).$$

This shows that the hyperbolic distance from 0 to z tends to $+\infty$ when z tends to the boundary of the unit disk.

A **geodesic triangle** is an area bounded by three hyperbolic geodesics. Since the hyperbolic geodesics and the angles between them are preserved



hyperbolic triangles

by conformal self-maps of $\mathbb{D}$, we can map any geodesic triangle to a triangle with vertex at 0 and with the same angles between sides. For a geodesic triangle with vertex at 0, two of the sides are radial segments, and the third is an arc of a circle lying inside the Euclidean triangle with the two radii as sides. From this representation we see that the sum of the angles of any geodesic triangle is strictly less than π, which is the sum of the angles of the corresponding Euclidean triangle.

In connection with complex analysis, we have now been in contact with three spaces with strikingly different geometries. The first space is the complex plane $\mathbb{C}$ with the usual Euclidean metric $|dz|$. In the Euclidean plane, the geodesics are straight lines, and the sum of the angles of a geodesic triangle is exactly equal to π. The second space is the open unit disk $\mathbb{D}$ with the hyperbolic metric $2|dz|/(1-|z|^2)$. For the hyperbolic disk, the geodesics are arcs of circles orthogonal to the unit circle, and the sum of angles of a geodesic triangle is strictly less than π.

The third space is the extended complex plane $\mathbb{C}^* = \mathbb{C} \cup \{\infty\}$ with the spherical metric, which can be introduced in a manner completely analogous to the hyperbolic metric. Recall (Section I.3) that the chordal metric induced on $\mathbb{C}$ by the Euclidean metric of the sphere via the stereographic projection is given explicitly by

$$\text{chordal distance from } z \text{ to } w \;=\; \frac{2|z-w|}{\sqrt{1+|z|^2}\sqrt{1+|w|^2}}.$$

The infinitesimal form of this metric is $2|dz|/(1+|z|^2)$. If γ is a path in $\mathbb{C}^*$, its **length in the spherical metric** is

$$\text{spherical length of } \gamma \;=\; 2\int_\gamma \frac{|dz|}{1+|z|^2} \;=\; 2\int \frac{|\gamma'(t)|}{1+|\gamma(t)|^2}\,dt\,.$$

This is the length of the corresponding path on the unit sphere in $\mathbb{R}^3$. The **distance from z_1 to z_2 in the spherical metric** is defined to be the infimum of the spherical lengths of the paths joining z_1 to z_2. Since the chordal metric is invariant under rotations of the sphere, so is the spherical metric, and consequently, the lengths of paths and the distances between points in the spherical metric are invariant under rotations. It is not difficult to show that the geodesics in the spherical metric correspond to great circles on the sphere, and the sum of the angles of a geodesic triangle is strictly greater than π.

Each of these three spaces is homogeneous, in the sense that any prescribed point can be transported to any other by an "isometry." Thus for each of these spaces, any scalar quantity that is invariant under isometries is constant. It turns out that a notion of "scalar curvature" can be associated to each of the spaces (see the exercises), and the curvature is invariant under isometries, so that in each case the curvature is constant. The Euclidean plane has constant zero curvature, the sphere has constant positive curvature, and the hyperbolic disk has constant negative curvature. The curvature can be related to the area and the sum of angles of geodesic triangles (Gauss-Bonnet formula). We summarize these properties in tabular form.

Geometry	Euclidean	Spherical	Hyperbolic
Infinitesimal length	$\lvert dz\rvert$	$\dfrac{2\lvert dz\rvert}{1+\lvert z\rvert^2}$	$\dfrac{2\lvert dz\rvert}{1-\lvert z\rvert^2}$
Oriented isometries	$e^{i\varphi}z+b$	rotations	conformal self-maps
Curvature	0	$+1$	-1
Geodesics	lines	great circles	circles $\perp$ unit circle
Angles of triangle	$=\pi$	$>\pi$	$<\pi$
Disk circumference	$2\pi\rho$	$2\pi\rho-\dfrac{\pi\rho^3}{3}+\mathcal{O}(\rho^5)$	$2\pi\rho+\dfrac{\pi\rho^3}{3}+\mathcal{O}(\rho^5)$

spherical disk

hyperbolic disk

Exercises for IX.3

1. Show by direct computation that $|w'(z)| = (1-|w|^2)/(1-|z|^2)$ for any conformal self-map $w = f(z)$ of $\mathbb{D}$.

2. A **hyperbolic disk** centered at $z_0 \in \mathbb{D}$ of radius $\rho > 0$ consists of all $z \in \mathbb{D}$ such that $\rho(z, z_0) < \rho$. (a) Show that the hyperbolic disk centered at 0 of radius ρ is a Euclidean disk of radius $r = (e^\rho - 1)/(e^\rho + 1)$. (b) Show that any hyperbolic disk is a Euclidean disk.

3. Denote by $c(z,\rho)$ and $r(z,\rho)$ the Euclidean center and Euclidean radius of the hyperbolic disk centered at z of hyperbolic radius ρ. (a) For fixed ρ, show that $r(z,\rho)/(1-|z|)$ tends to a constant $A > 0$ as $|z| \to 1$. (b) For fixed ρ, show that $|z - c(z,\rho)|/r(z,\rho)$ tends to a constant B, $0 < B < 1$, as $|z| \to 1$.

4. Show that the circumference of a hyperbolic disk of radius ρ is $2\pi \sinh \rho$. *Hint.* Show first that the hyperbolic circumference of a Euclidean disk of radius r centered at 0 is $4\pi r/(1-r^2)$.

5. We define the **hyperbolic area** of a subset E of $\mathbb{D}$ to be

$$4 \iint_E \frac{dx\, dy}{(1-|z|^2)^2}.$$

Show that the hyperbolic area is invariant under conformal self-maps of $\mathbb{D}$. Show that the hyperbolic area of a hyperbolic disk of radius ρ is given by

$$2\pi(\cosh \rho \;-\; 1) \;=\; \pi\rho^2 + \frac{\pi}{12}\rho^4 + \mathcal{O}(\rho^6).$$

6. Establish the following, for the spherical metric. (a) The circumference of a spherical disk of radius ρ is $2\pi \sin \rho$, $0 < \rho < \pi$. (b) The area of a spherical disk of radius ρ is given by

$$2\pi(1-\cos \rho) \;=\; \pi\rho^2 - \frac{\pi}{12}\rho^4 + \mathcal{O}(\rho^6).$$

(c) The geodesics in the spherical metric correspond to great circles on the sphere. *Hint.* It suffices to show that the shortest curve from 0 to ε in the spherical metric is the straight line segment joining them.

7. Show that an isometry of the hyperbolic disk $\mathbb{D}$ is either a conformal self-map of $\mathbb{D}$ or the composition of a conformal self-map and the reflection $z \mapsto \bar{z}$.

8. Let $f(z) = (az+b)/(cz+d)$, where $ad-bc=1$. Show that $f(z)$ is an isometry in the spherical metric if and only if the matrix $\begin{pmatrix} a & b \\ c & d \end{pmatrix}$ is unitary.

9. Show that the function $f(z) = z^2$ is strictly contracting with respect to the hyperbolic metric on any subdisk $\{|z| \le r\}$, $0 < r < 1$, and that any branch of the square root function is strictly expanding, by establishing the following. (a) For fixed r, $0 < r < 1$, show that

$$\rho(z^2, \zeta^2) \;\le\; \frac{2r}{1+r^2}\rho(z,\zeta), \qquad |z|, |\zeta| \le r.$$

When does equality hold? (b) Show that the constant $2r/(1+r^2)$ in (a) is sharp. (c) For fixed s, $0 < s < 1$, show that

$$\rho\left(\pm\sqrt{z}, \pm\sqrt{\zeta}\right) \;\ge\; \frac{1+s}{2\sqrt{s}}\rho(z,\zeta), \qquad |z|, |\zeta| \le s.$$

10. Show that

$$d(z,w) \;=\; \left|\frac{z-w}{1-\bar{w}z}\right|, \qquad |z|,|w|<1,$$

satisfies the triangle inequality, that is, $d(z,w) \le d(z,\zeta)+d(\zeta,w)$ for all $z,\zeta,w \in \mathbb{D}$. *Remark.* This can be regarded as the analogue of the chordal metric for the sphere (defined in Section I.3). Except for the constant factor 2, the hyperbolic metric is the infinitesimal version of the metric function $d(z,w)$.

11. Show that the metric function $d(z,w)$ defined in the preceding exercise satisfies

$$d(f(z),f(w)) \le d(z,w), \qquad |z|,|w|<1,$$

for any analytic function $f(z)$ from $\mathbb{D}$ to $\mathbb{D}$. Show that equality obtains whenever $f(z)$ is a conformal self-map of $\mathbb{D}$, and otherwise there is strict inequality for all $z \ne w$.

12. A conformal map $g(z)$ of a domain D onto the open unit disk $\mathbb{D}$ induces the metric ρ_D on D defined by

$$d\rho_D(z) = \frac{2|g'(z)|}{1-|g(z)|^2}|dz|, \qquad z \in D.$$

Show that ρ_D is independent of the conformal map $g(z)$ of D onto $\mathbb{D}$. *Remark.* The metric ρ_D is called the **hyperbolic metric** of the simply connected domain D.

13. Show that the hyperbolic metric of the upper half-plane $\mathbb{H}$ is given by

$$d\rho_{\mathbb{H}}(z) = \frac{|dz|}{y}, \qquad z = x+iy,\ y>0.$$

What are the geodesics in the hyperbolic metric? Illustrate with a sketch.

14. Show that the horizontal strip $S = \{-\pi/2 < \operatorname{Im} z < \pi/2\}$ has hyperbolic metric

$$d\rho_S(z) = \frac{|dz|}{\cos y}, \qquad z = x+iy,\ -\pi/2 < y < \pi/2.$$

Sketch the hyperbolic geodesics that are orthogonal to the vertical interval $\{iy : -\pi/2 < y < \pi/2\}$.

15. The **curvature** of the metric $\sigma(z)|dz|$ is defined to be

$$\kappa(z) \;=\; -\frac{1}{\sigma(z)^2}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)\log\sigma(z).$$

Find the curvature of each of the spherical, the hyperbolic, and the Euclidean metrics.

16. (Wolff-Denjoy Theorem.) Let $f(z)$ be an analytic function from $\mathbb{D}$ to $\mathbb{D}$. Let $f_n(z)$ denote the nth iterate of $f(z)$, and let K_r denote the closed disk $\{|z| \leq r\}$.
    (a) Show that if $f(z)$ is not a conformal self-map of $\mathbb{D}$, then for any $r < 1$ there is a constant $c < 1$ such that $\rho(f(z), f(w)) \leq c\rho(z, w)$ for $z, w \in K_r$.
    (b) Show that if the image $f(\mathbb{D})$ is contained in K_r for some $r < 1$, then the iterates $f_n(z)$ converge uniformly on $\mathbb{D}$ to a fixed point for $f(z)$.
    (c) Show that if $f(z)$ is not a conformal self-map of $\mathbb{D}$, and if there is $r < 1$ such that the iterates of some point $z_0 \in \mathbb{D}$ visit K_r infinitely often, then the iterates $f_n(z)$ converge normally on $\mathbb{D}$ to a fixed point of $f(z)$. *Hint.* First find the fixed point.
    (d) Show that if the iterates of some point $z_0 \in \mathbb{D}$ tend to the unit circle $\partial\mathbb{D}$, then there is a point $\zeta \in \partial\mathbb{D}$ (the **Wolff-Denjoy point**) such that the iterates $f_n(z)$ converge normally on $\mathbb{D}$ to ζ. *Hint.* Suppose $z_0 = 0$. Define $g_\varepsilon(z) = (1-\varepsilon)f(z)$, let z_ε be the fixed point of $g_\varepsilon(z)$, and let D_ε be the hyperbolic disk centered at z_ε with 0 on its boundary. Show that the limit D of the D_ε's is a Euclidean disk that is invariant under $f(z)$ and whose boundary meets $\partial\mathbb{D}$ in exactly one point.

X

Harmonic Functions and the Reflection Principle

In Section 1 we introduce the Poisson kernel function and we develop the Poisson integral representation for harmonic functions on the open unit disk. The Poisson kernel is the analogue for harmonic functions of the Cauchy kernel for analytic functions, and the Poisson integral formula solves the Dirichlet problem for the unit disk. In Section 2 we use this solution to characterize harmonic functions by the mean value property. This characterization is the analogue of Morera's theorem characterizing analytic functions. In Section 3 we apply the characterization of harmonic functions to establish the Schwarz reflection principle for harmonic functions. The reflection principle plays a key role in the study of boundary behavior of conformal maps.

1. The Poisson Integral Formula

We wish to extend a given continuous complex-valued function $h\left(e^{i\theta}\right)$ on the unit circle continuously to the closed unit disk $\{|z| \leq 1\}$ so as to be harmonic on the interior of the disk. Any such extension is unique, since the difference of two such extensions is zero on the boundary, hence zero on the entire disk, by the maximum principle. Our strategy is to derive a formula for the extension in the case that $h\left(e^{i\theta}\right)$ is a trigonometric polynomial, and then to show that the formula provides an extension even when $h\left(e^{i\theta}\right)$ is only continuous.

We start with the trigonometric monomial $e^{ik\theta}$. A harmonic extension is given explicitly by $r^{|k|}e^{ik\theta}$. If $k \geq 0$ this extension is $r^k e^{ik\theta} = z^k$, which is analytic. If $k < 0$ this extension is $r^{-k}e^{ik\theta} = \bar{z}^{(-k)}$, which is conjugate-analytic hence harmonic. Proceeding by linearity, we see that the trigonometric polynomial $h\left(e^{i\theta}\right) = \sum_{k=-N}^{N} a_k e^{ik\theta}$ has the (unique) harmonic extension

$$\tilde{h}\left(re^{i\theta}\right) \;=\; \sum_{k=-N}^{N} a_k r^{|k|} e^{ik\theta}.$$

We capture the coefficient a_m by multiplying $h\left(e^{i\theta}\right)$ by $e^{-im\theta}$ and integrating. The orthogonality relations for complex exponentials (Section VI.6) yield

$$a_m \;=\; \int_{-\pi}^{\pi} h\left(e^{i\theta}\right) e^{-im\theta} \frac{d\theta}{2\pi}\,.$$

Substituting this expression into the formula for $\tilde{h}\left(re^{i\theta}\right)$, we obtain

$$\begin{aligned}\tilde{h}(re^{i\theta}) \;&=\; \sum_{k=-\infty}^{\infty} \left(\int_{-\pi}^{\pi} h\left(e^{i\varphi}\right) e^{-ik\varphi} \frac{d\varphi}{2\pi} \right) r^{|k|} e^{ik\theta} \\ &=\; \int_{-\pi}^{\pi} h\left(e^{i\varphi}\right) \left[\sum_{k=-\infty}^{\infty} r^{|k|} e^{-ik\varphi} e^{ik\theta} \right] \frac{d\varphi}{2\pi}\,.\end{aligned}$$

In order to simplify this expression, we introduce the **Poisson kernel function** defined by

$$P_r(\theta) \;=\; \sum_{k=-\infty}^{\infty} r^{|k|} e^{ik\theta}. \tag{1.1}$$

For each fixed $\rho < 1$, this series converges uniformly for $r \leq \rho$ and $-\pi \leq \theta \leq \pi$, by the Weierstrass M-test, since then $\left| r^{|k|} e^{ik\theta} \right| \leq \rho^{|k|}$. In terms of the Poisson kernel, the formula for the harmonic extension $\tilde{h}\left(re^{i\theta}\right)$ becomes

$$\tilde{h}(re^{i\theta}) \;=\; \int_{-\pi}^{\pi} h\left(e^{i\varphi}\right) P_r(\theta - \varphi) \frac{d\varphi}{2\pi}\,, \qquad re^{i\theta} \in \mathbb{D}. \tag{1.2a}$$

If we make a change of variable $\varphi \mapsto \theta - \varphi$ and use the 2π-periodicity of $P_r(\theta)$, we obtain an alternative form of (1.2a),

$$\tilde{h}(re^{i\theta}) \;=\; \int_{-\pi}^{\pi} h\left(e^{i(\theta-\varphi)}\right) P_r(\varphi) \frac{d\varphi}{2\pi}\,, \qquad re^{i\theta} \in \mathbb{D}. \tag{1.2b}$$

Now we look at the Poisson kernel function $P_r(\theta)$ more closely. Setting $z = re^{i\theta}$ and setting $j = -k$ when $k < 0$ in (1.1), we obtain

$$P_r(\theta) \;=\; 1 + \sum_{k=1}^{\infty} z^k + \sum_{j=1}^{\infty} \bar{z}^j.$$

Summing these two geometric series, we obtain

$$P_r(\theta) \;=\; 1 + \frac{z}{1-z} + \frac{\bar{z}}{1-\bar{z}}\,, \qquad z = re^{i\theta} \in \mathbb{D}. \tag{1.3}$$

Putting this over the common denominator

$$|1-z|^2 \;=\; (1-z)(1-\bar{z}) \;=\; 1+r^2-2r\cos\theta,$$

we obtain

$$P_r(\theta) \;=\; \frac{1-|z|^2}{|1-z|^2} \;=\; \frac{1-r^2}{1+r^2-2r\cos\theta}, \qquad z = re^{i\theta}\in\mathbb{D}. \tag{1.4}$$

Since the Poisson kernel is 2π-periodic, we focus on its behavior on the period interval $-\pi \le \theta \le \pi$. From the Poisson integral representation formula (1.2b) for the constant function $h \equiv 1$, we have

$$\int_{-\pi}^{\pi} P_r(\theta)\frac{d\theta}{2\pi} \;=\; 1. \tag{1.5}$$

Three other properties of the Poisson kernel, which follow immediately from the formula (1.4), are

$$P_r(\theta) > 0, \qquad -\pi \le \theta \le \pi, \tag{1.6}$$

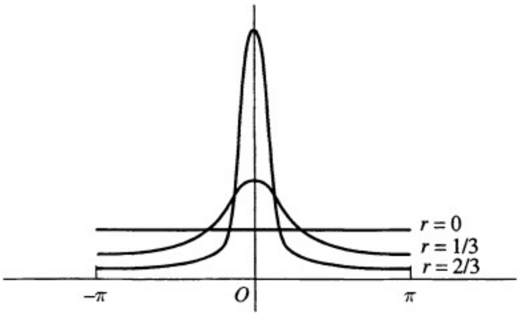
$$P_r(-\theta) = P_r(\theta), \qquad -\pi \le \theta \le \pi, \tag{1.7}$$

(1.8) $P_r(\theta)$ is increasing for $-\pi \le \theta \le 0$ and decreasing for $0 \le \theta \le \pi$.

Since $P_r(\delta) \to 0$ as $r \to 1$ for each fixed $\delta > 0$, we obtain from (1.8) the following key property of the Poisson kernel:

(1.9) for fixed $\delta > 0$, $\max\{\, P_r(\theta) \,:\, \delta \le |\theta| \le \pi \,\} \to 0$ as $r \to 1$.

These five properties, (1.5) through (1.9), are fundamental for understanding the Poisson kernel. Properties (1.5) and (1.6) together show that each $P_r(\theta)d\theta/2\pi$ is a "probability measure," that is, a positive "mass distribution" with unit total mass. Properties (1.5), (1.6), and (1.9) show that the family of functions $P_r(\theta)$ form an "approximate identity," in the sense that the mass of the probability measure $P_r(\theta)d\theta/2\pi$ concentrates at the point $\theta = 0$ as $r \to 1$. Identity (1.7) reflects the symmetry of the Poisson kernel.



Another important property of the Poisson kernel function is that $P_r(\theta)$ is a harmonic function of $z = re^{i\theta}$ for $z \in \mathbb{D}$. In fact, (1.3) yields an explicit representation of the Poisson kernel function as the real part of an analytic function,

$$P_r(\theta) \;=\; 1 + 2\,\mathrm{Re}\left(\frac{z}{1-z}\right) \;=\; \mathrm{Re}\left(\frac{1+z}{1-z}\right), \qquad z = re^{i\theta} \in \mathbb{D}.$$

The Poisson integral formula (1.2a) becomes

$$\tilde{h}(re^{i\theta}) \;=\; \int_{-\pi}^{\pi} h\left(e^{i\varphi}\right) \mathrm{Re}\left(\frac{1 + re^{i(\theta-\varphi)}}{1 - re^{i(\theta-\varphi)}}\right) \frac{d\varphi}{2\pi}.$$

Thus

$$\tilde{h}(z) \;=\; \int_{-\pi}^{\pi} h\left(e^{i\varphi}\right) \mathrm{Re}\left(\frac{e^{i\varphi}+z}{e^{i\varphi}-z}\right) \frac{d\varphi}{2\pi}, \qquad z \in \mathbb{D}. \tag{1.10}$$

If we substitute for $h\left(e^{i\theta}\right)$ a real-valued trigonometric polynomial $u\left(e^{i\theta}\right)$ in this formula, we may take real parts after integrating, and we obtain

$$\tilde{u}(z) \;=\; \mathrm{Re} \int_{-\pi}^{\pi} u(e^{i\varphi})\, \frac{e^{i\varphi}+z}{e^{i\varphi}-z}\, \frac{d\varphi}{2\pi}, \qquad z \in \mathbb{D}. \tag{1.11}$$

The integral depends analytically on the parameter z. Thus (1.11) expresses the Poisson integral $\tilde{u}(z)$ as the real part of an explicit analytic function.

Now we change our point of view. Instead of focusing on trigonometric polynomials, we consider an arbitrary continuous complex-valued function $h\left(e^{i\theta}\right)$ on the unit circle. We define the **Poisson integral** $\tilde{h}(z)$ of $h\left(e^{i\theta}\right)$ to be the function on the open unit disk $\mathbb{D}$ given by

$$\tilde{h}(z) \;=\; \int_{-\pi}^{\pi} h\left(e^{i\varphi}\right) P_r(\theta-\varphi) \frac{d\varphi}{2\pi}, \qquad z = re^{i\theta} \in \mathbb{D}. \tag{1.12}$$

This is just (1.2a), and it can be rewritten as (1.2b). Formula (1.10) still holds, and for real-valued continuous functions $u\left(e^{i\theta}\right)$, formula (1.11) holds.

The correspondence $h \mapsto \tilde{h}$ is linear, that is, the Poisson integral of $c_1h_1 + c_2h_2$ is $c_1\widetilde{h_1} + c_2\widetilde{h_2}$. Also, observe that the maximum principle holds, in the sense that if $|h\left(e^{i\theta}\right)| \le M$ for all θ, then $|\tilde{h}(z)| \le M$ for all $z \in \mathbb{D}$. This follows from (1.5) and (1.6), that is, from the fact that the Poisson kernel determines a probability measure.

Theorem. *Let $h\left(e^{i\theta}\right)$ be a continuous function on the unit circle. Then the Poisson integral $\tilde{h}(z)$ defined by (1.12) is a harmonic function on the open unit disk that has boundary values $h\left(e^{i\theta}\right)$, that is, $\tilde{h}(z)$ tends to $h(\zeta)$ as $z \in \mathbb{D}$ tends to $\zeta \in \partial\mathbb{D}$.*

The harmonicity can be checked by differentiating under the integral sign in (1.12). It can also be seen by decomposing $h\left(e^{i\theta}\right)$ into its real and imaginary parts, $h\left(e^{i\theta}\right) = u\left(e^{i\theta}\right) + iv\left(e^{i\theta}\right)$. Formula (1.11) shows that

$\tilde{u}(z)$ and $\tilde{v}(z)$ are harmonic, and hence $\tilde{h}(z) = \tilde{u}(z) + i\tilde{v}(z)$ is harmonic for $|z| < 1$.

Since the statement about the boundary values is important, we sketch two proofs. The first proof depends upon the fact that any continuous function on the unit circle can be approximated uniformly by trigonometric polynomials. (One way to see this is to approximate the continuous function by a smooth function and then to appeal to the result proved in Section VI.6 that the Fourier series of any smooth function on the unit circle converges uniformly to the function.) The second proof illustrates how the properties of an approximate identity are typically used.

The first proof boils down to the fact that a uniform limit of continuous functions is continuous. It runs as follows. Let $h\left(e^{i\theta}\right)$ be continuous, and let $\varepsilon > 0$. Let $g\left(e^{i\theta}\right) = \sum a_k e^{ik\theta}$ be a trigonometric polynomial such that $\left|h\left(e^{i\theta}\right) - g\left(e^{i\theta}\right)\right| \leq \varepsilon$ for all $e^{i\theta} \in \partial\mathbb{D}$. Then $\left|\tilde{h}(z) - \tilde{g}(z)\right| \leq \varepsilon$ for all $z \in \mathbb{D}$. Now, $\tilde{g}\left(re^{i\theta}\right) = \sum a_k r^{|k|} e^{ik\theta}$ attains the boundary values $g\left(e^{i\theta}\right)$ continuously on $\partial\mathbb{D}$. Hence the composite function equal to $h\left(e^{i\theta}\right)$ on $\partial\mathbb{D}$ and $\tilde{h}\left(re^{i\theta}\right)$ on $\mathbb{D}$ can be approximated to within ε by a continuous function. Consequently, the values $\tilde{h}(z)$ cluster to within ε of $h\left(e^{i\theta}\right)$ as $z \in \mathbb{D}$ tends to $e^{i\theta} \in \partial\mathbb{D}$. Since $\varepsilon > 0$ is arbitrary, $\tilde{h}(z)$ tends to $h\left(e^{i\theta}\right)$ as $z \in \mathbb{D}$ tends to $e^{i\theta} \in \partial\mathbb{D}$.

The second proof depends only on properties (1.5), (1.6), and (1.9) of the Poisson kernel. Again let $\varepsilon > 0$. Choose $M > 0$ such that $\left|h\left(e^{i\theta}\right)\right| \leq M$. Since $h\left(e^{i\theta}\right)$ is uniformly continuous, we can choose $\delta > 0$ so small that $\left|h\left(e^{i\theta}\right) - h\left(e^{i\varphi}\right)\right| < \varepsilon$ whenever $|\theta - \varphi| < \delta$. Using (1.5) we have

$$\tilde{h}(z) - h\left(e^{i\theta}\right) \;=\; \int_{-\pi}^{\pi} \left[h\left(e^{i(\theta-\varphi)}\right) - h\left(e^{i\theta}\right)\right] P_r(\varphi)\frac{d\varphi}{2\pi}\,.$$

Now we take absolute values, break the integral cleverly into pieces, and make the obvious estimate on each piece, to obtain

$$\begin{aligned}
|\tilde{h}\left(re^{i\theta}\right) - h\left(e^{i\theta}\right)| \;&\leq\; \left(\int_{-\delta}^{\delta} + \int_{\delta\leq|\varphi|\leq\pi}\right)\left|h\left(e^{i(\theta-\varphi)}\right) - h\left(e^{i\theta}\right)\right| P_r(\varphi)\frac{d\varphi}{2\pi} \\
&\leq\; \int_{-\delta}^{\delta} \varepsilon P_r(\varphi)\frac{d\varphi}{2\pi} + 2M \max_{\delta\leq|\varphi|\leq\pi} P_r(\varphi) \int_{\delta\leq|\varphi|\leq\pi} \frac{d\varphi}{2\pi} \\
&\leq\; \varepsilon + 2M \max_{\delta\leq|\varphi|\leq\pi} P_r(\varphi).
\end{aligned}$$

By (1.9), the summand on the right tends to 0 as $r \to 1$. Thus again the values $\tilde{h}(z)$ cluster to within ε of $h\left(e^{i\theta}\right)$ as $z \to e^{i\theta}$, this for any $\varepsilon > 0$, so $\tilde{h}(z) \to h\left(e^{i\theta}\right)$ as $z \to e^{i\theta}$.

Exercises for X.1

1. Show that the Fourier coefficients of $P_r(\theta)$ are $c_k = r^{|k|}$, $-\infty < k < \infty$. (Here we fix r, $0 \leq r < 1$, and we regard $P_r(\theta)$ as a function on the circle.)

2. Let $R > 0$, and let $h\left(Re^{i\theta}\right)$ be a continuous function on the circle $\{|z| = R\}$. Show that the function

$$\tilde{h}(z) \;=\; \int_{-\pi}^{\pi} \frac{R^2 - r^2}{R^2 + r^2 - 2rR\cos(\theta - \varphi)} h\left(Re^{i\varphi}\right) \frac{d\varphi}{2\pi}, \qquad |z| < R,$$

   is harmonic on the disk $\{|z| < R\}$ and has boundary values $h\left(Re^{i\theta}\right)$ on the boundary circle.

3. Suppose that $f(z) = u(z) + iv(z)$ is analytic for $|z| < 1$ and that $u(z)$ extends to be continuous on the closed disk $\{|z| \leq 1\}$. Show that

$$f(z) \;=\; \int_0^{2\pi} u(e^{i\varphi}) \frac{e^{i\varphi} + z}{e^{i\varphi} - z} \frac{d\varphi}{2\pi} + iv(0), \qquad |z| < 1.$$

   Remark. This is the **Schwarz formula**, expressing an analytic function in terms of the boundary values of its real part.

4. Let $\{f_n(z) = u_n(z) + iv_n(z)\}$ be a sequence of analytic functions on the open unit disk $\mathbb{D}$ such that $u_n(z)$ extends continuously to $\partial\mathbb{D}$, $u_n\left(e^{i\theta}\right)$ converges uniformly on $\partial\mathbb{D}$ to $u\left(e^{i\theta}\right)$, and $v_n(0)$ converges. Show that $f_n(z)$ converges normally on $\mathbb{D}$ to an analytic function $f(z)$ whose real part is $\tilde{u}(z)$. *Hint.* Use the Schwarz formula.

5. Let $h\left(e^{i\theta}\right)$ be a piecewise continuous function (or an integrable function) on the unit circle. Show that the Poisson integral $\tilde{h}(z)$ tends to $h(\zeta)$ as $z \in \mathbb{D}$ tends to any point ζ of the unit circle at which $h\left(e^{i\theta}\right)$ is continuous.

6. A function $f(z)$, $z \in \mathbb{D}$, is said to have **radial limit** L at $\zeta \in \partial\mathbb{D}$ if $f(r\zeta) \to L$ as r increases to 1. Let $h\left(e^{i\theta}\right)$ be a piecewise continuous function on the unit circle. Show that $\tilde{h}(z)$ has a radial limit at each $\zeta \in \partial\mathbb{D}$, equal to the average of the limits of $h\left(e^{i\theta}\right)$ at ζ from each side.

7. For each $t > 0$, define the kernel function $C_t(s)$ on the real line by

$$C_t(s) \;=\; \frac{t}{\pi} \frac{1}{s^2 + t^2}, \qquad -\infty < s < \infty.$$

   For $h(\xi)$ a bounded piecewise continuous function on the real line, define a function $\tilde{h}(s + it)$ on the open upper half-plane $\mathbb{H}$ by

$$\tilde{h}(s + it) \;=\; \int_{-\infty}^{\infty} C_t(s - \xi) h(\xi)\, d\xi, \qquad s + it \in \mathbb{H}.$$

(a) Sketch the graph of $C_t(s)$ for $t = 1$, $t = 0.1$, and $t = 0.01$. (b) Show that $C_t(s) > 0$ and $\int_{-\infty}^{\infty} C_t(s)\, ds = 1$. (Thus $C_t(s)ds$ is a probability measure.) (c) Show that for each $\delta > 0$, $\int_{\{|s|>\delta\}} C_t(s)\, ds \to 0$ as $t \to 0$. (Thus $C_t(s)ds$ is an approximate identity.) (d) Show that $\tilde{h}(s + it)$ is a bounded harmonic function in the upper half-plane. (e) Show that $\tilde{h}(s+it) \to h(\xi_0)$ as $s + it \in \mathbb{H}$ tends to ξ_0, whenever $h(\xi)$ is continuous at ξ_0. *Remark.* The kernel function $C_t(s)$ is the **Poisson kernel** for the upper half-plane.

8. Let $h\left(e^{i\varphi}\right)$ be a continuous complex-valued function on $\partial\mathbb{D}$, and let $\tilde{h}(z)$ be its Poisson integral.
   (a) Show that

$$\begin{aligned}\frac{\partial^m}{\partial z^m}\tilde{h}(z) &= m! \int_{-\pi}^{\pi} h(e^{i\varphi}) \frac{e^{i\varphi}}{(e^{i\varphi}-z)^{m+1}} \frac{d\varphi}{2\pi}, \qquad z \in \mathbb{D},\\ \frac{\partial^m}{\partial \bar{z}^m}\tilde{h}(z) &= m! \int_{-\pi}^{\pi} h(e^{i\varphi}) \frac{e^{-i\varphi}}{(e^{-i\varphi}-\bar{z})^{m+1}} \frac{d\varphi}{2\pi}, \qquad z \in \mathbb{D}.\end{aligned}$$

   Hint. Use the identity

$$P_r(\theta - \varphi) = 1 + \frac{ze^{-i\varphi}}{1 - ze^{-i\varphi}} + \frac{\bar{z}e^{i\varphi}}{1 - \bar{z}e^{i\varphi}}, \qquad z = re^{i\theta},$$

   and justify differentiating under the integral sign.
   (b) Show that if $\left|h\left(e^{i\theta}\right)\right| \le M$ on $\partial\mathbb{D}$, then

$$\left|\frac{\partial^m}{\partial z^m}\tilde{h}(z)\right| \le m!M \int_{-\pi}^{\pi} \frac{1}{|e^{i\varphi} - \rho|^{m+1}} \frac{d\varphi}{2\pi}, \qquad |z| \le \rho,$$

   with similar estimates for the $\bar{z}$-derivatives.
   (c) Show that if $h\left(e^{i\theta}\right) = e^{-i\theta}\left(e^{i\theta} - z\right)^{m+1}/|e^{i\theta} - z|^{m+1}$, then equality holds in (b) when $|z| = \rho$.

9. Let $\{h_n(e^{i\varphi})\}$ be a sequence of continuous functions on the unit circle $\partial\mathbb{D}$ that converges uniformly to $h(e^{i\varphi})$. Show that for each fixed $\rho < 1$, the partial derivatives of $\tilde{h}_n(z)$ converge to the corresponding partial derivatives of $\tilde{h}(z)$ uniformly for $|z| \le \rho$. *Remark.* It suffices to show this for the partial derivatives $\partial^m/\partial z^m$ and $\partial^m/\partial \bar{z}^m$. See Exercise IV.8.4.

2. Characterization of Harmonic Functions

Recall (Section III.4) that a continuous function $h(z)$ on a domain D has the mean value property if for each $z_0 \in D$, the value $h(z_0)$ is the average of $h(z)$ over any small circle centered at z_0. We have seen that harmonic functions have the mean value property. Here we prove the converse.

Theorem. *Let $h(z)$ be a continuous function on a domain D. Then $h(z)$ is harmonic on D if and only if $h(z)$ has the mean value property on D.*

The proof depends on solving the Dirichlet problem for disks in D. Roughly speaking, the **Dirichlet problem** for a domain U with boundary ∂U is to extend a given function $f(\zeta)$ on ∂U to a harmonic function $\tilde{f}(z)$ on U, so that the harmonic extension $\tilde{f}(z)$ has boundary values $f(\zeta)$. Typically we assume that $f(\zeta)$ is a continuous function on ∂U, and we ask that $\tilde{f}(z)$ attain the boundary values $f(\zeta)$ continuously, in the sense that $\tilde{f}(z)$ tends to $f(\zeta)$ as $z \in U$ tends to $\zeta \in \partial U$. In the preceding section we showed that the Poisson integral solves the Dirichlet problem for the open unit disk $\mathbb{D}$. By making a change of variable $z \mapsto az + b$, we can solve the Dirichlet problem on any disk. An explicit solution is obtained by changing variable in the Poisson integral formula. (See Exercise 1.2.)

So let U be any open disk in D whose boundary is also contained in D. Since the Dirichlet problem is solvable for U, there is a harmonic function $g(z)$ on U that has boundary values $h(z)$ on ∂U. Then $h(z) - g(z)$ is a continuous function on U that has the mean value property on U, and $h(z) - g(z)$ tends to 0 on ∂U. By the maximum principle for functions with the mean value property (Section III.4), $h(z) - g(z) = 0$ on U. Consequently, $h(z) = g(z)$ on U, and $h(z)$ is harmonic on U. Since this holds for all U, $h(z)$ is harmonic on D.

The characterization of harmonic functions by the mean value property is the analogue for harmonic functions of Morera's theorem for analytic functions. The hypothesis involves an integration, which is easier to perform than differentiation. The characterization can be exploited in the same way as the characterization of analytic functions by Morera's theorem. For instance, it can be used to give a simple proof that the limit of a uniformly convergent sequence of harmonic functions is harmonic, since it is easy to check that the uniform limit of functions with the mean value property has the mean value property. It can also be used (Exercise 1) to show that an integral of a function that depends harmonically on a parameter also depends harmonically on the parameter.

It is rather striking that a continuous function with the mean value property automatically has partial derivatives of all orders.

Exercises for X.2

1. Let $g(t, z)$ be a continuous function defined for $a \leq t \leq b$ and z in a domain D, and suppose that $g(t, z)$ is a harmonic function of z for each fixed t. Show that

$$G(z) \;=\; \int_a^b g(t, z)dt, \qquad z \in D,$$

is harmonic on D.

2. Assume that $u(x,y)$ is a twice continuously differentiable function on a domain D.
(a) For $(x_0, y_0) \in D$, let $A_\varepsilon(x_0, y_0)$ be the average of $u(x,y)$ on the circle centered at (x_0, y_0) of radius ε. Show that
$$\lim_{\varepsilon \to 0} \frac{A_\varepsilon(x_0, y_0) - u(x_0, y_0)}{\varepsilon^2} = \frac{1}{4}\Delta u(x_0, y_0),$$
where Δ is the Laplacian operator (Section II.5).
(b) Let $B_\varepsilon(x_0, y_0)$ be the area average of $u(x,y)$ on the disk centered at (x_0, y_0) of radius ε. Show that
$$\lim_{\varepsilon \to 0} \frac{B_\varepsilon(x_0, y_0) - u(x_0, y_0)}{\varepsilon^2} = \frac{1}{8}\Delta u(x_0, y_0).$$

3. For fixed $\rho > 0$, define $h(z) = e^{i\rho \operatorname{Im} z}$. Show that if ρ is a zero of the Bessel function $J_1(z)$, then $\int_\gamma h(z)dz = 0$ for all circles γ of radius 1. *Suggestion.* See the Schlömilch formula (Exercise VI.1.3).

4. Suppose that $r_1, r_2 > 0$ are such that r_2/r_1 is a quotient of two positive zeros of the Bessel function $J_1(z)$. Show that there is a continuous function $g(z)$ on the complex plane such that $\int_\gamma g(z)dz = 0$ for all circles of radius r_1 and for all circles of radius r_2, yet $g(z)$ is not analytic. Use the preceding exercise together with the fact (easily derived from the differential equation in Section V.4) that $J_1(z)$ has zeros on the positive real axis. *Remark.* The condition is sharp. If r_2/r_1 is not the quotient of two positive zeros of the Bessel function $J_1(z)$, then any continuous function $f(z)$ on the complex plane such that $\int_\gamma f(z)dz = 0$ for all circles of radius r_1 and r_2 is analytic, by a theorem of L. Zalcman. There is an analogous result for harmonic functions and the mean value property. According to a theorem of J. Delsarte, if r_1, $r_2 > 0$ are such that r_2/r_1 is not the quotient of two complex numbers for which $J_0(z) = 1$, then any continuous function on the complex plane that has the mean value property for circles of radius r_1 and r_2 is harmonic.

3. The Schwarz Reflection Principle

Suppose a given function is analytic on a domain that abuts on one side of an analytic curve. The Schwarz reflection principle asserts that under certain conditions, the analytic function extends analytically across the curve, and further, there is a formula for the extension. The formula reflects the function analytically to the mirror image of the domain, and the nub of the problem is to establish analyticity on the axis of reflection.

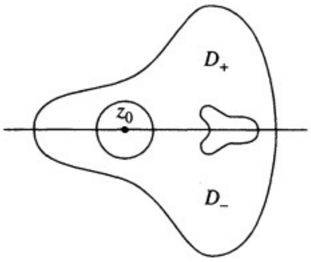
At its core, the Schwarz reflection principle is a theorem about harmonic functions. We begin by reflecting harmonic functions across the real line.

First note that if $u(z)$ is harmonic in a domain D, then $u^*(z) = u(\bar{z})$ is harmonic on the reflected domain $D^* = \{\bar{z} : z \in D\}$. Indeed, if $u(x, y)$ has the mean value property on circles, then so does $u(x, -y)$. Another way to see this is to note that the change of variables $(x, y) \mapsto (x, -y)$ does not change the Laplacian operator Δ.

Theorem. *Let D be a domain that is symmetric with respect to the real axis, and let $D^+ = D \cap \{\operatorname{Im} z > 0\}$ be the part of D in the open upper half-plane. Let $u(z)$ be a real-valued harmonic function on D^+ such that $u(z) \to 0$ as $z \in D^+$ tends to any point of $D \cap \mathbb{R}$. Then $u(z)$ extends to be harmonic on D, and the extension satisfies*

$$u(\bar{z}) = -u(z), \qquad z \in D. \tag{3.1}$$

For the proof, note that D is the disjoint union of $D^+ = D \cap \{\operatorname{Im} z > 0\}$, its reflection $D^- = D \cap \{\operatorname{Im} z < 0\}$, and $D \cap \mathbb{R}$. We extend $u(z)$ to D by defining $u(z) = -u(\bar{z})$ for $z \in D^-$, and setting $u(z) = 0$ for $z \in D \cap \mathbb{R}$. Then $u(z)$ is continuous on D, $u(z)$ is harmonic on D^+ and on D^-, and (3.1) holds. We claim that the extended function has the mean value property. Fix $z_0 \in D$. If z_0 is in D^+ or in D^-, then $u(z)$ has the mean value property for small disks centered at z_0, since $u(z)$ is harmonic near z_0. If $z_0 \in D \cap \mathbb{R}$, then by (3.1) the average value of $u(z)$ over the top half of a circle centered at z_0 cancels the average over the bottom half of the circle, and the average of $u(z)$ over the circle is 0, which coincides with $u(z_0)$. Thus $u(z)$ has the mean value property on D, and $u(z)$ is harmonic on D.



There is a corresponding result for analytic functions. First note that if $f(z)$ is analytic on a domain in the upper half-plane, then $g(z) = \overline{f(\bar{z})}$ is analytic on the reflected domain in the lower half-plane. This can be checked using the Cauchy-Riemann equations or a power series expansion. We can think of $g(z)$ as the composition of an anticonformal map $z \mapsto \bar{z}$, a conformal map $f(z)$ (except where $f'(z) = 0$), and an anticonformal map $w \mapsto \bar{w}$; hence it is conformal.

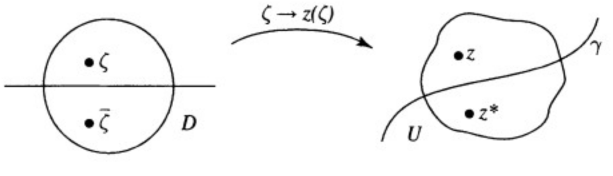
Theorem. *Let D be a domain that is symmetric with respect to the real axis, and let $D^+ = D \cap \{\operatorname{Im} z > 0\}$. Let $f(z)$ be an analytic function on D^+ such that* $\operatorname{Im} f(z) \to 0$ *as $z \in D^+$ tends to $D \cap \mathbb{R}$. Then $f(z)$ extends to be analytic on D, and the extension satisfies*

$$f(\bar{z}) \;=\; \overline{f(z)}, \qquad z \in D. \tag{3.2}$$

For the proof, write $f(z) = u(z) + iv(z)$ in D^+. By the preceding theorem, $v(z)$ extends to be harmonic on D and satisfies $v(\bar{z}) = -v(z)$, $z \in D$. Fix a point $x_0 \in D \cap \mathbb{R}$, and let D_0 be a disk in D centered at x_0. Since $v(z)$ is harmonic on D_0, it has a harmonic conjugate on D_0, and consequently $f(z)$ extends to be analytic on D_0. The function $\overline{f(\bar{z})}$ is also analytic on D_0, and it coincides with $f(z)$ on the real axis, so by the uniqueness principle it coincides with $f(z)$ in D_0. Hence (3.2) holds for $z \in D_0$. If we now extend $f(z)$ to $D^- = D \cap \{\operatorname{Im} z < 0\}$ by setting $f(z) = \overline{f(\bar{z})}$, $z \in D^-$, the extended $f(z)$ is analytic on D^- and coincides with the analytic continuation of $f(z)$ across $D \cap \mathbb{R}$ from D^+, and so is analytic on all of D. Further, it satisfies (3.2) for all $z \in D$.

The above theorem is somewhat easier to prove if it is assumed that $f(z)$ extends continuously from D^+ to $D \cap \mathbb{R}$ and is real-valued there. In this case, formula (3.2) defines a continuous extension of $f(z)$ to all of D, which is analytic on D^-, and we can use Morera's theorem to show that it is also analytic across $D \cap \mathbb{R}$.

We define a curve γ to be an **analytic curve** if every point of γ has an open neighborhood U for which there is a conformal map $\zeta \mapsto z(\zeta)$ of a disk D centered on the real line $\mathbb{R}$ onto U, such that the image of $D \cap \mathbb{R}$ coincides with $U \cap \gamma$. We also refer to such a γ as an **analytic arc**. The conjugation $\zeta \mapsto \bar{\zeta}$ induces a map $z \mapsto z^*$ of U onto itself, by $z(\zeta)^* = z(\bar{\zeta})$. The map is an "involution" in the sense that the map followed by itself is the identity, $z^{**} = z$. Further, $z^* = z$ if and only if $z \in \gamma$. The map $\zeta \mapsto \bar{\zeta}$ interchanges the top half and the bottom half of $D \backslash \mathbb{R}$, which are the two components of $D \backslash \mathbb{R}$, so the map $z \mapsto z^*$ interchanges the two components of $U \backslash \gamma$. We refer to these two components as the **neighborhoods of the sides of** γ, and we refer to the map $z \mapsto z^*$ as the **reflection across** γ. Since the map $\zeta \mapsto \bar{\zeta}$ is anticonformal, and the composition of an anticonformal map and conformal maps is anticonformal, the reflection $z \mapsto z^*$ is anticonformal.



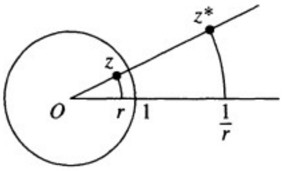
The reflection $z \mapsto z^*$ is unique, in the following sense. If there is an open neighborhood of a point $z_0 \in \gamma \cap U$ and an anticonformal map $z \mapsto z^+$

that fixes each point of γ in the neighborhood, then $z^+ = z^*$. Indeed, the map $z \mapsto (z^+)^*$ is the composition of two anticonformal maps, so it is conformal, hence analytic (Section V.8). Since it fixes points of γ, the uniqueness principle shows that it is the identity map. Thus $(z^+)^* = z$, and $z^+ = (z^+)^{**} = (z^{+*})^* = z^*$.

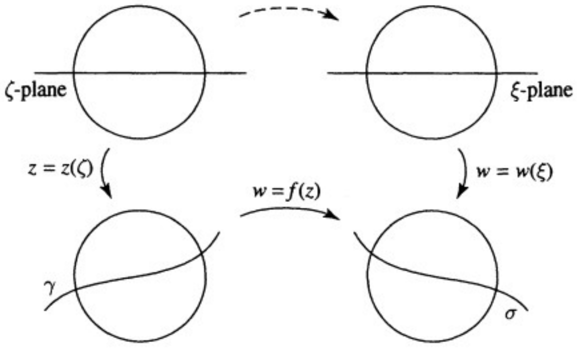
We can extend the involution $z \mapsto z^*$ to a neighborhood of the entire analytic arc γ, by covering γ with small coordinate sets U and using the uniqueness principle to see that the involutions agree on overlapping U's.

Example. The map $z(\zeta) = (\zeta - i)/(\zeta + i)$ sends the extended real line onto the unit circle. It induces a reflection across the unit circle,

$$z^* \;=\; (\bar\zeta - i)/(\bar\zeta + i) \;=\; \overline{(\zeta + i)/(\zeta - i)} \;=\; 1/\bar z \;=\; z/|z|^2.$$



From this formula we see that the reflected point z^* lies on the same ray through the origin as z. The reflection $z \mapsto z^*$ maps the circle centered at 0 of radius r to that of radius $1/r$, sending $re^{i\theta}$ to $e^{i\theta}/r$.

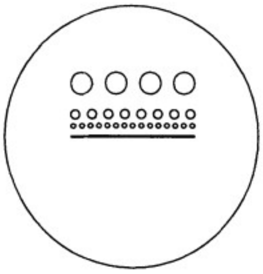


A more general version of the Schwarz reflection principle permits us to reflect harmonic and analytic functions across analytic curves. The idea is that if $w = f(z)$ is defined and analytic on one side of an analytic arc γ, and if the values w tend to another analytic arc σ as z tends to γ, then $f(z)$ extends analytically across γ, and the extension satisfies $f(z^*) = f(z)^*$ in a neighborhood of γ. (Here we use the same notation for both reflections.) It is a straightforward matter to justify the general version by coordinatizing both analytic arcs and reducing to the case of reflection across the real line.

Rather than state a precise theorem, we derive a version of the principle that will be used later.

Let D be a domain. An analytic arc $\gamma \subset \partial D$ is a **free analytic boundary arc** of D if every point of γ is contained in a disk U such that $U \backslash \gamma$ has two components, one contained in D and the other disjoint from D.

Example. Suppose D is obtained from the open disk $\{|z| < 2\}$ by excising a sequence of disjoint closed disks from the top half accumulating on the interval $[-1, 1]$, as in the figure. Then the boundary circle of each excised disk is a free analytic boundary arc of D, but the analytic arc $(-1, 1)$ is not a free analytic boundary arc.



Theorem. *Let D be a domain, and let γ be a free analytic boundary arc of D. Let $f(z)$ be analytic on D. If $|f(z)| \to 1$ as $z \in D$ tends to γ, then $f(z)$ extends to be analytic in a neighborhood of γ, and the extension satisfies*

$$f(z^*) = 1/\overline{f(z)} \tag{3.3}$$

in a neighborhood of γ, where $z \mapsto z^*$ is the reflection across γ.

For the proof, fix a point $z_0 \in \gamma$, and consider a conformal map $\zeta \mapsto z(\zeta)$ of a disk D_0 centered on $\mathbb{R}$ onto an open set containing z_0 so that $D_0 \cap \mathbb{R}$ corresponds to $U \cap \gamma$. Then $g(\zeta) = \log f(z(\zeta))$ is defined and analytic on one side of $D_0 \cap \mathbb{R}$. Further, $\operatorname{Re} g(\zeta) = \log |f(z(\zeta))| \to 0$ as $\zeta \to D_0 \cap \mathbb{R}$. By the Schwarz reflection principle, $g(\zeta)$ extends to be analytic on D_0, as does $f(z(\zeta)) = e^{g(\zeta)}$. Consequently, $f(z)$ extends analytically to U, and the extension is unique. To see that the extension satisfies (3.3), we argue as follows. The function $h(z) = 1/\overline{f(z^*)}$ is the composition of $f(z)$ and the two anticonformal maps $z \mapsto z^*$ and $w \mapsto 1/\bar{w}$. Thus it is conformal wherever $f'(z) \neq 0$. By the equivalence of analyticity and conformality (Section IV.8), $h(z)$ is analytic wherever $f'(z) \neq 0$, and it is continuous, hence analytic also at the isolated points where $f'(z) = 0$. Further, if $z \in \gamma$, then $z^* = z$, and $|f(z)| = 1$, so $h(z) = f(z)$ on γ. By the uniqueness principle, $h(z) = f(z)$ everywhere, and $f(z)$ satisfies (3.3).

Exercises for X.3

1. Show that the reflection in the circle $\{|z - z_0| = R\}$ is given by $z^* = z_0 + R^2(z - z_0)/|z - z_0|^2$.

2. Show that a reflection in a circle maps circles in the plane to circles.

3. What happens to angles between curves when they are reflected in an analytic arc?

4. Suppose the curve γ passing through 0 is the graph of a function $y = h(x)$ that can be expressed as a convergent power series $h(x) = \sum_{k=1}^{\infty} a_k x^k$, $-r < x < r$, where the a_k's are real. (a) Show that $z = \zeta + ih(\zeta)$ can be solved for $\zeta = \zeta(z)$ as an analytic function of z for $|z| < \varepsilon$. (b) Show that γ is an analytic arc. (c) Show that the reflection through γ is given by $z^* = 2\overline{\zeta(z)} - \bar{z}$.

5. Determine the reflection z^* of z across the parabola $y = x^2$. Expand z^* in a power series, in powers of $\bar{z}$. Determine the radius of convergence of the series. Try to explain graphically why the radius of convergence is finite.

6. Let $f(z)$ be an entire function whose modulus is constant on some circle. Show that $f(z) = c(z - z_0)^n$ for some $n \geq 0$ and some constant c, where z_0 is the center of the circle.

7. Show that if $f(z)$ is meromorphic for $|z| < 1$, and $|f(z)| \to 1$ as $|z| \to 1$, then $f(z)$ is a rational function. Show further that $f(z)$ is the quotient of two finite Blaschke products. (For the definition of finite Blaschke product, see Exercise IX.2.1.)

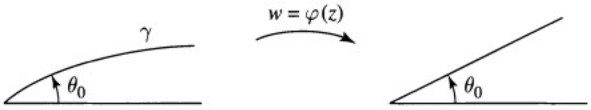
8. The **modulus of an annulus** $\{a < |z - z_0| < b\}$ is defined to be $(1/2\pi)\log(b/a)$. (a) Show that any conformal map from one annulus centered on the origin to another such annulus extends to a conformal self-map of the punctured plane. (b) Show that there is a conformal map of one annulus onto another if and only if the annuli have the same moduli. (c) Show that any conformal self-map of the annulus $\{a < |z| < b\}$ is either a rotation $z \mapsto e^{i\varphi}z$ or a rotation followed by the inversion $z \mapsto ab/z$.

9. Let γ be an analytic curve passing through the origin and tangent to the imaginary axis at 0. Suppose that $\gamma(t) = it + b_2t^2 + b_3t^3 + \cdots$, $-\delta < t < \delta$, where the b_n's are real. Show that there is a conformal map $\varphi(z)$ defined in a neighborhood of 0 such that $\varphi(0) = 0$, $\varphi'(0) = 1$, and $\varphi(z)$ maps the angle between the positive real axis and the segment of γ in the upper half-plane to the angle between the positive real and imaginary axes if and only if γ coincides with its reflection $\bar{\gamma}$ in the real axis. Show that this occurs if and only if $b_n = 0$ for n odd.

10. Let γ be an analytic curve passing through the origin and making an angle θ_0, $0 < \theta_0 < \pi/2$, with the positive real axis. Suppose γ is the image of an interval $(-\delta, \delta)$ under $h(z) = z + i(b_1 z + b_2 z^2 + \cdots)$, where the b_j's are real. Define

$$g(z) = \overline{h(\overline{h^{-1}(z)})}, \qquad \lambda = e^{-2i\theta_0}.$$

(a) Show that $g(z)$ is analytic at $z = 0$, $g'(0) = \lambda$, and $g(z) = \bar{z}$ for $z \in \gamma$.



(b) Show that if $\varphi(z)$ is analytic at $z = 0$, $\varphi(0) = 0$, $\varphi'(0) = 1$, and $\varphi(z)$ maps the angle between the positive real axis and the segment of γ in the first quadrant to the angle between the positive real axis and the straight line segment at angle θ_0, then $\varphi(g(z)) = \lambda\varphi(z)$. *Remark.* This equation for $\varphi(z)$ is **Schröder's equation**.

(c) Show by plugging in power series that any (normalized) solution $\varphi(z)$ of Schröder's equation is unique, if it exists, and is given by $\varphi(z) = z + c_2 z^2 + c_3 z^3 + \cdots$, where

$$c_n = \frac{1}{\lambda^n - \lambda} A_n(\lambda, a_2, \ldots, a_n, c_2, \ldots, c_{n-1}), \qquad n \geq 2,$$

A_n is a polynomial, and the a_n's are the power series coefficients of $g(z)$. *Remark.* The problem of estimating the c_n's to determine whether the series converges is called a "small denominator problem ." As the powers λ^{n-1} return sporadically near to 1, the denominators become sporadically small.

(d) Show that if $\varphi(z)$ is a solution of Schröder's equation (analytic at 0 and satisfying $\varphi(0) = 0$, $\varphi'(0) = 1$), and if $\varphi(x)$ is real when x is real, then $\varphi(z)$ maps the angle between the positive real axis and γ to the angle between the straight line segments at angles 0 and θ_0.

317. The notion of *sine of an angle*, introduced for simplicity in the foregoing article, is of the highest importance for all following geometrical study. But perhaps a more fundamental notion is that of cosine, which we may define thus:

Def. The *ratio of the projection of a tract on a ray to the tract itself* is called the **cosine** of the angle between the ray and the tract (Fig. 187).

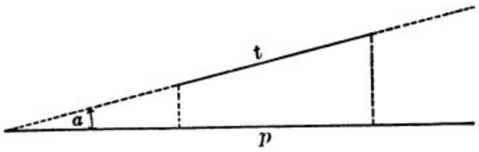

FIG. 187.

317. The notion of *sine of an angle*, introduced for simplicity in the foregoing article, is of the highest importance for all following geometrical study. But perhaps a more fundamental notion is that of cosine, which we may define thus:

Def. The *ratio of the projection of a tract on a ray to the tract itself* is called the **cosine** of the angle between the ray and the tract (Fig. 187).

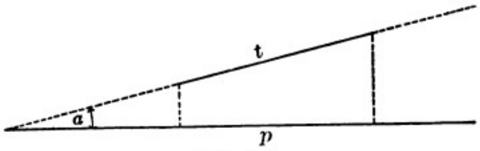

FIG. 187.

Thus the ratio of the projection p of the tract t to the tract itself is the cosine of the angle α between them; or $p : t = \underline{\alpha}$, as we may write **cosine of** α, which is commonly abbreviated into **cos** α.

318. It is plain that the projections of t on parallel rays are all equal; hence we may suppose the ray of projection drawn through the beginning of t, as in Fig. 188. Then as t turns about o and α changes its value, the projection p of t will also change. Thus: for

$$\alpha = 0,\ 60°,\ 90°,\ 120°,\ 180°,\ 270°,\ 360°,\ 420°,\ \cdots$$

$$\underline{\alpha} = 1,\ \tfrac{1}{2},\ 0,\ -\tfrac{1}{2},\ -1,\ 0,\ 1,\ \tfrac{1}{2},\ \cdots$$

319. In the 2d and 3d quadrants the projection p is reckoned leftward; it is opposite in sense to the projection when α is in the 1st or 4th quadrants, and accordingly the cosine is marked $-$. When α increases by 360° (or 2π, see Art. 336) from any value, the revolving tract resumes its original position, the projection resumes its original value, and so too does the cosine; hence

$$\cos(360^\circ + \alpha) = \cos(2\pi + \alpha) = \cos\alpha;$$

that is, *the cosine is not changed by increasing* (or decreasing) *the angle by a round angle.*

Hence, plainly, $\cos(\alpha \pm 2n\pi) = \cos\alpha$.

Hence the cosine is called a **periodic function*** of the angle, the **period** being 2π, that is, a *round angle* (see Art. 336).

320. If t be turned through any angle α from the position OA, its projection p is the same whether the turning be clockwise or counter-clockwise; that is, the projection is the same whether the angle be negative or positive; hence, too, the cosine is the same.

That is, $\cos(-\alpha) = \cos\alpha$;

that is, *the cosine of the angle is unchanged by changing the sense* (or sign) *of the angle.* Now we learn in Algebra that only the even powers, not the odd powers, of a symbol are unchanged by changing the sign of the symbol; thus:

$$(-\alpha)^2 = \alpha^2,\ (-\alpha)^4 = \alpha^4, \text{ but } (-\alpha)^3 = -\alpha^3.$$

Hence the cosine is called an **even** function of the angle.

Its *periodicity* and its *evenness* are the two cardinal properties of the cosine, on which all others hinge.

321. We may now arbitrarily define the **sine** of an angle to be the **cosine of the complemental angle**; *i.e.* $\underline{90^\circ - \alpha} = \alpha|$, as we may write **sine of** α, which is commonly abbreviated into **sin** α.

---

* Two magnitudes such that the values of the one *correspond* to values of the other are called *functions* of each other.

Now write $90^\circ - \beta$ for α;

we obtain

$$\cos\{90^\circ - (90^\circ - \beta)\} = (90^\circ - \beta)|, \text{ or } \underline{\beta} = (90^\circ - \beta)|;$$

i.e. *the cosine of an angle is the sine of the complemental angle.*

Hence the sine (or cosine) of either of two complemental angles, as α and β, is the cosine (or sine) of the other; *i.e.* if $\alpha + \beta = 90^\circ$, then $\underline{\alpha} = \beta|$, and $\alpha| = \underline{\beta}$. When either changes by 2π, so does the other oppositely; hence the sine as well as the cosine returns into its original value; *i.e. the sine is also periodic with the period* 2π.

322. If the tract t be reversed, that is, turned through a straight angle, its projection will also be reversed, but otherwise unchanged; hence the cosine will be reversed; that is,

$\cos(\alpha + \pi) = -\cos\alpha$; also $\cos(\alpha - \pi) = \cos(\alpha + \pi)$ (why?);

hence $$\cos(\alpha - \pi) = -\cos\alpha,$$

or, *to change the angle by the half-period, π, changes the sign of the cosine.*

323. Since the cosine is an even function,

$$\cos(\alpha - \pi) = \cos(\pi - \alpha);$$

hence $$\cos(\pi - \alpha) = -\cos\alpha.$$

That is, since α and $\pi - \alpha$ are supplemental, *the cosines of supplemental angles are counter* — equal in size, but opposite in sense (or sign).

324. Again, if $\alpha + \beta = 90^\circ$, then $\alpha| = \beta$ (why?).

Then $$(\alpha + \pi)| = \underline{\beta - \pi} \text{ (why?)} = -\underline{\beta} = -\alpha|.$$

That is, *to change the angle by the half-period, π, changes the sense of the sine* as well as of the cosine.

FIG. 190.

We now ask, how is the sine affected by changing the sense of the angle? We have

$(-\alpha)| = \underline{90^\circ + \alpha}$ (why?) $= -(\underline{90^\circ - \alpha})$ (why?) $= -(\alpha)|$;

that is, *the sense of the sine changes when the sense of the angle changes*. But this is the property only of *odd* powers, not of even powers, of a symbol;

thus $\quad (-a)^3 = -a^3,\ (-a)^5 = -a^5,$ etc.

Hence the sine is called **odd** function of the angle.

Its *periodicity* and its *oddness* are the cardinal properties of the sine, on which all others hinge.

325. If q be the projector of the tract t then $\frac{q}{t}$ is plainly the sine of the angle α for every position of t. We may indeed *define* the sine of α as equal to this ratio, and from this definition readily deduce all the foregoing properties (Figs. 188, 189, 190).

Exercises. 1. Prove that $(\alpha|)^2 + (\underline{\alpha})^2 = 1$.

2. Find the value of $\alpha|$ for $\alpha = 0, 30^\circ, 45^\circ, 60^\circ, 90^\circ, 120^\circ, 150^\circ, 180^\circ, 210^\circ, 225^\circ, 240^\circ, 270^\circ, 300^\circ, 330^\circ, 360^\circ, 390^\circ$.

3. If a, b, c, be the sides of a $\triangle$, α, β, γ the opposite angles, r the circumradius, prove that

$$\frac{a}{\alpha|} = \frac{b}{\beta|} = \frac{c}{\gamma|} = 2\,r.$$

Such is the **Law of Sines** (Fig. 191).

4. Prove that $a^2 = b^2 + c^2 - 2\,bc\underline{\alpha}$, — **Law of Cosines.**

5. If a and b are adjacent sides of a $\square$, and $\widehat{ab}$ denote the angle between them, prove that $\square = ab \cdot \widehat{ab}|$.

N.B. We may *define* the sine from this important theorem thus: *The sine of the angle between two sides of a $\square$ is that* *number which taken as a multiplier turns the area of the rectangle of the sides into the area of the* ▱.

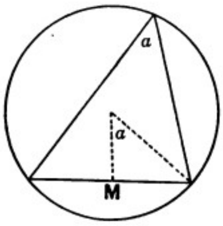

FIG. 191.

326. If we project successively the sides of a closed polygon on any ray, *the sum of the projections will be* 0; for the end of the projection of the last side falls on the beginning of the projection of the first. This fact is very important in surveying, where in compassing a field the sum of the northings must equal the sum of the southings, and these two sums, having opposite senses, together make the whole sum 0.

So for the eastings and westings.

We may express this fact in symbols thus:

$$s_1\underline{\alpha}_1 + s_2\underline{\alpha}_2 + s_3\underline{\alpha}_3 + \cdots + s_n\underline{\alpha}_n = 0 = \Sigma s\underline{\alpha}.$$

Here the s's are the sides, the α's are the angles of the sides with a fixed ray, as the east and west line, $s\underline{\alpha}$ is the projection of a side, and Σ is the symbol of summation.

Exercise. Show by projecting on a ray normal to the first ray that $\Sigma s\alpha| = 0$.

327. If we project consecutively all the sides of a polygon but one on that one, *the sum of the projections will be that one itself.* For the beginning of that side is the projection of the beginning of the first, and its end is the projection of the end of the last, of the projected sides (Fig. 192).

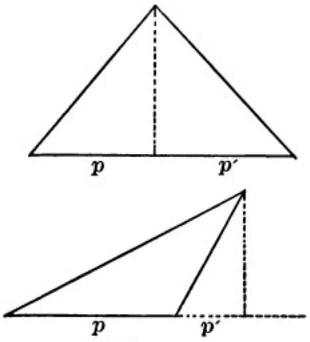

FIG. 192.

Thus, in a △, the sum of the projections of two sides on the third is the third.

328. We make a most important application of this simple fact in finding the *cosine of the difference of two angles* (Fig. 193).

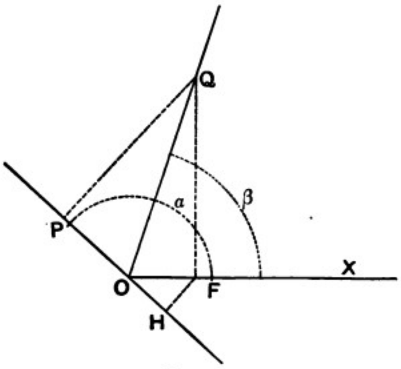

FIG. 193.

Let OP and OQ make angles α and β with any fixed ray OX. Then angle $QOP = \alpha - \beta$. Now project any tract OQ on OP; there $OP = OQ \cdot \underline{\alpha - \beta}$. But instead of projecting OQ directly we shall obtain the same result by projecting consecutively OF and FQ. The projection of OF is $OF \cdot \underline{\alpha}$, and of FQ is $FQ \cdot \alpha|$. But $OF = OQ \cdot \underline{\beta}$, and $FQ = OQ \cdot \beta|$.

$$\text{Hence} \quad OP = OQ \cdot \underline{\alpha - \beta} = OQ \cdot \underline{\alpha} \cdot \underline{\beta} + OQ \cdot \alpha| \cdot \beta| .$$

$$\text{Or,} \qquad \alpha - \beta = \alpha \cdot \beta + \alpha| \cdot \beta| .$$

By changing the sense of β and by putting $90 - \alpha$ instead of α, let the student show that $\underline{\alpha + \beta} = \underline{\alpha} \cdot \underline{\beta} - \alpha| \cdot \beta|$, $(\alpha + \beta)| = \alpha| \cdot \underline{\beta} + \underline{\alpha} \cdot \beta|$, $(\alpha - \beta)| = \alpha| \cdot \underline{\beta} - \underline{\alpha} \cdot \beta|$.

These four formulæ express the **Addition-Theorem** of Sine and Cosine.

The doctrine of Functions of Angles constitutes Trigonometry — an extremely important subject, which cannot be pursued any further here. See Smith's *Clew to Trigonometry.*

MEASUREMENT OF THE CIRCLE.

329. Thus far our linear measurements, or comparisons of length, have been wholly of tracts. The peculiar simplicity of such operations is due to the fact that any tract may be superposed (at least in thought) on any other, and thus their equality or inequality infallibly tested. We may similarly compare arcs of equal circles, but not arcs of unequal circles, nor arcs and tracts; for these cannot be made to fit on each other to even the smallest extent. We feel sure indeed that a circle or arc has a perfectly definite length, that it is longer than some tracts, shorter than others, and equal to some others. For if we suppose an inextensi-

ble cord wrapped around a circular disk, on unwinding and straightening the cord we should obtain a tract equal to the circle in length. But it remains difficult or impossible to fix the notion of the length or to determine the length itself without some preliminary definitions and assumptions.

We assume then that a circle has a definite length, neither more nor less; also, that it bounds a definite area, neither more nor less.

330. We now inscribe in the circle of radius r a regular n-side, and parallel to this latter we circumscribe a regular n-side; then bisecting each arc subtended by a side of the inscribed n-side we inscribe a regular $2n$-side and also circumscribe parallel to it a regular $2n$-side.

Then the following facts are at once evident:

1. The area of any inscribed polygon is less, and the area of every circumscribed polygon is greater, than the area of the circle; or if I_n, S, and C_n designate these areas, then

$$I_n < S < C_n \text{ (why?)}.$$

2. The area of the inscribed $2n$-side is greater than that of the inscribed n-side, while the area of the circumscribed $2n$-side is less than that of the circumscribed n-side; or,

$$I_{2n} > I_n,\ C_{2n} < C_n \text{ (why?)}.$$

3. The area of each regular n-side is half that of the rectangle of the perimeter and the central normal on a side, and in case of the circumscribed polygons this normal is the radius r, but in case of the inscribed polygons this normal, or **apothem**, a_n, is less than r.

4. The perimeters of inscribed and circumscribed n-sides are to each other as a_n and r; for they are similar polygons, and a_n corresponds to r.

5. Since the area of the circumscribed n-side decreases as n increases, and since one dimension, the radius, remains constant, it follows that the other dimension, the (half) perimeter, must decrease with increasing n. For $n = 4$ the polygon is a circumsquare, and the perimeter is $8r$.

6. Since the sum of two sides of a △ is greater than the third side, it follows that the perimeter of the inscribed n-side increases with increasing n. For $n = 6$ the perimeter is $6r$. Hence for all higher values of n the perimeters of both inscribed and circumscribed polygons lie between $6r$ and $8r$.

7. Since then the sum of the n-sides is certainly less than $8r$, by making n large enough we can make each side, whether of inscribed or circumscribed polygon, as small as we please, smaller than one millionth, smaller than one billionth, smaller than any assigned magnitude however small.

8. But the half-side of the regular inscribed n-side is a geometric mean between the segments of the normal diameter; *i.e.*

$$r + a_n : \frac{S_n}{2} :: \frac{S_n}{2} : r - a_n.$$

As S_n is small at will, so is $\frac{S_n}{2}$, and still more is $r - a_n$, which we may call d_n, the distance between the parallel sides of the inscribed and circumscribed polygons.

N.B. A magnitude small at will is often called an **infinitesimal.** Since $r - a_n$ or d_n is infinitesimal with respect to $\frac{S_n}{2}$, which is itself infinitesimal, it (d_n) is called an infinitesimal of *2d order*. But we are not now concerned with this fact.

9. The difference in area between the circumscribed and the inscribed n-sides is a trapezoid the half-sum of whose parallel sides is less than $8r$, the altitude being d_n. Since $8r$ is finite and definite while d_n is small at will, it follows that the difference in area of the circumscribed and inscribed regular polygons is small at will.

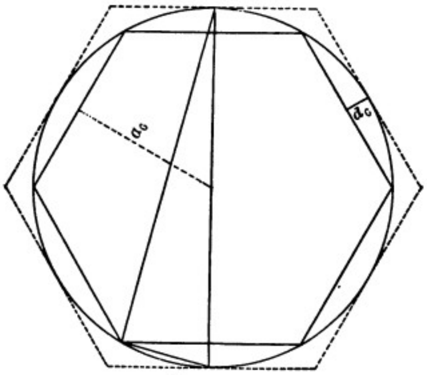

FIG. 194.

10. Again, we have from similar homothetic figures,

$$\text{Perimeter of } C_n : \text{Perimeter of } I_n :: r : r - d_n.$$

Hence, *dividendo*,

$$\text{Perimeter } C_n : \text{Perimeter } C_n - \text{Perimeter } I_n :: r : d_n.$$

But d_n is small at will; so too then is $D_n =$ Perimeter C_n − Perimeter of I_n; *i.e.* the difference in perimeter of the circumscribed and inscribed regular polygons is *small at will.*

11. The circle lying always wholly between the two polygons inscribed and circumscribed both in position and in areal value, it follows that the difference between its area

and the area of either polygon is small at will; and since the circle is fixed both in area and in position, it follows that the circle is the **Limit** of both polygons, and that the polygons close down upon it close at will as *n* grows ever larger and larger.

331. Think of the polygonal strip between the inscribed and circumscribed *n*-sides as growing ever narrower and narrower; the circle is a fixed *boundary* toward which the circumscribed *n*-side shrinks down as *n* increases, and in such a way that there is no assignable point outside of the circle, no matter how close to it, that will not also fall outside of the circumscribed *n*-side as *n* increases. Likewise the circle is the fixed *boundary* toward which the inscribed *n*-side swells out as the *n* increases, and in such fashion that there is no assignable point inside of the circle (no matter how close to it) that will not fall inside of the inscribed *n*-side as *n* increases. Thus the inscribed and circumscribed *n*-sides close down upon each other so as to leave no point between *except the points of the circle itself.* As *n* increases, the polygons *tend* to absolute coincidence with each other and with the circle. This fact is expressed fully and accurately by saying that the circle is the common **Limit** in length, in area, in position, of the inscribed and circumscribed regular *n*-sides for increasing *n*; it is expressed elliptically and inaccurately, but conveniently and frequently, by saying that the circle is or may be regarded as a *regular polygon of an infinite number of sides.*

332. The area of a circumscribed *n*-side is half the area of the rectangle of the radius of the circle and the perimeter of the polygon, for all values of *n*. Hence the area of the circle is half the rectangle of radius and the perimeter; that

is, the circle. The numeric expressing the ratio of the circle to its diameter is called the *perimetric ratio*, and is designated by the Greek initial of perimeter, π. It is an irrational and hence not expressible exactly as a fraction, whether common or decimal, but its value has been calculated in various ages to various degrees of exactitude, and may be calculated to any degree of exactitude. Of late years it has been calculated (by Shanks) to the 707th decimal place, and verified to the 500th — a degree of accuracy immensely higher than can be attained in any measurement. For most practical purposes the value $\pi = 3.14159$ or even 3.1416 is close enough.

If then r be the radius, $2\pi r$ is the length of the circle, and $\pi r \cdot r$, or πr^2, is its area.

333. Because the ratio π is irrational it by no means follows that it cannot be constructed geometrically; that is, that we cannot with ruler and compasses draw a tract that shall be exactly equal to the circle of radius r. The ratio $\sqrt{2}$ is irrational, yet we can easily construct $\sqrt{2} \cdot r$, by drawing the diagonal of a square of side r. If we could draw a tract πr, equal to a half-circle, then, by Problem III, p. 193, we could construct the geometric mean of r and πr, which would be the side of a square precisely equal to the circle in area. This famous problem of *squaring the circle* is therefore not an irrational one; it is unsolved, but possibly not in itself unsolvable. But see Math. Ann., xx., p. 213.

MEASUREMENT OF ANGLES.

334. We have denoted by π the so-called *perimetric* ratio, namely, of the circle to its diameter, $2r$, so that, if r be the radius, then $2\pi r$ is the (length of the) circle, and πr^2 is its area. But there is another important use of π.

335. We have learned the ordinary sexagesimal division of the round angle into 360 equal parts called *degrees*. This *artificial* unit, degree, does not recommend itself for purposes of mathematical investigation, but a *natural* unit is suggested by the measurement of the circle itself. For it is plain that *whatever part an arc is of the whole circle, that same part the central angle of the arc is of the round angle*. Thus, if m times the arc make out the circle, then m times the central angle will make out the round angle; for, in adding the arcs about the centre O, we at the same time add the angles at O subtended by the arcs. If, however, arc and circle be incommensurable, cut the arc and also the angle into q very small equal parts. Then p of these arc-parts will be less and $p + 1$ will be greater than the circle, while, similarly, p of the angle-parts will be less and $p + 1$ will be greater than the round angle; and this will always hold, no matter how great q and p may be. Hence, using the arc as unit-arc and the angle as unit-angle, we see that the metric numbers of circle and round angle lie always between the same fractions, $\frac{p}{q}$ and $\frac{p+1}{q}$; and for increasing p and q these fractions *close down upon each other*, so that the metric numbers of circle and round angle cannot differ by ever so little, but must be precisely the same. If instead of circle and round angle we take any other arc and its corresponding central angle, the reasoning remains unchanged, so that we have

Theorem CXLVI. — *If any arc and its corresponding central angle be taken as units, the metric numbers of any other arc* (of the same or equal circle) *and its corresponding central angle are the same.*

In other words,

Central angles and their subtending arcs (in the same or equal circle) *are proportional* (see Art. 337).

The latter statement is conciser; the former is preciser.

336. Now a natural unit for arc-measurement is plainly *radius;* hence a natural unit for angle-measurement is *the angle whose arc is radius* (in length); accordingly we adopt it as unit-angle and name it **Radian.** The metric number of the circle, radius being unit, is 2π; hence the metric number of the round angle, radian being unit, is 2π. The radian equals about $57° 17' 33''$.

Corollary. If n be the metric number of any angle, and therefore of its corresponding arc, radian and radius being units, then of any other arc, subtending the same or equal angle, but described with a radius whose metric number is r, the metric number will be nr; for all circles are similar. That is,

The metric number of an arc equals the product of the metric numbers of its central angle and its radius.

Exercise. What are the natural metric numbers of a straight angle? A right angle? An angle of 60°? Of 45°? Of 30°? Of 120°? 150°? 225°? 240°? 270°? 420°? 600°? 720°? 1080°?

THE EUCLIDIAN DOCTRINE OF PROPORTION.

337. According to Euclid, *four magnitudes, a, b, c, d, are in proportion, taken in order, when any m-fold of the first is less than, equal to, or greater than, any n-fold of the second, according as the same m-fold of the third is less than, equal to, or greater than, the same n-fold of the fourth.*

In symbols

$$a : b :: c : d$$ (*read* a is to b as c is to d)

when, and only when,

$$ma < nb, \ ma = nb, \text{ or } ma > nb,$$

according as

$$mc < nd, \ mc = nd, \text{ or } mc > nd.$$

We may also say equivalently that *a has the same ratio to b that c has to d when, and only when, etc.*

338. Hereby is defined, then, precisely, not indeed *ratio*, but at least *equality of ratios*. However, it still remains to be proved that the axiom of equal *magnitudes*, namely, *magnitudes equal to the same or equal magnitudes, are equal to eath other*, can be applied to equal *ratios*; for it has not yet been shown that ratios are magnitudes or may be treated as magnitudes. The all-important fact that, *whatever these ratios may be*, they obey the axiom of magnitudes, is expressed in the

Theorem CXI^a. — If $a : b :: c : d$ and $a : b :: e : f$,

then $c : d :: e : f$ (see Theorem CXI.).

For herein is declared that when two ratios, $c : d$ and $e : f$, are equal to the same ratio, $a : b$, they are equal to each other. *After* establishing this fundamental proposition, but *not before*, we may drop the double colon, ::, and write $a : b = c : d$.

339. We may illustrate both the idea and the method of Euclid, in demonstrating the following extremely useful

Theorem CXLVII. — *Areas of similar figures are to each other as the squares on homologous tracts* (in the figures).

Data: F and F' two similar figures, t and t' two homologous tracts, t^2 and t'^2 the squares upon them.

Proof. If the figures be curvilinear, and in general even if they be rectilinear, it will not be possible to cut them up into corresponding squares, however small, as is manifest. Nevertheless, we may cut each one up into congruent squares so small that the remainder shall be less than any assigned area, however small; that is, shall be *small at will.* For (Fig. 195) draw two corresponding series of equidistant horizontals and verticals, d apart in F, and d' apart in F'.

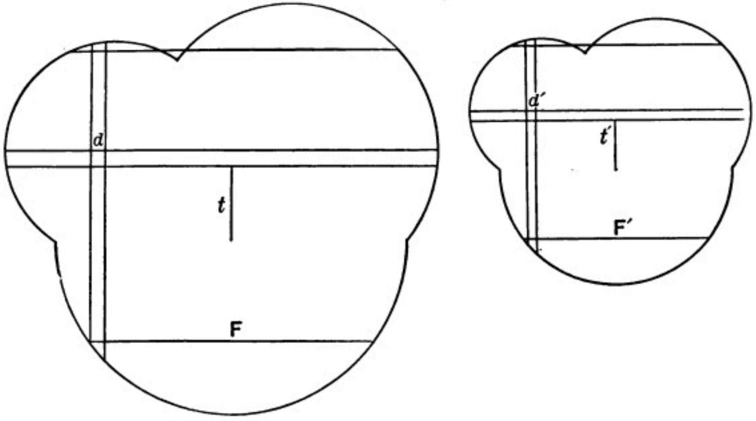

FIG. 195.

Let the extreme verticals in F be g apart, and let there be $v + 1$ of them, so that $g = v \cdot d$. Then the excess of the area of F over the sum of the squares will be the sum of the pairs of pieces at the end of each vertical strip; hence it will be less than $2v$ little squares, or less than a rectangle of base $2g$ and altitude d, *i.e.* $< 2gd$. But this rectangle is small at will, since its base $2g$ is constant and finite while its altitude d is small at will. Similarly, in F', $2g'd'$ is small as we please.

Now suppose there are p little squares cut out in F and also in F', where p is some very large but perfectly definite integer. Then the areas A and A' of F and F' will differ from the sums of the squares, pd^2 and pd'^2, by s and s', two magnitudes small at will; *i.e.*

$$A = pd^2 + s \quad \text{and} \quad A' = pd'^2 + s'.$$

Now suppose $md^2 = m'd'^2$; *i.e.* the sum of m squares in F equals the sum of m' squares in F'. Plainly then

$$p\,(md^2) = p\,(m'd'^2)\,; \quad \text{or} \quad m \cdot pd^2 = m' \cdot pd'^2 \text{ (why?)}.$$

Now

$$mA = m \cdot pd^2 + ms \quad \text{and} \quad m'A' = m' \cdot pd'^2 + m's'\,;$$

hence $$mA - m'A' = ms - m's'.$$

But s and s' are small as we please, while m and m' are finite; hence ms and $m's'$ are small at will; hence their difference, $ms - m's'$, is less than a magnitude small at will; hence *it is* 0. (Why? Because there is only one definite magnitude, namely, zero, that is less than a magnitude small at will.)

Hence, if $md^2 = m'd'^2$, then $mA = m'A'$.

Now suppose $md^2 > m'd'^2$. Then, as before, $mpd^2 > m'pd'^2$, and $mA = mpd^2 + ms$ while $m'A' = m'pd'^2 + m's'$.

Hence $$mA - m'A' = (m \cdot pd^2 - m' \cdot pd'^2) + ms - m's'.$$

Here again $ms - m's'$ is small at will, while $m \cdot pd^2 - m' \cdot pd'^2$ is some finite magnitude; hence $mA - m'A'$ is also some finite magnitude of the same sense; *i.e.*

$$\text{if } md^2 > m'd'^2, \text{ then } mA > m'A'.$$

Precisely in like fashion we prove that

$$\text{if } md^2 < m'd'^2, \text{ then } mA < m'A'.$$

That is,

$$mA < m'A', \quad mA = m'A', \text{ or } \quad mA < m'A',$$

according as

$$md^2 < m'd'^2, \quad md^2 = m'd'^2, \quad md^2 > m'd'^2.$$

Hence, by definition, the areas are proportional to the squares on the corresponding tracts, d and d'; or

$$A : A :: d^2 : d'^2.$$

Now compare the squares on t and t', d and d'. Since all squares are similar, and since d and d' are corresponding tracts or the equals of corresponding tracts in the squares on t and t', we have from the foregoing,

$$t^2 : t'^2 :: d^2 : d'^2.$$

Hence, by the Axiom of Magnitudes, applicable to ratios,

$$A : A' :: t^2 : t'^2.$$ Q. E. D.

340. Care has been taken to conduct the foregoing demonstration so that it shall apply quite as well to circles, to regular triangles, in fact to any similar figures drawn on homologous tracts as to squares; so that we may affirm

Theorem CXLVII^a. — *Areas of similar figures are proportional to areas of any similar figures on homologous tracts* (in the original similar figures).

341. The peculiar propriety and advantage of using the **square** are seen on stating the analogous arithmetical

Theorem CXLVII^b. — *The metric numbers of similar figures are proportional to the metric numbers of any other similar figures in the same ratio of similitude.*

Now the figure (or area) whose metric number is easiest to find is the *square*, whose metric number is the *second power* of the metric number of its side. Instead of *second* *power* it is usual, almost universal, to say *square* and thus employ this latter term in two entirely different senses, — the proper geometrical sense and the tropical arithmetical sense. This double use of the term "square" is very regrettable as being especially confusing to beginners.

342. We may now restate our proposition thus:

The metric numbers of two similar figures are proportional to the metric numbers of squares on homologous tracts;

Or, are proportional to the second powers of the metric numbers of homologous tracts;

Or, are in the duplicate ratio of similitude of the figures themselves.

Thus, if the ratio of similitude be $2:5$ or $a:b$, the ratio of the areas will be $4:25$ or $a^2:b^2$.

343. Observe carefully that the Euclidian doctrine of proportion is not a geometrical doctrine, but an arithmetical doctrine applied to Geometry. The same may be said of the accepted doctrine in modern texts: it is Arithmetic applied to Geometry. Nevertheless, the difference between the two is very great. Euclid's is based wholly on the operation of *multiplication* and employs only positive integers, not fractions nor irrationals, which indeed the Greek did not recognize as numbers; the modern, on the other hand, is based on the operation of *division*, and necessarily involves some general theory of fractions and irrationals. Moreover, Euclid's, while regarded as cumbrous and very difficult for the beginner, is yet a model of logical elegance and rigor: the like can hardly be said of the modern treatment.*

---

* The usual algebraical treatment of proportion is not really sound.
O. HENRICI, ENC. BRIT., VOL. X., *Geometry*, § 47.

The doctrine developed in this text is *purely geometrical,* implying no numerical knowledge or calculus. It is grounded in the notions of parallelism and similarity, to stand or fall with them. Hence it will be found to have no place in bi-dimensional spherics, the doctrine of the sphere-surface, which is in many particulars quite analogous to Planimetry, the doctrine of the plane, but in which there are no similar figures.

MAXIMA AND MINIMA.

344. Already, in Art. 135, the notions of maximum and minimum have been defined, but it is well to add here that not absolute but merely relative size is referred to, inasmuch as a varying magnitude may pass through a number of maxima and minima, and of these some maximum may be less than some minimum. Thus, a boy may inflate his elastic balloon till the diameter becomes 9 inches, then let it shrink to a diameter of 7 inches, again inflate it to a diameter of 12 inches, let it shrink to one of 10 inches, again inflate it, and so on. Here 9 and 12 are maxima, while 7 and 10 are minima of the diameter. Plainly, maxima and minima alternate with each other, and the course of the

CHAPTER XII.

INVERSION.

145. We have already in § 13 explained what is meant by two 'inverse points' with respect to a circle. O being the centre of a circle, P and P' are inverse points if they lie on the same radius and $OP.OP' =$ the square of the radius. P and P' are on the same side of the centre, unless the circle have an imaginary radius, $= ik$, where k is real.

As P describes a curve S, the point P' will describe another curve S'. S and S' are called *inverse curves*. O is called the *centre of inversion*, and the radius of the circle is called the *radius of inversion*.

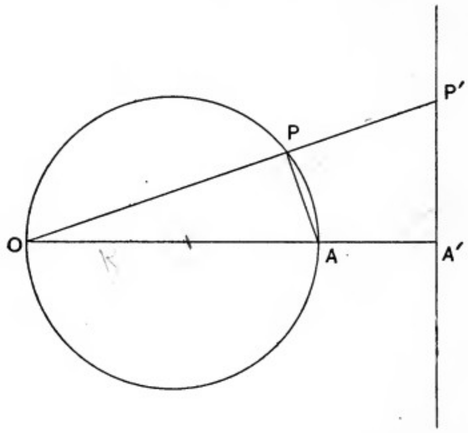
If P describe a curve in space, not necessarily a plane curve, then we must consider P' as the inverse of P with respect to a *sphere* round O. That is, whether P be confined to a plane or not, if O be a fixed point in space and P' be taken on OP such that $OP.OP' =$ a constant k^2, P' is called the inverse of P, and the curve or surface described by P is called the inverse of that described by P', and *vice versa.*

It is convenient sometimes to speak of a point P' as inverse to another point P *with respect to a point* O. By this is meant that O is the centre of the circle or sphere with respect to which the points are inverse.

146. Prop. *The inverse of a circle with respect to a point in its plane is a circle or straight line.*

First let O, the centre of inversion, lie on the circle.

Let k be the radius of inversion.



Draw the diameter OA, let A' be the inverse of A.

Let P be any point on the circle, P' its inverse.

Then $\qquad OP . OP' = k^2 = OA . OA'$.

$\therefore$ $PAA'P'$ is cyclic.

$\therefore$ the angle $AA'P'$ is the supplement of APP', which is a right angle.

$\therefore$ $A'P'$ is at right angles to AA'.

$\therefore$ the locus of P' is a straight line perpendicular to the diameter OA, and passing through the inverse of A.

Next let O not be on the circumference of the circle.

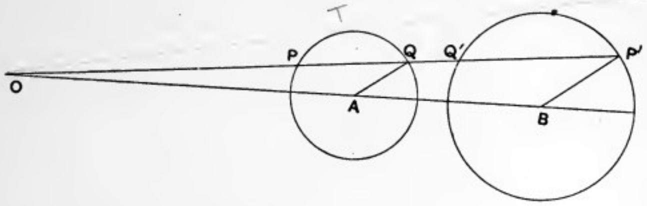
Let P be any point on the circle, P' its inverse.

Let OP cut the circle again in Q.

Let A be the centre of the circle.

Then $OP \,.\, OP' = k^2$,
and $OP \,.\, OQ =$ sq. of tangent from O to the circle $= t^2$ (say).

$$\therefore \frac{OP'}{OQ} = \frac{k^2}{t^2}.$$



Take B on OA such that $\dfrac{OB}{OA} = \dfrac{k^2}{t^2}$. $\therefore B$ is a fixed point and BP' is parallel to AQ.

And $$\frac{BP'}{AQ} = \frac{OB}{OA} = \frac{k^2}{t^2} \text{ a constant.}$$

$\therefore P'$ describes a circle round B.

Thus the inverse of the circle is another circle.

Cor. 1. The inverse of a straight line is a circle passing through the centre of inversion.

Cor. 2. If two circles be inverse each to the other, the centre of inversion is a centre of similitude (§ 25); and the radii of the circles are to one another in the ratio of the distances of their centres from O.

The student should observe that, if we call the two circles S and S', and if OPQ meet S' again in Q', Q' will be the inverse of Q.

Note. The part of the circle S which is convex to O corresponds to the part of the circle S' which is concave to O, and *vice versa*.

Two of the common tangents of S and S' go through

O, and the points of contact with the circles of each of these tangents will be inverse points.

147. Prop. *The inverse of a sphere with respect to any point is a sphere or a plane.*

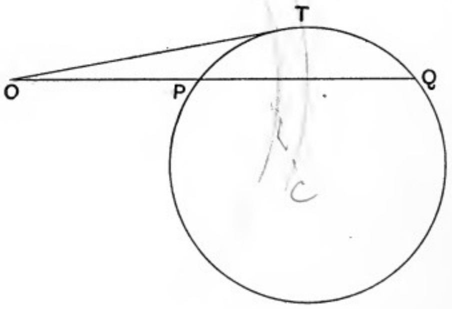
This proposition follows at once from the last by rotating the figures round *OA* as axis; in the first figure the circle and line will generate a sphere and plane each of which is the inverse of the other; and in the second figure the two circles will generate spheres each of which will be the inverse of the other.

148. Prop. *The inverse of a circle with respect to a point O,* **not in its plane,** *is a circle.*

For the circle may be regarded as the intersection of two spheres, neither of which need pass through *O*.

These spheres will invert into spheres, and their intersection, which is the inverse of the intersection of the other two spheres, that is of the original circle, will be a circle.

149. Prop. *A circle will invert into itself with respect to a point O in its plane if the radius of inversion*



be the length of the tangent to the circle from the centre of inversion.

This is obvious at once, for if OT be the tangent from O and OPQ cut the circle in P and Q, since $OP \,.\, OQ = OT^2$ it follows that P and Q are inverse points.

That is, the part of the circle concave to O inverts into the part which is convex and *vice versa.*

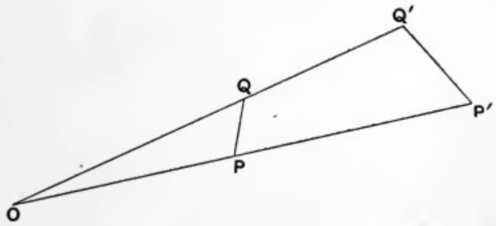
Cor. 1. Any system of coaxal circles can be simultaneously inverted into themselves if the centre of inversion be any point on the axis of the system.

Cor. 2. Any three coplanar circles can be simultaneously inverted into themselves.

For we have only to take the radical centre of the three circles as the centre of inversion, and the tangent from it as the radius.

150. Prop. *Two coplanar curves cut at the same angle as their inverses with respect to any point in their plane.*

Let P and Q be two near points on a curve S, P' and Q' their inverses with respect to O.



Then since $\quad OP \,.\, OP' = k^2 = OQ \,.\, OQ'$.

$\therefore$ $QPP'Q'$ is cyclic.

$\therefore$ $\angle OPQ = \angle OQ'P'$.

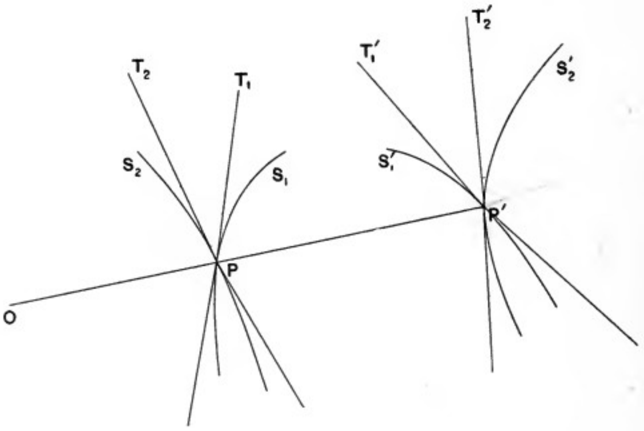
Now let Q move up to P so that PQ becomes the tangent to S at P; then Q' moves up at the same time to

P' and $P'Q'$ becomes the tangent at P' to the inverse curve S'.

$\therefore$ the tangents at P and P' make equal angles with OPP'.

The tangents however are antiparallel, not parallel.

Now if we have two curves S_1 and S_2 intersecting at P, and PT_1, PT_2 be their tangents there, and if the inverse curves be S_1', S_2' intersecting at P', the inverse of P, and $P'T_1'$, $P'T_2'$ be their tangents, it follows at once from the above reasoning that $\angle T_2PT_1 = \angle T_1'P'T_2'$.

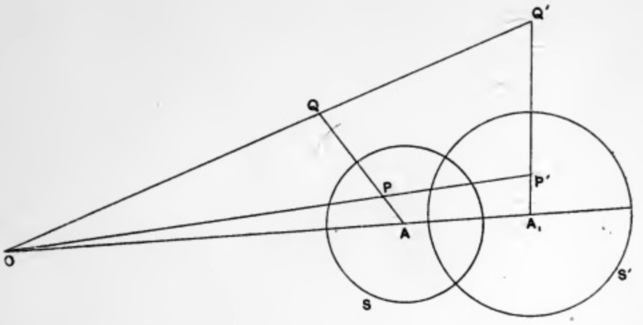


Thus S_1 and S_2 intersect at the same angle as their inverses.

Cor. If two curves touch at a point P their inverses touch at the inverse of P.

151. Prop. *If a circle S be inverted into a circle S', and P, Q be inverse points with respect to S, then P' and Q', the inverses of P and Q respectively, will be inverse points with respect to S'.*

Let O be the centre of inversion.



Since P and Q are inverse points for S, therefore S cuts orthogonally every circle through P and Q, and in particular the circle through O, P, Q.

Therefore the inverse of the circle OPQ will cut S' orthogonally.

But the inverse of the circle OPQ is a line; since O, the centre of inversion, lies on the circumference.

Therefore $P'Q'$ is the inverse of the circle OPQ.

Therefore $P'Q'$ cuts S' orthogonally, that is, passes through the centre of S'.

Again, since every circle through P and Q cuts S orthogonally, it follows that every circle through P' and Q' cuts S' orthogonally (§ 150).

Therefore, if A_1 be the centre of S',

$$A_1P' \,.\, A_1Q' = \text{square of radius of } S'.$$

Hence P' and Q' are inverse points for the circle S'.

152. Prop. *A system of non-intersecting coaxal circles can be inverted into concentric circles.*

The system being non-intersecting, the limiting points L and L' are real.

Invert the system with respect to L.

Now L and L' being inverse points with respect to each circle of the system, their inverses will be inverse points for each circle in the inversion.

But L being the centre of the circle of inversion, its inverse is at infinity. Therefore L' must invert into the centre of each of the circles.

153. **Feuerbach's Theorem.**

The principles of inversion may be illustrated by their application to prove Feuerbach's famous theorem, viz. *that the nine-points circle of a triangle touches the inscribed and the three escribed circles.*

Let ABC be a triangle, I its incentre and I_1 its ecentre opposite to A.

Let M and M_1 be the points of contact of the incircle and this ecircle with BC.

Let the line AII_1 which bisects the angle A cut BC in R.

Draw AL perpendicular to BC. Let O, P, U be the circumcentre, orthocentre and nine-points centre respectively.

Draw OD perpendicular to BC and let it meet the circumcircle in K.

Now since BI and BI_1 are the internal and external bisectors of angle B,

$$\therefore (AR, II_1) = -1,$$

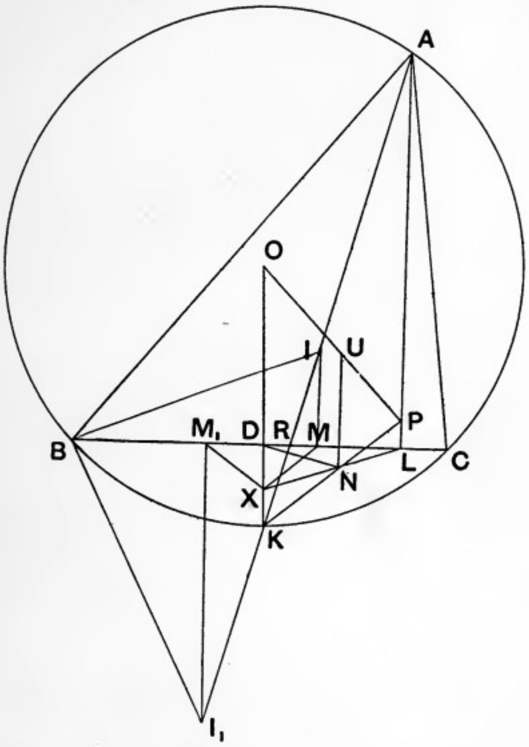
$$\therefore L\,(AR, II_1) = -1.$$

$\therefore$ since RLA is a right angle, LI and LI_1 are equally inclined to BC (§ 27, Cor. 2).

$\therefore$ the polars of L with regard to the incircle and the ecircle will be equally inclined to BC.

Now the polar of L for the incircle goes through M and that for the ecircle through M_1.

Let MX be the polar of L for the incircle cutting OD in X.



Then since D is the middle point of MM_1 (§ 12, Cor.)

$$\triangle XM_1D \equiv \triangle XMD.$$

$$\therefore \angle XM_1D = \angle XMD.$$

$\therefore M_1X$ is the polar of L for the ecircle, i.e. L and X are conjugate points for both circles.

Let N be the middle point of XL, then the square of the tangent from N to both circles $= NX^2 = ND^2$.

$\therefore$ N is on the radical axis of the two circles; but so also is D since $DM = DM_1$.

$\therefore$ ND is the radical axis, and this is perpendicular to II_1.

Now the pedal line of K goes through D, and clearly also, since K is on the bisector of the angle A, the pedal line must be perpendicular to AK.

$\therefore$ DN is the pedal line of K.

But the pedal line of K bisects KP.

$\therefore$ KNP is a straight line and N its middle point.

And since U is the middle point of OP, $UN = \frac{1}{2}OK$.

$\therefore$ N is a point on the nine-points circle.

Now invert the nine-points circle, the incircle and ecircle with respect to the circle whose centre is N and radius ND or NL.

The two latter circles will invert into themselves; and the nine-points circle will invert into the line BC; for N being on the nine-points circle the inverse of that circle must be a line, and D and L, points on the circle, invert into themselves, $\therefore$ DL is the inverse of the nine-points circle.

But this line touches both the incircle and ecircle.

$\therefore$ the nine-points circle touches both the incircle and ecircle.

Similarly it touches the other two ecircles.

Cor. The point of contact of the nine-points circle with the incircle will be the inverse of M, and with the ecircle the inverse of M_1.

CHAPTER IV.

PARALLELS.

IV. Assumption of Parallels (Euclid's Postulate).

IV. *Through a given point there is not more than one parallel to a given straight.*

71. The introduction of this assumption greatly simplifies the foundation and facilitates the construction of geometry.

72. Theorem. *Two straights parallel to a third are parallel.*

Proof. Were 1 and 2 not parallel, then there would be through their intersection point two parallels to 3, which is in contradiction to IV.

73. Theorem. *If a transversal cuts two parallels, the alternate angles are congruent.*

Proof. Were say $\sphericalangle BAD$ not $\equiv \sphericalangle ABC$, then we could through A (by III 4) take a straight making $\sphericalangle BAD' \equiv \sphericalangle ABC$ [D' and D on same side of AB], and so we would have (by 69) through A two parallels to a, in contradiction to IV.

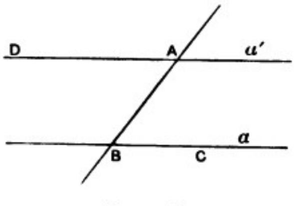

FIG. 26.

74. Corollary to 73. A perpendicular to one of two parallels is perpendicular to the other also.

75. Theorem. If a transversal cuts two parallels, the corresponding angles are congruent.

Proof. The angle vertical to one is alternate to the other.

Ex. 27. A straight meeting one of two parallels meets the other also.

Ex. 28. A straight cutting two parallels makes conjugate angles supplemental.

Ex. 29. If alternate or corresponding angles are unequal or if conjugate angles are not supplemental, then the straights meet. On which side of the transversal?

76. Theorem. A perpendicular to one of two parallels is parallel to a perpendicular to the other.

Proof. Either of the two given parallels makes (by 74) right angles with both perpendiculars, which therefore are parallel by 69.

77. Corollary to 76. Two straights respectively perpendicular to two intersecting straights cannot be parallel.

Proof. For if they were parallel, then (by 76) the intersecting straights would also be parallel.

78. Convention. When two angles are set off from the vertex of a third against its sides so that no point is interior to two, if the two sides not common are costraight, the three angles are said together to form two right angles.

79. *The angles of a triangle together form two right angles.*

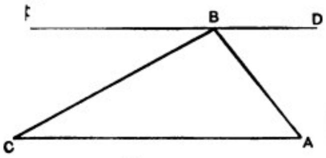

FIG. 27.

Proof. Take alternate $\sphericalangle CBF \equiv \sphericalangle C$ and $\sphericalangle ABD \equiv \sphericalangle A$; then (by 69) can neither BF nor BD cut AC. By the parallel postulate IV, then is FBD a straight.

80. Theorem. If two angles of one triangle are congruent to two of another, then the third angles are congruent.

Proof. Given $\measuredangle A \equiv \measuredangle A'$ and $\measuredangle B \equiv \measuredangle B'$. Take CP parallel ($\|$) to AB and $C'P' \parallel$ to $A'B'$. Then

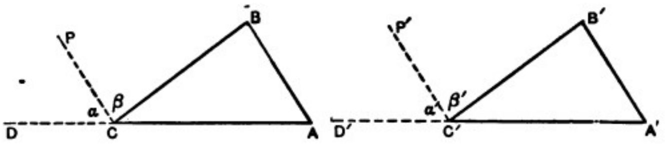

FIG. 28.

$\measuredangle \alpha \equiv \measuredangle A$ and $\measuredangle \beta \equiv \measuredangle B$, $\measuredangle \alpha' \equiv \measuredangle A'$ and $\measuredangle \beta' \equiv \measuredangle B'$. $\therefore$ (by 49) $\measuredangle BCD \equiv \measuredangle B'C'D'$. $\therefore$ (by 45) the adjacent angles $\measuredangle ACB \equiv \measuredangle A'C'B'$.

81. Theorem. *Two triangles are congruent if they have a side, an adjoining and the opposite angle respectively congruent.*

Proof. By 80 and 44.

Ex. 30. Every triangle has at least two acute angles.

Ex. 31. If the rays of one angle are parallel or perpendicular to those of another, the angles are congruent or supplemental.

Ex. 32. In a *right-angled* triangle [a triangle one of whose angles is a right angle] the two acute angles are complemental (calling two angles *complements* which together form a right angle).

82. Theorem. *In any sect AB there is always one and only one point C such that $AC \equiv BC$.*

Proof. Take any angle BAD at A against AB, and the angle congruent to it at B against BA and on the opposite side of a in the plane BAD; and take any sect AD on the free ray from A, and one

BF congruent to it on the free ray from B. The sect DF must cut a, say in C, since D and F are on opposite sides of a. Moreover, C is between A and B. Otherwise one of them, say A, would be between B and C. But then DA would have a point A on BC, a side of triangle FBC, and so (by II 4) must meet another side. But this is impossible, since it meets FC produced at D and is parallel to BF. Since thus $\sphericalangle A \equiv \sphericalangle B$, and $\sphericalangle ACD \equiv \sphericalangle BCF$ [vertical], therefore (by 81) $\triangle ACD \equiv \triangle BCF$.

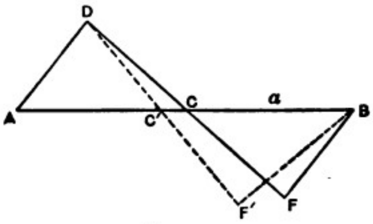

FIG. 29.

Therefore $AC \equiv BC$.

If we suppose a second such point C', then on ray DC' take $C'F' \equiv DC'$. Therefore (by 43) $\sphericalangle C'BF' \equiv \sphericalangle DAC \equiv \sphericalangle ABF$, and $BF' \equiv AD \equiv BF$. Therefore F' is F and C' is C.

83. Convention. The point C of the sect AB such that $AC \equiv BC$ may be called the *bisection-point* of AB, and to *bisect* AB shall mean to take this point C.

Ex. 33. Parallels through the end-points of a sect intercept congruent sects on any straight through its bisection-point.

Ex. 34. In a right-angled triangle the bisection-point of the *hypothenuse* (the side opposite the r't $\sphericalangle$) makes equal sects with the three vertices.

Hint. Take one acute $\sphericalangle$ in the r't $\sphericalangle$.

84. Theorem. *Within any* $\measuredangle (h, k)$ *there is always one and only one ray,* l*, such that* $\measuredangle (h, l) \equiv \measuredangle (k, l)$.

Proof. From the vertex O take $OA \equiv OA'$. By 82 take C, the bisection-point of AA'. Then $\triangle AOC \equiv \triangle A'OC$ [$\triangle$s with 3 sides $\equiv$ are $\equiv$]. $\therefore \measuredangle AOC \equiv \measuredangle A'OC$.

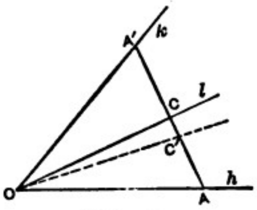

FIG. 30.

If we suppose a second such ray OC', then $\triangle AOC' \equiv \triangle A'OC'$ [$\triangle$s with 2 sides and the included $\measuredangle \equiv$ are $\equiv$]. $\therefore AC' \equiv A'C'$. $\therefore$ (by 82) C' is C.

85. Convention. The ray l of $\measuredangle (h, k)$ such that $\measuredangle (h, l) \equiv \measuredangle (l, k)$ may be called the *bisection ray* or bisector of $\measuredangle (h, k)$, and to *bisect* $\measuredangle (h, k)$ shall mean to take this ray l.

Ex. 35. An angle may be separated into 2, 4, 8, 16, . . . , 2^n congruent angles.

SYMMETRY.

86. Definition. Two points are said to be *symmetrical* with regard to a straight, when it bisects at right angles their sect. The straight is called their *axis of symmetry*. Two points have always one, and only one, symmetry axis.

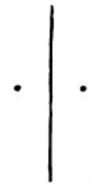

FIG. 31.

A point has, with regard to a given axis of symmetry, always one, and only one, symmetrical point, namely, the one which ends the sect from the given point perpendicular to the axis and bisected by the axis.

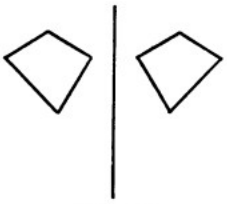

FIG. 32.

87. Definition. Two figures have an axis of symmetry when, with regard to this straight, every point of each has its symmetrical point on the other.

One figure has an axis of symmetry when, with regard to this straight, every point of the figure has its symmetrical point on the figure.

One figure is called symmetrical when it has an axis of symmetry.

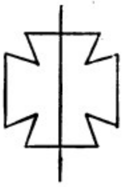

FIG. 33.

Any figure has, with regard to any given straight as axis, always one, and only one, symmetrical figure.

88. Theorem. *An angle is symmetrical with regard to its bisector and the end-points of congruent sects from the vertex are symmetrical.*

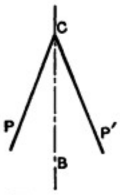

FIG. 34.

Proof. Their sect is bisected at right angles by the angle-bisector.

89. Definition. A symmetrical quadrilateral with a diagonal as axis is called a *deltoid*.

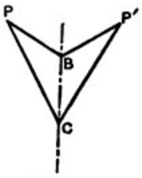

FIG. 35.

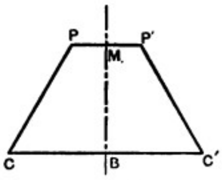

FIG. 36.

90. Definition. A sect whose end-points are the bisection-points of opposite sides of a quadrilateral is called a *median*. So is the sect from a vertex of a triangle to the bisection-point of the opposite side.

91. Definition. A symmetrical quadrilateral with a median as axis is called a *symtra*.

Ex. 36. In a r't Δ if to set off one acute ∡, α, in the other, β, bisects, so is it with β's sides.

Ex. 37. The st' through the bisection-point of the base of a ∔ Δ, and the opposite vertex is ⊥ to the base and bisects ∡.

Ex. 38. The r't bi' of the base of a ∔ Δ bisects ∡ at the vertex.

Ex. 39. The ⊥ from vertex bisects base and ∡ in a ∔ Δ.

Ex. 40. The bisector of ∡ at vertex of a ∔ Δ is r't bi' of base.

Ex. 41. If a r't bi' of a side contains a vertex, the Δ is ∔.

Ex. 42. The bisector of an exterior ∡ at vertex of ∔ Δ is ‖ to base, and inversely.

Ex. 43. The end of sect from intersection of congruent sides of a ∔ Δ costraight and ≡ to one determines with end of other a ⊥ to base.

Ex. 44. To erect a ⊥ at the end-point of a sect without producing the sect.

Ex. 45. A ‖ to one side of an ∡ makes with its bisector and other side a ∔ Δ.

Ex. 46. The bisectors of the ≡ ∡s of a ∔ Δ are ≡.

Ex. 47. Every symmetrical quadrilateral not a deltoid is a symtra.

Ex. 48. The intersection point of two symmetrical straights is on the axis.

Ex. 49. The bisector of an angle is symmetrical to the bisector of the symmetrical angle.

Ex. 50. A figure made up of a straight and a point is symmetrical.

Ex. 51. In any deltoid [1] One diagonal (the axis) is the perpendicular bisector of the other. [2] One diagonal (the axis) bisects the angles at its two vertices. [3] Sides which meet on one diagonal (the axis) are congruent; so each side equals one of its adjacent sides. [4] One diagonal (not the axis) joins the vertices of congruent angles and makes congruent angles with the congruent sides. [5] The triangles made by one diagonal (the axis) are congruent. [6] One diagonal (not the axis) makes two isosceles triangles.

Ex. 52. Any quadrilateral which has one of the six preceding pairs of properties (Ex. 51) is a deltoid.

Ex. 53. A quadrilateral with a diagonal which bisects the angle made by two sides, and is less than each of the other two sides, and these sides congruent, is a deltoid with this diagonal as axis.

Ex. 54. A quadrilateral with a side meeting a congruent side in a greater diagonal which is opposite congruent angles is a deltoid with that diagonal as axis.

Ex. 55. In any symtra [1] Two opposite sides are parallel, and have a common perpendicular bisector. [2] The other two sides are congruent and make congruent angles with the parallel sides.

[3] Each angle is congruent to one and supplemental to the other of the two not opposite it.

[4] The diagonals are congruent and their parts adjacent to the same parallel are congruent.

[5] One median bisects the angle between the two diagonals, and also the angle between the non-parallel sides (produced).

Ex. 56. Any quadrilateral which has one of the preceding five pairs of properties (Ex. 55) is a symtra.

92. Definition. A *trapezoid* is a quadrilateral with two sides parallel.

93. Definition. A *parallelogram* is a quadrilateral with each side parallel to another (its opposite).

94. Definition. A parallelogram with one angle right is called a *rectangle*. A parallelogram with two consecutive sides congruent is called a *rhombus*. A rectangle which is a rhombus is called a *square*.

95. Theorem. *The opposite sides and angles of a parallelogram are congruent, and its diagonals bisect each other.*

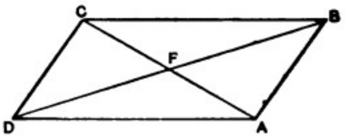

FIG. 37.

Proof. $\triangle ABC \equiv \triangle ADC$ [side and 2 adjoining $\sphericalangle$s $\equiv$]. $\therefore BC \equiv AD$. $\therefore$ (as in 82) $AF \equiv FC$ and $BF \equiv FD$.

96. Theorem. *If three parallels make congruent sects on one transversal, they do on every transversal.*

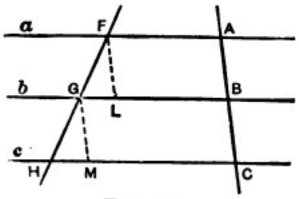

FIG. 38.

Given $a \parallel b \parallel c$, also $AB \equiv BC$.

To prove $FG \equiv GH$.

Proof. Take $FL \parallel GM \parallel AB$. Then $FL \equiv AB \equiv BC \equiv GM$ [95, opposite sides of a $\parallel$gm are $\equiv$]. $\therefore \triangle FLG \equiv \triangle GMH$ [side and 2 adjoining $\sphericalangle$s $\equiv$]. $\therefore FG \equiv GH$.

97. Corollary to 96. A straight through the bisection-point of one side of a triangle and parallel to a second side bisects the third side. [In figure let F coincide with A.]

98. Inverse of 97. The straight through the bisection-points of any two sides of a triangle is parallel to the third side. [For, by 97, it is identical with the $\parallel$ to the third side through either bisection-point.]

99. Theorem. *The sect whose end-points are the bisection-points of two sides of a triangle is congruent to each sect made in bisecting the third side.*

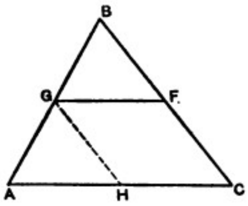

Fig. 39.

Proof. By 97 $GH \parallel BC$ bisects AC. Since (by 98) $FG \parallel CH$, $\therefore$ (by 95) $FG \equiv CH$.

100. Theorem. *If two sides of a quadrilateral are congruent and parallel it is a parallelogram.*

Given $AB \equiv$ and $\parallel CD$.

Proof. $\triangle ABC \equiv \triangle ADC$.

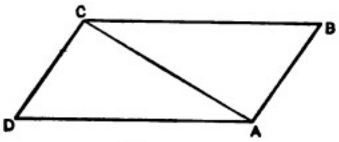

Fig. 40.

$$\therefore \measuredangle ACB \equiv \measuredangle CAD. \quad \therefore CB \parallel AD.$$

Ex. 57. Every straight through the intersection of its diagonals cuts any parallelogram into congruent trapezoids.

Ex. 58. A quadrilateral with each side equal to its opposite is a parallelogram.

Ex. 59. A quadrilateral with a pair of opposite sides equal, and each greater than a diagonal, making equal alternate angles with the other sides, is a parallelogram.

Ex. 60. A quadrilateral with a side equal to its opposite, and less than a diagonal opposite equal angles, is a parallelogram.

Ex. 61. A quadrilateral with each angle equal to its opposite is a parallelogram.

Ex. 62. A quadrilateral whose diagonals bisect each other is a parallelogram.

101. Theorem. In any sect AB there are always two, and only two, points, C, D, such that $AC \equiv CD \equiv DB$.

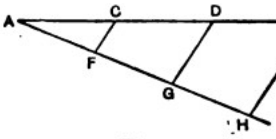

FIG. 41.

Proof. Take on any ray from A, any sect AF, and a sect $FG \equiv AF$, and a sect $GH \equiv FG$. Take $FC \parallel GD \parallel HB$. Then, by 96, $AC \equiv CD \equiv DB$.

Suppose two other such points C', D'. Then, by 98, $C'F \parallel D'G$. Now $HB' \parallel GD'$ (by 96) makes $D'B' \equiv D'C'$. $\therefore$ from our hypothesis and III 1, B' is identical with B. $\therefore$ since $GD \parallel HB$ (by IV) D' is identical with D. $\therefore$ since $FC \parallel GD$ (by IV) C' is identical with C.

102. The two points, C, D, of the sect AB such that $AC \equiv CD \equiv DB$ may be called the *trisection-points* of AB.

103. Theorem. *The three medians of a triangle are copunctal in that trisection-point of each remote from its vertex.*

Proof. Any median AG must meet any other CF, since A and G are on different sides of the straight CF, and so the cross of st' AG with st' CF is on sect AG, and similarly it is on sect CF. If P, Q, are bisection-points of OC and OA, then (by 98 and 99) $PQ \parallel$ and $\equiv GF$. $\therefore$ by 100 $PQFG$ is a $\parallel$gm and (by 95) PF and QG bisect each other.

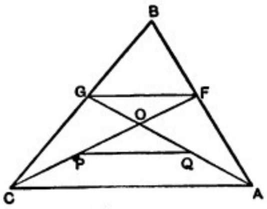

FIG. 42.

104. Definition. The cointersection-point of its medians is called the triangle's *centroid.*

105. Definition. A perpendicular from a vertex to the straight of the opposite side is called an *altitude* of the triangle. This opposite side is then called the *base.* The perpendicular from a vertex of a parallelogram to the straight of a side not through this vertex is called the altitude of the parallelogram with reference to this side as base.

Ex. 63. The bisectors of the four angles which two intersecting straights make with each other form two straights perpendicular to each other.

Ex. 64. If four coinitial rays make the first angle congruent to the third, and the second congruent to the fourth, they form two straights.

Ex. 65. How many congruent sects from a given point to a given straight?

Ex. 66. Does the bisector of an angle of a triangle bisect the opposite side?

Ex. 67. The bisectors of vertical angles are costraight.

Ex. 68. If two isosceles triangles be on the same base the straight determined by their vertices bisects the base at right angles.

Ex. 69. Suppose a Δ to be 3 bars freely jointed at the vertices. Is it rigid? Are the ∡s fixed and the joints of no avail? Of what theorem is this a consequence? How is it with a jointed quadrilateral? Why?

Ex. 70. Joining the bisection-points of the sides of a Δ cuts it into 4 ≡ Δs.

Ex. 71. Joining the bisection-points of the consecutive sides of a quadrilateral makes a ‖ g'm.

Ex. 72. The medians of a quadrilateral and the sect joining the bisection-points of its diagonals are all three bisected by the same point.

Ex. 73. If the bisection-points of two opposite sides of a ∥ g'm are joined to the vertices the diagonals are trisected.

Ex. 74. The ⊥s from any point in the base of an ∔ Δ to the sides are together an altitude.

Ex. 75. The diagonals of a rectangle are ≡, of a rhombus are ⊥.

Ex. 76. If 2 ∥s are cut by a transversal, the bisectors of the interior ∡s make a rectangle.

Ex. 77. The angle-bisectors of a rectangle make a square.

Ex. 78. If the ∡s adjoining one of the ∥ sides of a trapezoid are ≡, so are the others.

Ex. 79. The bisectors of the interior ∡s of a trapezoid make a quad' with 2 r't ∡s.

Ex. 80. The bisection-point of one sect between ∥s bisects any through it.

Ex. 81. The ≡ altitudes in ∔ Δ make with the base ∡s ≡ to those made in bisecting the other ∡.

Ex. 82. Through a given point within an ∡ draw a sect terminated by the sides and bisected by the point.

Ex. 83. Sects from the vertex to the trisection-points of the base of ∔ Δ are ≡.

Ex. 84. If the ∡s made by producing a side of a Δ are ≡, so are the other sides.

Ex. 85. If a quad' has 2 pairs of congruent consecutive sides, the other ∡s are ≡.

Ex. 86. Two Δs are ≡ if two sides and one's median are respectively ≡.

Ex. 87. Two ∔ Δs are ≡ if one ∡ and altitude are ≡ to the corresponding.

Ex. 88. Two Δs are ≡ if a side, its altitude and an adjoining ∡ are respectively ≡.

Ex. 89. If 2 altitudes are ≡ the Δ is ∔.

Ex. 90. Two Δs are ≡ if two sides and one's altitude are ≡ to the corresponding.

Ex. 91. Two Δs are ≡ if a side, its altitude and median are respectively ≡.

Ex. 92. Two Δs are ≡ if a side and the other 2 altitudes are respectively ≡.

Ex. 93. Two △s are ≅ if a side, an adjoining ∡ and its bisector are respectively ≅.

Ex. 94. Two equilateral △s are ≅ if an altitude is ≅.

Ex. 95. The bisector is within the ∡ made by altitude and median.

Ex. 96. In a right △ one bisector also bisects ∡ between its altitude and median.

Ex. 97. Two sects from the vertices of a △ to the opposite sides cannot bisect each other.

Ex. 98. The ⊥s from 2 vertices of a △ upon the median from the third are ≅.

Ex. 99. Two ∥g'ms having an ∡ and the including sides ≅ are ≅.

Ex. 100. The ⊥ from the circumcenter to a side is half the sect from the opposite vertex to the orthocenter.

Ex. 101. The centroid is the trisection point of the sect from orthocenter to circumcenter remote from the orthocenter

Thus the pole of perspective is at infinity in the direction perpendicular to x. The perspective relation between the circle and ellipse figures is equivalent to a stretch (*cf.* Art. 13), the stretch-ratio being $\cos\theta$.

Also because the projection is cylindrical the lines at infinity correspond: therefore their poles, that is, the centres, correspond. It follows that conjugate diameters of the circle project into conjugate diameters of the ellipse: in particular x and the perpendicular diameter of the circle, being conjugate diameters, project into perpendicular conjugate diameters of the ellipse, since a perpendicular to x remains perpendicular to x. These give the axes of the ellipse. If a be the radius of the circle, a and $a\cos\theta$ are the major and minor semi-axes of the ellipse.

Conversely an ellipse of semi-axes a and b $(a > b)$ can be obtained in this manner by projecting a circle of radius a orthogonally upon a plane making with the plane of the circle an angle

$$\theta = \cos^{-1}\left(\frac{b}{a}\right).$$

An ellipse being completely given by its principal axes (*see* Art. 61), it follows that every ellipse can be obtained in this way from a circle on its major axis as diameter.

The circle on the major axis of an ellipse as diameter is called its **auxiliary circle.** Thus **the ellipse and its auxiliary circle are derivable one from the other by a stretch parallel to the minor axis.**

EXAMPLES

1. Show that, if P, P' be points where a perpendicular to the major axis of an ellipse meets the curve and the auxiliary circle respectively, the tangents at P, P' meet on the major axis.

2. Prove that an ellipse can be obtained from the circle on its minor axis as diameter by a stretch parallel to the major axis.

79. The conjugate parallelogram. A **conjugate parallelogram** is one whose sides are the tangents at the extremities of two conjugate diameters. Clearly no real conjugate parallelogram can exist, except in the case of the ellipse.

Consider the ellipse as defined by the stretch of its auxiliary circle. Since by Art. 78 conjugate diameters correspond to conjugate diameters and parallel lines to parallel lines (because the vanishing lines are at infinity) it follows that a conjugate parallelogram for the ellipse corresponds to a conjugate parallelogram for the circle.

But a conjugate parallelogram for a circle is a circumscribed square, because conjugate diameters of a circle are at right angles.

Now, in any stretch, corresponding areas are to one another in the stretch ratio. For consider an elementary parallelogram $PQRS$ (Fig. 32) of which the sides PQ, RS are parallel to the stretch axis and the sides PS, QR are parallel to the direction of stretch. Let these meet the stretch axis at X, Y respectively. $PQRS$ transforms into a parallelogram $P'Q'R'S'$ in which $P'Q'$, $R'S'$ are parallel to the stretch axis. For if λ be the stretch ratio

$$P'X = \lambda . PX = \lambda . QY = Q'Y \quad \text{and} \quad S'Y = R'Y = \lambda . SZ.$$

Hence $$P'S' = \lambda(XS - XP) = \lambda . PS$$

and parallelogram $P'Q'R'S$: parallelogram $PQRS = S'P' : SP = \lambda$.

Breaking up any area into such elementary parallelograms and adding we see that λ = ratio of two corresponding areas.

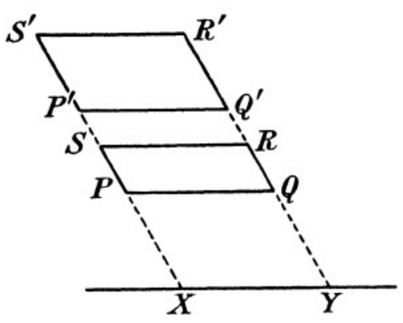

Fig. 32.

Hence area of any conjugate parallelogram of the ellipse

$= \frac{b}{a} \times$ area of corresponding circumscribed square of the auxiliary circle

$= \frac{b}{a} . 4a^2 = 4ab.$

Thus **the conjugate parallelogram of an ellipse is of constant area.** Calling p the perpendicular from the centre on any given tangent, d the length of the semi-diameter parallel to this tangent, the area of the conjugate parallelogram of which the given tangent is a side is clearly $4pd$, for $2d$ is the base of the parallelogram and $2p$ is the height. $\therefore 4pd = 4ab$, *i.e.* $pd = ab$.

Examples

1. Show that the diagonals of a conjugate parallelogram are themselves conjugate diameters.

2. Show how to construct geometrically the equal conjugate diameters of an ellipse, given its axes.

3. Show that the area of the ellipse is πab.

80. Sum of squares of two conjugate semi-diameters. Let CP', CQ' (Fig. 33) be two perpendicular semi-diameters of the auxiliary circle, CP, CQ the corresponding diameters of the ellipse.

Then CP, CQ are conjugate. Also $P'PM$, $Q'QN$ are perpendicular to the major axis.

Then from the stretch property, if ϕ be the angle ACP',

$$PM = \frac{b}{a} P'M = \frac{b}{a} a \sin \phi = b \sin \phi ;$$

$$QN = \frac{b}{a} Q'N = \frac{b}{a} a \cos \phi = b \cos \phi .$$

$$CM = a \cos \phi ; \; CN = a \sin \phi ;$$

$$\begin{aligned} CP^2 + CQ^2 &= CM^2 + PM^2 + QN^2 + CN^2 \\ &= a^2 \cos^2 \phi + b^2 \sin^2 \phi + b^2 \cos^2 \phi + a^2 \sin^2 \phi \\ &= a^2 + b^2. \end{aligned}$$

Hence **the sum of the squares of two conjugate diameters of an ellipse is constant.**

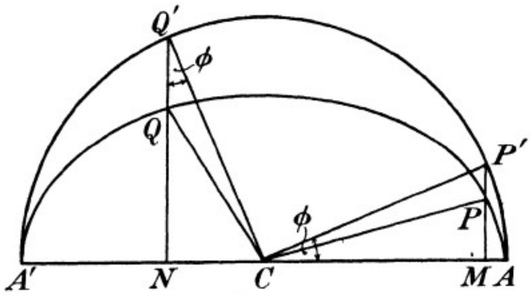

FIG. 33.

81. Pseudo-conjugate parallelogram. Let ACA' (Fig. 34) be a diameter of a hyperbola meeting the curve at real points A, A'. Let the tangent at A meet the asymptotes at D, E and the tangent at A' meet them at F, G. Then, because the tangents at A, A' are parallel, $DEFG$ is a parallelogram of which the asymptotes are diagonals.

If P be a point on the curve and PN the chord through P conjugate to ACA' meeting ACA' at N,

$$\frac{PN^2}{AN.NA'} = -\frac{CB_1^2}{CA^2},$$

CB_1 being the absolute length (*see* Art. 76) of the diameter conjugate to ACA'.

But $$\frac{PN^2}{AN.NA'} = -\left(\frac{AN}{A'N}\right)\left(\frac{PN}{AN}\right)^2.$$

If P moves off to infinity on the hyperbola in the direction of the asymptote CD, AP becomes parallel to CD. The triangles CAD, ANP become similar, and $\left(\frac{PN}{AN}\right)^2$ becomes equal to $\left(\frac{AD}{CA}\right)^2$; also $\frac{AN}{A'N}$ approaches unity.

Hence $$\frac{CB_1^2}{CA^2} = \frac{AD^2}{CA^2},$$

or $$CB_1 = AD.$$

Thus the intercept of a tangent between the asymptotes measures

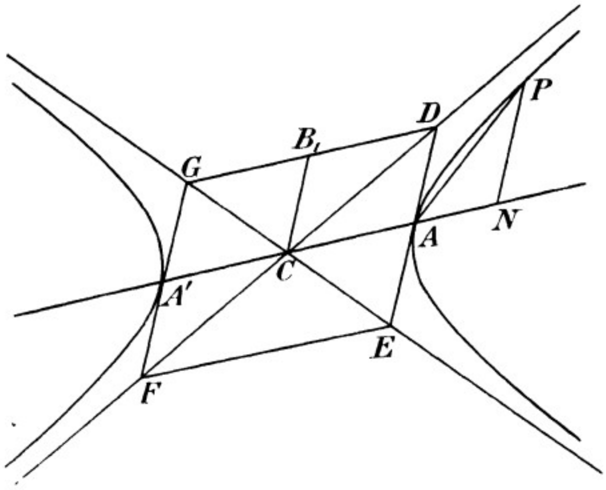

FIG. 34.

the absolute length of the parallel diameter. The parallelogram $DEFG$ is therefore a **pseudo-conjugate** parallelogram. Its median lines are conjugate diameters, but only one pair of sides touches the curve.

We have seen (Art. 67) that the area of the triangle ECD cut off from the asymptotes by any tangent to the curve is constant. **The area of the pseudo-conjugate parallelogram** $DEFG$ is four times the area of the triangle ECD and **is therefore also constant.**

If p = perpendicular from C on tangent at A, $d = CB_1$ = absolute length of diameter conjugate to CA, $DE = 2d$, and area of triangle $ECD = \frac{1}{2}p \,.\, 2d = pd$. Hence **in the hyperbola as in the ellipse** pd = **constant.** Taking the case where the sides of the pseudo-conjugate parallelogram are parallel to the axes, the constant $= ab$ where a is the semi-transverse axis and b is the absolute length of the conjugate semi-axis.

Further, in Fig. 34, the area of the triangle GCD is equal to that of the triangle CDE, and therefore constant. Hence GD touches at its middle point B_1 a second hyperbola having the same asymptotes. This second hyperbola, which is also the locus of B_1, is termed the **conjugate hyperbola** of the first one; the transverse and conjugate axes are interchanged, in position and absolute length, when we pass from a hyperbola to its conjugate hyperbola.

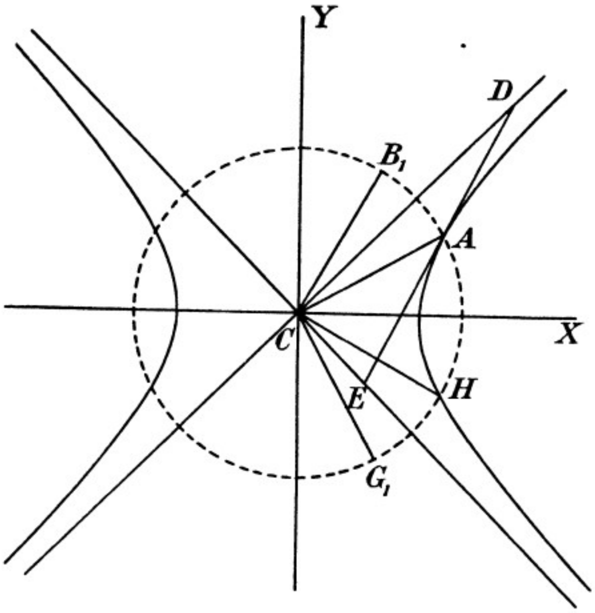

FIG. 35.

82. Difference of squares of absolute lengths of conjugate semi-diameters of a hyperbola. From the triangle CED (Fig. 35) we have, since CA is the median,

$$CD^2 + CE^2 = 2(CA^2 + AD^2)$$

by a well-known relation.

Also $\quad DE^2 = CE^2 + CD^2 - 2CE.CD \cos ECD,$

that is, $\quad 4AD^2 = 2CA^2 + 2AD^2 - 2CE.CD \cos ECD,$

or $\quad CA^2 - AD^2 = CE.CD \cos ECD.$

CHAPTER XI

RECIPROCATION AND INVERSION

170. Reciprocal transformation or correlation. If in the equations (3), (4) and (5) of Art. 161 we interchange l', m' and x', y' we find, writing for shortness

$$\alpha_1 = B_2C_3 - B_3C_2,\ \alpha_2 = B_3C_1 - B_1C_3,\ \alpha_3 = B_1C_2 - B_2C_1,$$

with corresponding meanings for β's and γ's :

$$l' = \frac{A_1x + B_1y + C_1}{A_3x + B_3y + C_3}, \qquad m' = \frac{A_2x + B_2y + C_2}{A_3x + B_3y + C_3},$$

$$l = \frac{A_1x' + A_2y' + A_3}{C_1x' + C_2y' + C_3}, \qquad m = \frac{B_1x' + B_2y' + B_3}{C_1x' + C_2y' + C_3},$$

$$x = \frac{\alpha_1l' + \alpha_2m' + \alpha_3}{\gamma_1l' + \gamma_2m' + \gamma_3}, \qquad y = \frac{\beta_1l' + \beta_2m' + \beta_3}{\gamma_1l' + \gamma_2m' + \gamma_3},$$

$$x' = \frac{\alpha_1l + \beta_1m + \gamma_1}{\alpha_3l + \beta_3m + \gamma_3}, \qquad y' = \frac{\alpha_2l + \beta_2m + \gamma_2}{\alpha_3l + \beta_3m + \gamma_3}.$$

These equations may be shown as in Art. 161 to be the necessary equations of transformation in any one-one algebraic correspondence of plane fields in which lines correspond to points and points to lines. Clearly any pencil is homographic, and therefore equianharmonic, with the corresponding range. This transformation is therefore of the type discussed in Art. 56.

It is, however, much more general than this transformation; for the transformation by reciprocal polars is limited to fields in the same plane, whereas the present transformation is for any plane fields. Also in the transformation by reciprocal polars the same line p corresponds to the same point P whether P be considered as belonging to one field or to the other. Whereas here, if the fields be taken coplanar and the axes of co-ordinates identical, if we put $x' = x$, $y' = y$ we do not in general obtain $l' = l$ or $m' = m$.

The present transformation is the most general case of a plane reciprocal transformation.

An obvious modification of the reasoning of Art. 162 will show that such a transformation is determined when four points A_1, B_1, C_1, D_1 of one field, no three of which are collinear, are made to correspond to four lines a_2, b_2, c_2, d_2 of the other field, no three of which are concurrent.

For if P_1 correspond to p_2 we have

$$A_1\{B_1C_1D_1P_1\}=a_2\{b_2c_2d_2p_2\},$$
$$B_1\{A_1C_1D_1P_1\}=b_2\{a_2c_2d_2p_2\},$$

which determine a_2p_2 and b_2p_2, and therefore p_2.

And it is easy to show that if P_1 describes a straight line, p_2 passes through a point.

Two such fields will be said to be **reciprocal** or **correlative.** The relation between them may be spoken of as a **reciprocity** or a **correlation.**

171. Two reciprocal transformations are equivalent to a projective transformation. Consider two reciprocal plane fields ϕ_1, ϕ_2, and a third field ϕ_3 reciprocal with ϕ_2. ϕ_1 and ϕ_3 now correspond point by point and line by line and since the correspondence between elements of ϕ_1 and ϕ_2 is one-one and algebraic, and that between elements of ϕ_2 and ϕ_3 is one-one and algebraic, the correspondence between elements of ϕ_1 and ϕ_3 is also one-one and algebraic.

Accordingly the fields ϕ_1 and ϕ_3 are homographic and therefore projective.

172. Any reciprocal transformation is equivalent to a projective transformation and a transformation by reciprocal polars. For let ϕ_1 and ϕ_2 be given reciprocal fields. Let ϕ_3 be the reciprocal polar field of ϕ_2 with regard to any conic in its own plane. Then by the last Article ϕ_1 and ϕ_3 are projective. Thus a projective transformation transforms ϕ_1 to ϕ_3 and the transformation by reciprocal polars transforms ϕ_3 to ϕ_2.

173. Locus of incident points and envelope of incident lines of two coplanar reciprocal fields. If two reciprocal fields ϕ, ϕ' be coplanar, we proceed to find the condition that a point and its corresponding line shall be incident.

If P be a point on its corresponding line p', P being considered as belonging to ϕ, it also lies on its corresponding line when considered as belonging to ϕ'. For let $P=Q'$. Then, since P, *i.e.* Q', lies on p', q passes through P, *i.e.* through Q'. But it should be noted that q is, in general, distinct from p'.

In like manner, if a line $p = q'$ passes through P' it also passes through Q, but P', Q are, in general, distinct.

Such points and lines will be called **incident points and lines** of the correlation.

Consider now an incident point A of ϕ, assuming for the moment that such exist. Let a' be its corresponding line which is then an incident line, and on a' take any point B distinct from A. If B is incident, b' passes through B, and, since A is distinct from B, a' must be distinct from b', otherwise the correspondence would not be one-one.

But AB, which is identical with a', corresponds to $a'b'$ in ϕ', which is identical with B. If then there were two such points B on a', incident and distinct from A, they would correspond to the same line a' in ϕ, which is not possible. Thus there can only be two points on a' which are incident, namely A and one point B, so that it is impossible for an incident line to contain more than two incident points. Thus all the points of the plane cannot be incident points, nor all the lines incident lines.

Let now l be any line whatever, P any point of it, p' the line corresponding in ϕ' to P, P' the meet of l and p'. If to P' in ϕ' corresponds p in ϕ, then since P' lies on p', p passes through P. Each of the points P, P' is thus uniquely determined as soon as the other is known. The ranges $[P]$, $[P']$ are therefore homographic and have in general two self-corresponding points S, T, which may be real coincident or imaginary, and which are such that they lie on their corresponding lines and so are incident points.

The locus k_1 of incident points has thus two intersections with any straight line in the plane. Hence it is a conic by Art. 159.

In like manner through any point M two incident lines can be drawn. The envelope of incident lines is therefore a conic k_2.

The conics k_1, k_2 correspond doubly in the correlation, since a tangent to k_2, being an incident line, corresponds in either field to an incident point, which lies on k_1.

The double character of this correspondence does not, however, extend to the individual elements of the conics.

A point $P = Q'$ (Fig. 54) of k_1 corresponds, in general, to two different incident lines p', q, which are the two tangents from the point to k_2. The tangent $t = u'$ to k_1 at $P = Q'$ corresponds to the point T' of ϕ' where p' touches k_2; and to it corresponds in ϕ the point U where q touches k_2.

In like manner a tangent $p = q'$ to k_2 corresponds, in general, to two different incident points P', Q, which are the intersections of this tangent with k_1. The point of contact $T = U'$ of $p = q'$ with k_2 corresponds to the line t' of ϕ' which touches k_1 at P'; and to it corresponds in ϕ the tangent u to k_1 at Q. It should be noticed that we can here use the same letters without confusion, because p has no necessary relation to p' or T to T', the corresponding elements being p, P'; P, p'; T, t'; t, T'.

If $P = Q'$ comes into coincidence with an intersection X of k_1, k_2, the lines p', q coincide with the tangent x_2 to k_2 at X; thus X corresponds doubly to x_2. But, further, T' and U then both coincide with X, and they correspond to the tangent x_1 to k_1 at $P = Q' = X$; thus X corresponds doubly to x_1. Since the same point cannot correspond to two distinct lines, x_1 must be identical with x_2, and the conics k_1, k_2 touch at any intersection X.

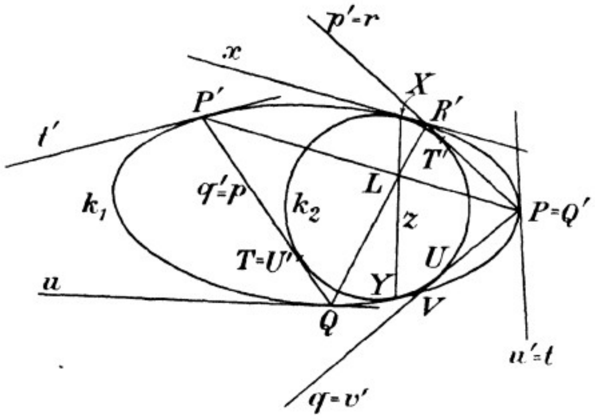

FIG. 54.

Thus k_1, k_2 either touch at two points X, Y, or else have four-point contact at a point X.

As a special case k_1 may break up into a line-pair, in which case k_2 breaks up into a point-pair. Neither the points of the pair nor the lines of the pair can be incident points or lines, so the point-pair cannot lie upon the line-pair. Each point of k_2 corresponds to the two components of k_1, one in each field.

If the given correlation reduces to a transformation by reciprocal polars, the two conics k_1, k_2 coincide with the base conic, since every point of the base conic lies on its polar and every tangent of this conic passes through its pole. By analogy the conics k_1, k_2 will be termed the **base conics** in the general case.

174. Correspondence of points and tangents on the base conics. In Fig. 54 it is clear that some rule of selection must be given, which enables us to discriminate which end of a chord of k_1 tangent to k_2 is to be treated as P' and which as Q. For the correspondence is not here a double one; thus in Fig. 54 two such chords are p' and q, their intersection being $P=Q'$. If their other extremities are R', V, it is clear that R' belongs to $p'=r$ and V to $q=v'$. Thus if, in this relation, P corresponds to R', the same point, treated as Q' does not correspond to R' but to a different point V.

Since, in the correlation, homographic ranges and pencils of the second order correspond to homographic pencils and ranges respectively, we have at once

$$[P']^2 \barwedge [p]^2 \equiv [q']^2 \barwedge [Q]^2,$$

so that the ranges $[P']^2$ and $[Q]^2$ are homographic ranges of the second order on the conic k_1. They are not, however, in involution.

But, if P' approaches X, $P'Q$ approaches the tangent at X and Q approaches X. Hence X is a self-corresponding point of the ranges $[P']^2$, $[Q]^2$, and so is Y. Thus the common chord XY of contact of k_1, k_2 is the cross axis of these ranges (Art. 86), and cross-joins such as QR', $P'P$ meet at a point L of XY.

The above will still apply if the base conics have four-point contact at X, since the cross-axis of the ranges is still determinate, being the common tangent at X.

This shows that, once the discrimination has been effected in the case of a single pair of points on k_1, the process of selection is determinate, for, by varying L and keeping P, R' fixed, we can make P', Q represent any required pair of corresponding points and identify the field to which each belongs. Once the points have been identified, the tangents are also identified without ambiguity.

In the first instance, however, we have nothing to guide us in the identification of the original pair of points. But a little consideration will readily show that the choice is really immaterial. For it amounts to interchanging the fields ϕ and ϕ' consistently throughout. This does not affect the base conics since they correspond doubly. The correlation remains the same, the notation only being altered.

175. A correlation is uniquely determined by the base conics. Suppose the base conics k_1, k_2 of a correlation are given, and also the selection rule of Art. 174. This fixes the order of the extremities of two chords such as $P'Q$, $R'S$ (Fig. 55), with the proviso that, if one pair be interchanged, so also must the other pair. Let $A = B'$ be any point of the plane and let the two tangents from this point to k_2 be $p = q'$, $r = s'$, meeting k_1 at P', Q; R', S, respectively.

Now, in ϕ, $A = pr$ and corresponds to $P'R' = a'$ in ϕ'. Similarly $B' = q's'$ in ϕ' and corresponds to $QS = b$ in ϕ. We have thus the two lines which correspond to $A = B'$ when treated as a point of either field.

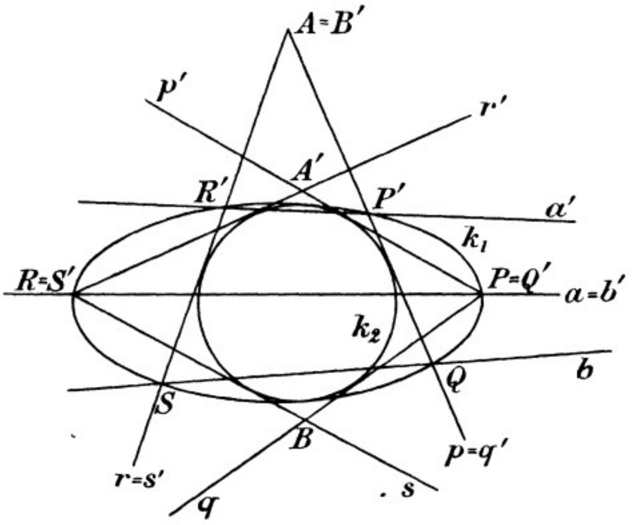

FIG. 55.

Again, let $a = b'$ be any given line, meeting s_1 at $P = Q'$ and $R = S'$ (Fig. 55). From these latter points draw tangents p', q and r', s to k_2, the identification following the selection rule. Then $p'r' = A'$, $qs = B$, so that we have constructed the two points corresponding to the line $a = b'$, treated as a line of either field.

Thus the base conics, together with the selection rule, fix the correlation completely and uniquely.

Further, reversal of the selection rule interchanges P' and Q, R' and S, a' and b, A' and B. This simply amounts to interchanging

ϕ and ϕ', as pointed out in the last Article. Thus the correlation is really determined by the base conics alone.

It is to be noted that, although the constructions here given fix the correlation theoretically, as drawing-board methods they are of limited application, since, in general, imaginary elements may enter into them.

The above argument has assumed that the conics k_1 and k_2 were already known to be the base conics of a correlation. If, however, k_1 and k_2 are two conics having either double or four-point contact and arbitrarily given, we may still, provided we definitely allot one of the extremities of a chord of k_1 tangent to k_2 to each the two fields in one particular case and so fix the homographic ranges on k_1, apply the above construction to find the line corresponding to any given point of the plane. In order to show that we then obtain a correlation, it is necessary and sufficient to prove that, if a point A describes a straight line l, its corresponding line a' passes through a fixed point L'.

In such a case the tangents $p=q'$, $r=s'$ (Fig. 55) form an involution of tangents to k_2, of which l is the axis. Since there is a unique correspondence between p and P', r and R', the ranges $[P']^2$, $[R']^2$ are homographic; moreover, if P' is taken at R', p and r are interchanged and R' is at P'. Thus P' and R' correspond doubly and so are mates in an involution on k_1. Hence $P'R'=a'$ passes through a fixed point L', which corresponds in ϕ' to l in ϕ. Similarly $QS=b$ passes through a fixed point which corresponds in ϕ to l in ϕ'. Thus the points of a line correspond to the lines through a point and the relation between the fields is a correlation.

If now the point A lies on a', it must coincide with either P' or R' and so lie on k_1; thus k_1 is the locus of incident points of the correlation. Similarly if a contains A', it must coincide with either p' or r' and so be a tangent to k_2; thus k_2 is the envelope of incident lines of the correlation.

No distinction need be drawn between the cases where the points of contact of k_1, k_2 are separate or coincident. Thus any two conics having either double or four-point contact determine a unique correlation, provided that (1) we assign which is the incident locus k_1 and which the incident envelope k_2; (2) we assign the intersections with k_1 of one tangent to k_2 each to its proper field. By varying the above assignments we obtain four possible correlations from two given conics.

EXAMPLES

1. Show that, in the case where k_1, k_2 degenerate into a line-pair and point-pair respectively, the join of the point-pair passes through the meet of the line-pair, and the points of contact X, Y of the general case coincide at this point.

2. Give a construction for the line and point corresponding to a given point and line, when the base conics are a line-pair and point-pair.

176. The self-corresponding triangle. Fig. 55 gives us at once the condition that a point $A = B'$ shall have the same corresponding line in the two fields. For if $a' = b$, then $P' = Q$ and $R' = S$ and the lines $p = q'$, $r = s'$ are tangents to k_1. But they are also tangents to k_2 and so are common tangents to the base conics. There are only two such tangents, namely, those at X, Y (Fig. 54). Moreover, if $P' = Q$ approaches X, $P'Q$ or $p = q'$ approaches the tangent at X. So that the tangent at X is the line corresponding to X in either field. Similarly the tangent at Y is the line corresponding to Y in either field. Calling these tangents x, y, and denoting XY by z, and its pole with regard to either k_1 or k_2 by Z, we have X, Y, Z corresponding to x, y, z in either field. Thus the triangle XYZ corresponds to itself. It should, however, be noted that only one vertex, namely Z, corresponds to the opposite side, the others being incident with their corresponding lines.

177. Reciprocation with respect to a circle. We have already dealt with polar reciprocal figures in Art. 56. There is, however, one special case of polar reciprocation with respect to a conic which is particularly important from the point of view of obtaining what are known as *metrical* properties, that is relations between magnitudes of lengths and angles, especially the latter. This special case arises when the base conic is a circle.

The centre O of the circle with respect to which reciprocal polars are taken is called the **origin of reciprocation** and its radius the **radius of reciprocation.**

Any point P then corresponds to its polar p' with respect to the base circle, and if p' meet OP at N', then $ON'.OP = k^2$, where k is the radius of reciprocation (Art. 54). Similarly a straight line p corresponds to its pole P', so that if N be the foot of the perpendicular from O upon p, P' lies on ON and $ON.OP' = k^2$.

A change in the radius of reciprocation has merely the effect of altering the *scale* of the reciprocal figure. Thus, if a figure ϕ transforms into ϕ' when the radius of reciprocation is k_1 and into ϕ'' when the radius of reciprocation is k_2, the line p transforms in the first case to P' on ON where $OP'.ON = k_1^2$ and in the second case to P'' also on ON, where $OP''.ON = k_2^2$. Thus $OP' : OP'' = k_1^2 : k_2^2$ and the figures ϕ', ϕ'' are similar and similarly situated, O being the centre of similarity, and $k_1^2 : k_2^2$ the ratio of similarity. Hence results independent of the scale of the figure are independent of the choice of the radius of reciprocation and the latter may often be chosen so as to have any convenient value, or be left altogether unspecified.

When this last is the case, the reciprocation is specified by the origin O and is often described briefly as reciprocation with respect to O.

Note also that it is not essential that k^2 should be *positive*: if k^2 is negative the construction still leads to a real reciprocal figure, only in this case a line and its reciprocal are on opposite sides of the origin.

The fundamental property of reciprocation with respect to an origin O is the following.

If a, b be any two lines, A', B' their reciprocal points, then OA', OB' are perpendicular to a, b respectively.

Since OA', OB' are drawn either both towards or both away from a and b, $A'OB'$ is *equal* to that angle between a, b which does not include O and supplementary to that which does include O.

Thus: **the angle between any two lines is equal (or supplementary) to the angle subtended by their reciprocal points at the origin of reciprocation.**

Other important properties relate to points at infinity. Thus a point P^∞ reciprocates into the line through O at right angles to OP^∞. The line at infinity reciprocates into O itself.

A circular point at infinity Ω therefore reciprocates into a straight line through O perpendicular to $O\Omega$. But $O\Omega$, being a double ray of a rectangular involution (Art. 141) is at right angles to itself. Thus Ω reciprocates into $O\Omega$ and similarly Ω' reciprocates into $O\Omega'$.

178. Reciprocation of a circle with respect to an excentric origin. Let C (Fig. 56) be the centre of the given circle, O the origin of reciprocation, AB the diameter of the given circle passing through O. The reciprocal curve of the circle will be a conic (Art. 56). Also, by symmetry, one of the axes of this conic will be along AB.

Since Ω, Ω' lie on the circle, $O\Omega$, $O\Omega'$ are tangents to the conic. Hence O is a real focus of the conic, so that AB is the focal axis.

Now C is the pole of the line at infinity with respect to the circle. Hence in the conic the reciprocal c' of C is the polar of O with respect to the conic, that is, the directrix corresponding to O.

Again, the centre C' of the conic is the pole of the line at infinity with respect to the conic, and so is the reciprocal of the polar c of O with respect to the circle. The second focus H is the point such that C' bisects OH.

The tangents from H to the conic are circular lines $H\Omega$, $H\Omega'$ which reciprocate into points I, J of the circle, where OI, OJ are perpendicular, and therefore, by the property of circular lines, also parallel, to $H\Omega$, $H\Omega'$ respectively. Accordingly OI, OJ pass through Ω, Ω' respectively, so that IJ and the line at infinity $\Omega\Omega'$ are opposite common chords of the given circle and the line-pair $(O\Omega, O\Omega')$, which latter is (Art. 140) identical with the point-circle O. IJ is therefore the radical axis of the given circle and O, and so is a real line h' at right angles to OC. Thus H is the reciprocal of this radical axis, a property which we shall require later.

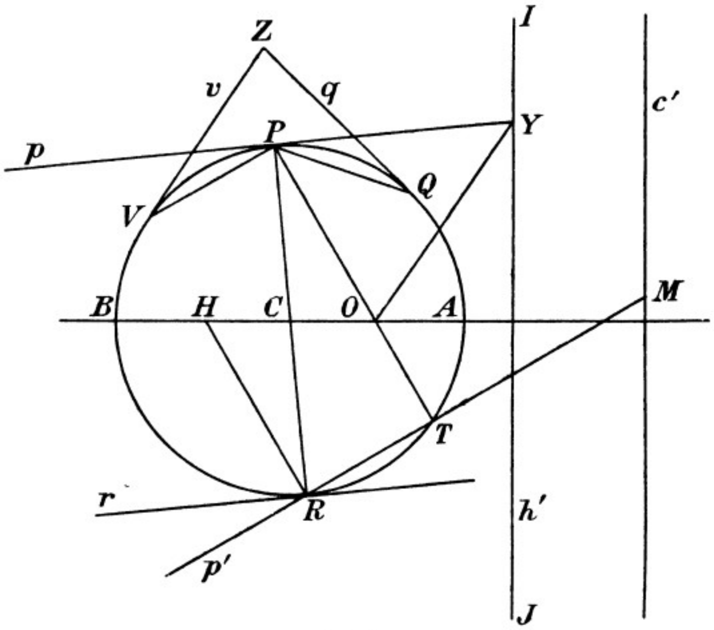

FIG. 56.

To find the eccentricity of the conic, reciprocate the tangents a, b at A, B. This gives the vertices A', B' of the focal axis.

Then $OA' = k^2/OA$, $B'O = k^2/BO$, leading to :

$$\text{major axis} = B'O + OA' = k^2\left(\frac{1}{OA} + \frac{1}{BO}\right);$$

$$\text{distance between foci} = OA' + OB' = k^2\left(\frac{1}{OA} - \frac{1}{BO}\right).$$

By division, eccentricity $= \dfrac{BO - OA}{BO + OA} = \dfrac{CO}{CA}$ numerically.

The conic is therefore an ellipse, parabola or hyperbola according as O lies inside, on, or outside the circle.

A very important particular case is that actually shown in Fig. 56. This is when the radius of reciprocation is so chosen that $A' = B$ and $B' = A$. This requires $k^2 = OA.OB$, so that for the elliptic case as in the figure, k^2 is negative.

When k^2 is so chosen, the given circle is the circle on the focal axis of the conic as diameter. We see then that a conic and its auxiliary circle are polar reciprocals with respect to an origin at a focus.

Note that in this case C and C' coincide, and also c and c'.

Examples

1. Given a focus, the corresponding directrix and the eccentricity of a conic show how to construct, without drawing the curve, the two tangents from a given external point O.

Prove that the angle between the tangents from a point O to a parabola is $\cos^{-1}(q/r)$, where r is the distance of O from the focus, and q is the perpendicular distance of O from the directrix.

2. Two circles meet at A and B. Taking A as centre of reciprocation, find the reciprocal theorem of the result that AB is perpendicular to the line joining the centres of the circles.

3. Reciprocate the theorem : circles of constant radius which touch one straight line also touch a parallel line, and their centres lie on the line midway between the two lines.

4. Given a circle centre C and radius r, show how to determine the centre and radius of the circle of reciprocation so that the given circle reciprocates into a rectangular hyperbola of which the real axis is of length $2r$.

5. If the reciprocal of a circle of radius a and centre C is taken with respect to a circle of radius b and centre O, where $OC = c$, find the eccentricity and latus rectum of the conic obtained.

Conics are described with a fixed focus O, their latera recta of the same given length l, and their corresponding directrices tangent to a given conic with focus O and latus rectum l'. Prove that their envelope consists of two conics, each of which has a focus at O, and that the reciprocals of the latera recta of these conics are the sum and difference of the reciprocals of l and l'.

179. Examples of focal properties of conics deduced by reciprocation with respect to a circle. A number of the focal properties discussed in Chapter VIII are very readily deduced from simple properties of the circle by this form of reciprocation. As they give valuable examples of the method, we shall set out the proofs of a few such properties. It will be convenient to assume for k that value which reciprocates the circle into a conic of which it is the auxiliary circle, so that C is the common centre of circle and conic and the foci O, H are symmetrically situated with respect to C.

(*a*) Let v, q (Fig. 56) be any two tangents to the circle, then they are equally inclined to their chord of contact VQ.

Using the fundamental property of reciprocation with regard to a circle (Art. 177), OV', OQ' are equally inclined to $O(v'q')$, where $v'q'$ is the intersection of the tangents at V', Q' to the conic.

Hence the theorem that two tangents to a conic subtend equal or supplementary angles at a focus.

In the figure, which is drawn for the ellipse, the angles ZVQ and ZQV either both include or both exclude O, and we get the case of equal angles.

If O is outside the circle, the points of contact of tangents from O reciprocate into the asymptotes, and divide the arcs of the circle which correspond to the two branches of the curve. The reader will find the discrimination of the two cases for the hyperbola a useful exercise.

(*b*) Let PO (Fig. 56) meet the circle again at T. Then $OP.OT = OA.OB = k^2$. The line through T perpendicular to OT is then a tangent to the conic; it meets the circle again at R, and, since PTR is a right angle, PR is a diameter. Hence by symmetry HR is parallel and equal to PO, and

$$HR.OT = PO.OT = BO.OA = a^2(1-e^2) = b^2,$$

where a is the semi-major and b the semi-minor axis.

We thus obtain the two theorems of Art. 125.

(*c*) Let the tangent p at P meet IJ at Y. By a well-known property of the radical axis of two circles, the lengths of tangents from Y to the given circle and to the point circle O are equal. Thus OPY is an isosceles triangle and PY, OY are equally inclined to OP. Now Y is ph' and reciprocates into $P'H$, so that OY reciprocates into the point at infinity on $P'H$. Similarly OP reciprocates into the point at infinity on p'. Finally PY is p and reciprocates into P'. Hence by the fundamental property OP'

and the parallel through O to $P'H$ are equally inclined to the parallel through O to p', *i.e.* OP', $P'H$ are equally inclined to p' or the tangent and normal bisect the angles between the focal distances.

(*d*) If V, Q are fixed points on the circle, P a variable point, the angle VPQ is constant.

Hence, in the reciprocal figure, the angle between $O(v'p')$ and $O(q'p')$ is constant, *i.e.* the intercept on a variable tangent p' made by two fixed tangents v', q' subtends a constant angle at the focus (Art. 122).

(*e*) The tangent p to the circle at P is perpendicular to the radius vector CP. Therefore OP' is perpendicular to $O(c'p')$, that is, the part of the tangent to a conic intercepted between the point of contact and a directrix subtends a right angle at the corresponding focus (*cf.* Art. 121).

(*f*) ZV, ZQ being two tangents v, q to the circle are equally inclined to CZ. Hence OV', OQ' are equally inclined to $O\{c'(V'Q')\}$, *i.e.* if a chord $V'Q'$ meet the directrix corresponding to focus O at, say X, then OX is a bisector of the angle $V'OQ'$ (*cf.* Art. 121).

(*g*) Two parallel tangents p, r to the circle are a constant distance apart.

But perpendicular distance of O from $p = k^2/OP'$,
and perpendicular distance of O from $r = k^2/R'O$.

Hence $\dfrac{1}{OP'} + \dfrac{1}{R'O} = \text{const.}$, where $P'OR'$ is a chord of the conic through O. By taking this chord to be the latus rectum we find this constant $= 2/(\text{semi-latus rectum})$, and thus obtain the first theorem of Art. 123.

(*h*) The locus of the intersection Z of tangents v, q to a circle which cut at a given angle α is a concentric circle: this leads at once to the following.

The envelope of a chord $V'Q'$ of a conic which subtends a given angle at the focus is a conic having the same focus and directrix.

Further, in the above VQ touches another fixed circle concentric with the original circle. Hence the locus of the pole $v'q'$ of a chord $V'Q'$ subtending a constant angle at the focus of a conic is a conic having the same focus and directrix.

180. Case where O lies on the circle. When the origin of reciprocation lies on the circle, the line at infinity touches the reciprocal conic, which thus becomes a parabola.

If through O, now on the circle, two perpendicular chords OP, OQ of the circle are drawn, the join PQ passes through the centre C.

We have then : p', q' are perpendicular and $p'q'$ lies on the directrix c', *i.e.* the intersection of two perpendicular tangents to a parabola lies on the directrix (*cf.* Art. 128).

If OA is a diameter of the circle, P any point on the circle, OPA is a right angle. Therefore the reciprocal point $(a'p')$ of AP lies on OP, so that a', p', OP are concurrent. But p' is perpendicular to OP, so that (p', OP) is the foot of the perpendicular from the focus on the tangent p' and this lies on a', which is clearly the tangent at the vertex (*cf.* Art. 127).

There is a well-known theorem on the circle, known as Simson's Theorem, that if L, M, N are the feet of the perpendiculars from a point O of the circle upon the sides f, g, h of a triangle inscribed in the circle, then L, M, N are collinear.

Reciprocating this result with regard to O, we have l' is a line through F' perpendicular to OL, that is, to OF'. Hence if, through the vertices F', G', H' of a triangle circumscribed to a parabola of which O is the focus, we draw lines perpendicular to OF', OG', OH', these are concurrent at some point U. It follows that a circle on UO as diameter passes through F', G', H' or the circumcircle of a triangle formed by three tangents to a parabola passes through the focus (Art. 130).

EXAMPLES

1. Show that the vertices of a triangle can be reciprocated into the opposite sides if the origin of reciprocation be taken at the orthocentre.

2. Reciprocate the theorem that the orthocentre of a triangle circumscribing a parabola lies on the directrix, the origin of reciprocation being the orthocentre.

181. Coaxal circles reciprocate into confocal conics. Consider a set of coaxal circles k with real limiting points O, K (Fig. 57). Then O, K are harmonically conjugate with regard to the points P, Q in which any circle of the set meets the line of centres, that is, the polars of O, K with regard to any circle of the set pass through K, O. Also by symmetry these polars are perpendicular to the line of centres.

Therefore O, K have the same polars with regard to all the circles of the coaxal system, and these polars are the perpendiculars to the line of centres through K, O respectively.

Now reciprocate the coaxal circles with regard to any circle centre O. The circles k reciprocate into conics k' having O for a focus.

O reciprocates into the line at infinity, and the line c which is the common polar of O with respect to the coaxal circles reciprocates into a point C' on the line of centres. Thus C' is the common centre of all the conics k'. Since the conics k' have O for a common focus, and C' for a common centre, their second real focus S is also common, so that they are confocal conics. S lies on the line of centres, and $OS = 2.OC'$. The reciprocal of S is a line x perpendicular to the line of centres. If it meet this line at X, then

$$OX.OS = OK.OC'.$$

But since $OS = 2.OC'$, therefore $OK = 2.OX$, or X is the middle point of OK, that is, x is the radical axis.

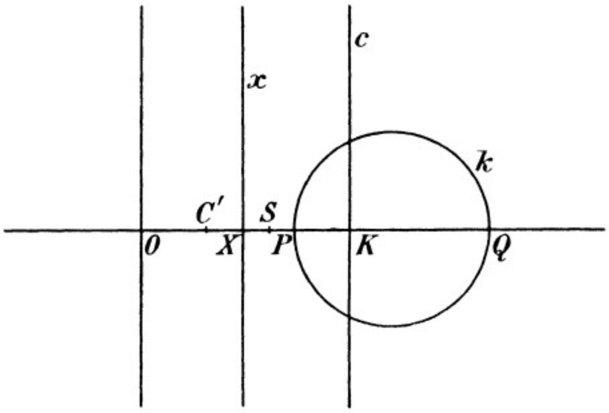

Fig. 57.

Accordingly the two foci are O and the reciprocal of the radical axis.

Conversely, it is easily shown that confocal conics reciprocate with respect to one of the real foci, into a set of coaxal circles with real limiting points.

182. Inversion. Let O be the centre of a circle c, of radius k, P any point in the plane of the circle, P' the point of OP conjugate to P with respect to c, so that

$$OP.OP' = k^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(1)$$

The point P' is then said to be the **inverse point** of P with respect to c, and the symmetry of the relation (1) then shows that P is the inverse point of P' with respect to c. The relation between the field formed by the points P and that formed by the points

P' is termed **inversion,** either field being spoken of as the **inverse** of the other with respect to the circle; c, O and k are called the **circle, centre** and **radius** of **inversion** respectively.

Since the polar of P with respect to a circle is perpendicular to OP, it is clear that the inverse point P' is the foot of the perpendicular from O on the polar of P.

Although the correspondence of the points is unique, inversion is not a homography, for a straight line does not correspond to a straight line, but to a circle through the origin.

To prove this, let a (Fig. 58) be any straight line, A the foot of the perpendicular from O on a, P any other point on a. Let A', P' be the inverse points of A, P. Then $OA.OA' = OP.OP'$, or $OP' : OA' = OA : OP$.

Since the angle at O is common, the triangles AOP, $P'OA'$ are similar, and the angle at P' is equal to the angle at A, and therefore to a right angle. Therefore P' describes a circle on OA' as diameter.

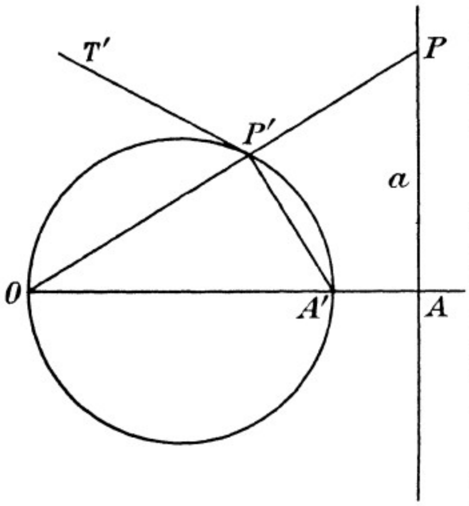

FIG. 58.

183. The inverse of a circle is, in general, a circle. Let c (Fig. 59) be any circle whose centre is C and radius a. Let P be any point of c, P' its inverse point. Let OP meet c again at Q.

Then: $$OP.OP' = k^2,$$
$$OP.OQ = OC^2 - a^2.$$

Hence $$OP'.OQ = k^2 : (OC^2 - a^2),$$

whence the locus of P' is similar and similarly situated to the locus of Q, O being the centre of similarity, and the ratio of similarity being $k^2/(OC - a^2)$.

Since the locus of Q is the original circle, the locus of P' is also a circle c', whose centre K is in the line OC. If O is outside c, a pair of common tangents to c, c' pass through it.

Thus every circle inverts into another circle, except when the first circle passes through the centre of inversion, when, as in Art. 182, it inverts into a straight line perpendicular to OC.

It should be noted that the centre of the circle c does not invert into the centre of the circle c', so that K is not C'.

It is also important to remember that a *conic* does not, in general, invert into a conic. For, consider the inverse s' of a conic s, and the intersections of s' with a straight line t'. This line t' inverts into a circle t, which has four real or imaginary intersections with the conic s. The inverse points of these four intersections are the intersections of t' and s'. These latter are thus four in number, so that s' is, in general, a quartic curve.

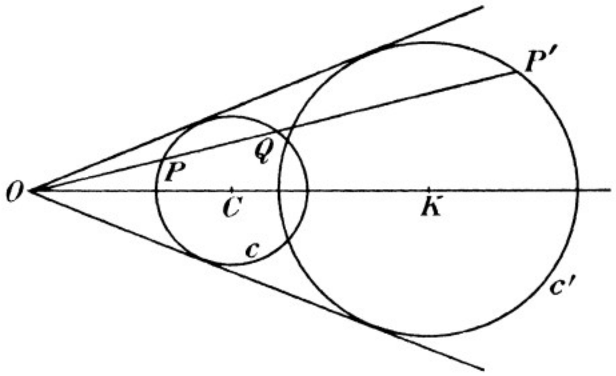

FIG. 59.

EXAMPLE

Given a point O and a circle centre C and radius r, show how to determine the radius of a circle of inversion, centre O, so that the circle, centre C, inverts into another of radius $2r$, and find the position of the centre of this inverse circle.

184. Circles through two inverse points. Let P, P' be any two inverse points with respect to a circle v of centre O and radius k, and let c be any other circle passing through P and P'.

Let Q be an intersection of v and c. Then $OQ=k$, the radius of inversion, and $OP.OP'=OQ^2$.

Hence, by a well-known property of the circle, OQ is a tangent from O to the circle c, and the circles c, v cut at right angles.

Thus **any circle through two inverse points is orthogonal to the circle of inversion.**

Conversely, if two points P, P' are such that two circles c_1, c_2

through P, P' are orthogonal to the circle of inversion v, then P, P' must be inverse points.

Let Q_1 be an intersection of v and c_1. Since these cut at right angles, OQ_1 is tangent to c_1 at Q_1.

Join OP and produce it to meet c_1 again at R_1. Then by a well-known property of the circle, $OP.OR_1 = OQ^2 = k^2$. R_1 is therefore the inverse point of P with respect to v.

Similarly, if OP meet c_2 again at R_2, R_2 is the inverse point of P with respect to v, and so is identical with R_1, which is thus an intersection, other than P, of the circles c_1, c_2. Since, by hypothesis, this second intersection is P', P' is identical with R_1 and so must be the inverse point of P.

It follows that, if two circles through P, P' are orthogonal to the circle of inversion, every circle through P, P' will be orthogonal to this circle.

EXAMPLES

1. The limiting points of a set of coaxal circles are inverse points with respect to every circle of the set.

2. If the radius of the circle of inversion is made infinite, so that the accessible part of the circle is a straight line, show that any two inverse points are images of one another in the straight line.

3. Prove that a circle passing through two inverse points inverts into itself.

185. Homography on circular bases is preserved by inversion. Although inversion, considered as a relation between plane fields, is not homògraphic, yet it preserves homographic properties as regards ranges on corresponding circles (including straight lines as a particular case).

Referring to Fig. 59, it is clear that, since P', Q are corresponding points in a similarity, and a similarity is a particular case of a plane perspective and therefore of a homography, we must have

$$[Q]^2 \barwedge [P']^2.$$

But, since OPQ is a chord of the circle c through a fixed point, P, Q are mates in an involution on the circle.

Hence $[P]^2 \barwedge [Q]^2$ and $[P]^2 \barwedge [P']^2$.

Thus **a range of the second order on a circle inverts into a homographic range of the second order on the inverse circle.**

The case of a range on a straight line follows immediately from Fig. 58; here $[P] \barwedge O[P] \barwedge [P']^2$.

Since straight lines do not invert into straight lines, this property is not applicable to pencils.

If now we have, in any figure, two homographic ranges $[P_1]^2$, $[P_2]^2$ on circular (or rectilineal) bases, then the inverse ranges $[P_1']^2$, $[P_2']^2$ are such that

$$[P_1']^2 \barwedge [P_1]^2, \ [P_2']^2 \barwedge [P_2]^2$$

and since $[P_1]^2 \barwedge [P_2]^2$, therefore $[P_1']^2 \barwedge [P_2']^2$, or : **homographic ranges on circular bases invert into homographic ranges on the inverse bases.**

186. Angles invert into equal angles. In Fig. 58, let the tangent at P' to the locus of P' be drawn, as $P'T'$.

Then the angle $T'P'O$ is equal to $OA'P'$ in the alternate segment, and this again, by the similarity of the triangles AOP, $P'OA'$, is equal to OPA.

The line a and its inverse circle a' therefore make equal angles with OPP', but on opposite sides of it. By considering small elements it is easily seen that the same holds good of any two corresponding curves.

If now we have two curves s, t intersecting at any angle at P, and the two corresponding curves s', t' intersecting at the corresponding point P', then s, t make with OP, on one side of $OP'P$, angles equal to those which s', t' make with OP' on the other side of $OP'P$. By subtraction, the angle between s, t at P is equal to the angle between s', t' at P'.

Inversion is therefore what is usually termed a **conformal transformation,** that is, any elementary *small* figure inverts into a similar figure. It will be found, however, that they are oppositely, and not directly, similar, that is, they cannot be brought into similar situation by a relative displacement in their plane, but one of them must be turned over as a preliminary.

Note that, as a particular case of the theorem of the present article, an orthogonal intersection of two curves inverts into an orthogonal intersection of the two inverse curves.

Examples

1. Describe, with diagrams, the possible geometrical configurations which may be obtained by inverting the plane figure formed by two parallel straight lines and a line meeting them at right angles, with respect to a circle in the plane.

Three circles touch one another in pairs. Prove that the circle through the three points of contact cuts the three circles orthogonally.

2. Show that if σ, σ' are two very small corresponding areas at corresponding points P, P' in inverse fields, then in the limit $\sigma : \sigma' = OP^4 : k^4$.

187. Inversion of coaxal circles. Let c_1, c_2, c_3, etc., be a set of concentric circles, whose common centre is C. All straight lines l through C are then orthogonal to the circles c.

Now invert the field with regard to any given point O. The straight lines l invert into circles l' passing through O and through the inverse point C' of C, that is, into coaxal circles with real intersections O, C'.

The circles c then invert into circles c' which are orthogonal to the circles l' and therefore, by Art. 113, form a set of coaxal circles with imaginary intersections but real limiting points.

One of these limiting points is clearly C', since C is the point-circle of the set c, and a point-circle must invert into a point-circle.

To find the second limiting point, we note that, if c^{∞} is the circle centre C, of infinite radius, all the points of c^{∞} invert into O, which is therefore a point circle inverse to c^{∞}.

Thus **a set of concentric circles invert into a set of coaxal circles having for real limiting points the centre of inversion and the inverse point of the common centre.**

Conversely, if we invert such a set of coaxal circles with respect to one of their limiting points, we obtain a set of concentric circles. For the coaxal circles through the limiting points are orthogonal to the given coaxal circles, and invert into straight lines through the inverse of the second limiting point, which straight lines are orthogonal to every one of the new set of circles. But a circle which is orthogonal to a pencil of rays through a point has that point for centre ; the required result follows.

Note also that, since coaxal circles are circles through two fixed points (real or imaginary), coaxal circles necessarily invert into coaxal circles, whatever the centre of inversion.

We may therefore regard concentric circles as a particular case of coaxal circles. In this case the (ordinary) common points A, B of the circles coincide with Ω, Ω', so that the circles touch at Ω, Ω', as we should expect, and the common radical axis is the line at infinity.

EXAMPLES

1. Prove that two circles of a given coaxal system touch an arbitrary fixed straight line, and also that they are inverse with respect to that circle of the system which has its centre on the given straight line.

2. If a circle touches two given circles c_1, c_2, the points of contact are concyclic with the limiting points of the coaxal system determined by c_1, c_2.

3. If two variable circles touch one another, and also each of two given

circles c_1, c_2, show that the locus of their mutual point of contact is a circle coaxal with c_1, c_2.

4. Two given coplanar circles a, b have centres A, B; the inverse of a point P_1 with respect to a is P and the inverse of P with respect to b is P_2. Prove that, when P_1 describes a circle or a line, the corresponding point P_2 describes either a circle or a line; and show that, in the correspondence between the fields $[P_1]$, $[P_2]$, the system of coaxal circles with limiting points A, P_1 corresponds to the system of coaxal circles with limiting points B, P_2.

5. Invert the theorem: the locus of centres of circles which touch two concentric circles is two concentric circles.

188. Inverse figures invert into inverse figures. Let ϕ, ϕ' be two figures which are inverse with regard to a circle k.

Invert both ϕ and ϕ' with respect to another circle s. We obtain two new figures ϕ_1 and ϕ_1'; the circle k inverts, in general, into a circle k_1.

Let P, P' be any two corresponding points of ϕ, ϕ' and let their inverses with regard to s be P_1, P_1'.

Let c_1 be any circle through P_1, P_1'. This corresponds, in the inversion with regard to s, to a circle c passing through P, P'.

By Art. 184, c and k cut orthogonally. Hence, by Art. 186, c_1 and k_1 cut orthogonally. Thus any circle through P_1, P_1' cuts k_1 orthogonally, and, by Art. 184, P_1, P_1' are inverse points with regard to k_1. Since P_1, P_1' are an arbitrary pair of corresponding points, the figures ϕ_1, ϕ_1' are inverse with regard to k_1.

Thus two inverse figures invert into two inverse figures, the circles of inversion being inverted into one another.

EXAMPLE

Prove that two fields inverse with respect to a circle can be inverted into two fields which are the reflection of one another in a straight line.

EXAMPLES XIA

1. Show that a correlation projects into a correlation, and the base conics into base conics.

2. In two coplanar reciprocal fields ϕ_1, ϕ_2 the lines a_2, b_2, c_2 in ϕ_2 which correspond to the vertices A_1, B_1, C_1 of a triangle in ϕ_1 coincide respectively with the opposite sides B_1C_1, C_1A_1, A_1B_1. Show that every point of the plane corresponds to the same line in either field.

3. Show that the only correlation in which every point corresponds to the same line in either field is the transformation by reciprocal polars.

4. Discuss the characteristics of the correlation in which the base conics are concentric circles centre O. Show that the two lines which correspond to any point P are equally inclined to OP and that they intersect on OP

at a point P' which lies on the polar of P with respect to the circle k_1 which is the locus of incident points.

Prove also that the angle between the two lines corresponding to P is constant and equal to the angle between the tangents to k_2 from any point of k_1. Hence show that, if the correlation is real, k_2 must be interior to k_1.

5. By projecting the circular points into any given points, deduce the results corresponding to those of Ex. 4 in the case of a general correlation.

6. In a correlation three lines a, b, c through a vertex U correspond to three points A', B', C' on a line u' through U. Obtain a construction, using the ruler only, for the point V' corresponding to the line $v=u'$, and also for the line t corresponding to the point $T'=U$.

7. Reciprocate the theorem, that the angle in a segment of a circle is constant, with respect to the point at which one of the arms of the angle meets the circle, and hence show that if through the focus O of a parabola a line OP is drawn to meet a variable tangent to the parabola at P and making a fixed angle with this tangent, the locus of P is a fixed tangent to the parabola.

8. From the result that a chord of a circle which touches a concentric circle subtends a constant angle at the common centre deduce the following theorem.

If there be two conics having the same focus and corresponding directrix and if two tangents to one conic meet on the other conic and intersect the directrix at XY, then XY subtends a fixed angle at the focus.

9. If from a fixed point tangents are drawn to a series of concentric circles, find the locus of their points of contact. Hence obtain the following theorem by reciprocation. A fixed line meets a number of conics which have the same focus and corresponding directrix; then the envelope of the tangents at the points of intersection is a conic touching the fixed line and also the common directrix.

Hence find the envelope of the asymptotes of conics having a common focus and directrix.

10. If the two common tangents to two conics having a common focus O intersect at A and through A a line APQ be drawn meeting one conic at P and the other at Q, then, if the tangents at P and Q meet at R, OR is a bisector of the angle POQ.

[Reciprocate the theorem that tangents to two circles from a point on their radical axis are equally inclined to the line joining their points of contact.]

11. A variable chord of a rectangular hyperbola subtends a right angle at a fixed point O. By reciprocation with respect to a circle having O as centre show that the locus of the foot of the perpendicular from O on the chord is a straight line.

12. Prove that the polar reciprocal of a circle, taken with regard to a rectangular hyperbola, is a conic of which the centre of the rectangular hyperbola is a focus.

13. A conic is inscribed in a triangle ABC and has one focus at the circumcentre. Prove that the other real focus is the orthocentre.

14. Through a point O in the plane of a circle perpendicular rays OP, OQ are drawn to the circle. Show that PQ touches a fixed conic with a focus at O.

[Reciprocate the property of the orthoptic circle.]

15. Prove that if through a fixed point O inside a circle a straight line be drawn, meeting the circle at P and Q, the sum of the reciprocals of the perpendiculars from O on the tangents at P, Q is constant.

Obtain from this the theorem that the sum of the focal distances in an ellipse is constant.

16. Show that if ABC is a triangle and O any point in its plane, and if through O perpendiculars OP, OQ, OR are drawn to OA, OB, OC to meet BC, CA, AB respectively at P, Q, R, then PQR are collinear.

17. s' is the reciprocal of a curve s with respect to a point O, and P' is the point of s' corresponding to the tangent to s at P. If ρ, ρ' are the radii of curvature of s, s' at P, P' respectively, prove that $\rho\rho' = k^2 \operatorname{cosec}^3 \phi$, where k is the radius of reciprocation, and ϕ is the angle between OP and the tangent to s at P.

Illustrate this result by using it to find the radius of curvature at a point of a conic.

18. A circle c touches an ellipse k at P, and has its centre O on the orthoptic circle of k; the other common tangents q, r of c and k touch the circle c at Q, R respectively. By reciprocation with regard to c, show that there is one rectangular hyperbola which touches k at P and passes through Q and R; and that its asymptotes are parallel to the tangents from O to k.

Prove also that chords of this hyperbola which subtend right angles at O touch a certain parabola whose focus is O.

19. Prove by reciprocation the following.

A variable tangent p to a conic having S as focus meets two fixed tangents a and b at P and Q respectively; a line q through Q meets a at a point L such that the angle PSL is a constant angle. Show that the envelope of q is a conic having S for focus and touching a and b.

20. Prove that the reciprocal of a parabola k with respect to a circle c, whose centre O lies on k, is another parabola k', which touches at O the perpendicular from O to the axis of k, and has its axis parallel to the normal at O to k.

Show also that the directrix of k' is the reciprocal, with respect to c, of the Frégier point of O with respect to k.

If c has its centre O at an extremity of the latus rectum of k, prove that the focus of k' lies on the tangent at O to k.

21. Reciprocate, with respect to a circle with centre at a focus, the property that confocal conics intersect at right angles.

22. If one conic s is its own polar reciprocal for another conic t then the conic t is its own polar reciprocal for the conic s.

[Show that the conics have double contact at A, B and that if C be the common pole of AB then if a ray through C meet t at U, T the tangent at U is the polar of T with regard to s.]

23. Show that given two points A, B of a conic s, a conic t can be found touching s at A, B and such that s is its own polar reciprocal with regard to t.

24. If a figure be inverted with regard to any origin, show that an involution on a circle inverts into an involution on the corresponding circle.

25. Invert the theorem: tangents to a fixed circle cut a fixed concentric circle at a constant angle, the centre of inversion being a point in the circumference of the second circle.

26. Prove that the circles which pass through a given point L and cut a

fixed circle c at a given angle α all touch a second fixed circle k; and that L is a limiting point of the coaxal system determined by c and k.

Show also how to construct the circle k.

27. PQ is a common tangent to two circles and L, M are the limiting points of the set of coaxal circles determined by the two circles. Prove that PLQ, PMQ are right angles.

Transform this result by inversion, (i) from L, (ii) from M.

If PR, QS are chords of the circles passing through L, prove that RS is also a common tangent.

28. P_1 and P_2 are the inverses of a point P with respect to two different circles k_1 and k_2 respectively. If the inverse of P_1 with respect to k_2 coincides with the inverse of P_2 with respect to k_1, show that k_1 and k_2 are orthogonal.

EXAMPLES XIB

[The axes of co-ordinates are to be taken rectangular.]

1. The points $(3, 1)$, $(-3, 0)$, $(1, 2)$, $(1, -2)$ correspond to the lines $x=3$, $x=-3$, $y=2$, $y=-2$ in a correlation.

Find (i) the other incident points on the four given lines; (ii) the other incident lines through the four given points. Hence construct the base-conics.

2. With the data of Ex. 1, construct (i) the lines corresponding to the origin; (ii) the points corresponding to the line at infinity.

3. The base-conics of a correlation are the hyperbola

$$x^2-3y^2=1$$

and its auxiliary circle. Construct the conic corresponding to the conjugate hyperbola.

4. The circles $(x-2)^2+y^2=9$, $(x+4)^2+y^2=1$ are reciprocated with respect to the circle $x^2+(y-1)^2=1$.

Without drawing the reciprocal curves of the first two circles, find their four intersections.

5. Two circles centres A and B have radii 1 inch and 2 inches respectively, and $AB=4$ inches. Find (i) a circle with respect to which they reciprocate into confocal conics, (ii) the four intersections of these conics, (iii) the tangents at these four intersections.

6. Two circles centres A and B have radii 3 and 4 inches respectively, and $AB=2$ inches. Find a centre of inversion which inverts the above circles simultaneously into straight lines. If P, Q are two points such that $AP=7$ inches, $AQ=1{\cdot}5$ inches, and the angles BAP, BAQ are 30°, 135° respectively, construct the circles orthogonal to the given circles and passing through P, Q respectively. Construct also the circles inverse to the last found circles.

7. A circle passes through the point P $(3, 4)$, and touches the axis of x at the origin O of co-ordinates. If its inverse circle passes through the point P' $(2, -1)$ inverse to P, and the chord of this inverse circle corresponding to OP is of length 4 units, construct the circle of inversion.

($a = 1$). Compare the result with exact value of the arc length.

7.9.4. Find approximately the arc length of the hyperbola $xy = -1$ between the points with $x = 0.5$ and $x = 1$. [*Hint.* In this case we cannot obtain an exact value because the integral in (7.9.2) cannot be expressed in terms of elementary functions.]

7.9.5. Obtain approximate values of the number π by computing the arc length of a circle with a central angle of 45° (retain three, four, and five terms in the series).

7.10 Curvature and the Osculating Circle

Related to the arc length is the problem of determining the ***curvature*** k and the ***radius of curvature*** R of a curve at a point. For a circle the radius of curvature R is simply the circle's radius, and the reciprocal of the radius is the curvature, $k = 1/R$. The smaller the radius R of a circle (i.e. the greater the curvature k), the tighter the circle (Figure 7.10.1). When R is very large, on the contrary, the curvature is hardly noticeable, that is, the circle is "almost" a straight line; for instance, the fact that the earth's radius is so large means that we do not notice the curvature of the earth's surface (to notice it, we would have to observe the earth from outer space, and this is not common practice).

Let us take an arbitrary curve Γ now. It is clear (Figure 7.10.2) that the curve is curved more on the portion PQ, where it sharply turns to the left, than on the portion MN, where its direction does not change so rapidly. But what is the exact meaning of the last statement? The explanation is as follows.

Consider the angle φ between the tangents of the curve at the endpoints M and N of the arc MN. If over this arc the tangent rotates only in one direction when we move from point m to point N, the angle φ shows the magnitude of the rotation of the tangent on arc MN (or the magnitude of the "rotation" of the curve, since the direction of the curve is specified by the direction of the tangent). To determine the extent to which the curve is curved we must also know the arc length s of MN: if s is large, then even a slow change in the direction of the tangent can lead to a large value of φ.

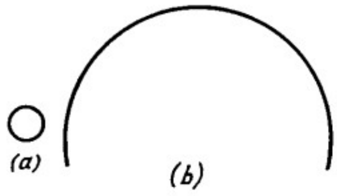

Figure 7.10.1

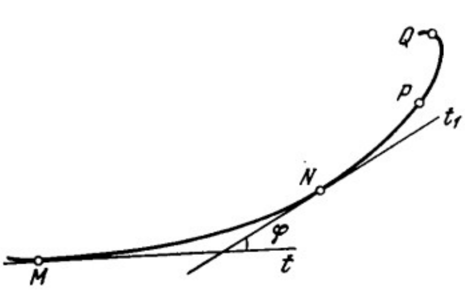

Figure 7.10.2

Thus, the ratio

$$k_{\text{av}} = \varphi/s \tag{7.10.1}$$

specifies the *average* (or *specific*) curvature of the curve over arc MN. *The curvature at point M of the curve* is defined then as the *limit* of the average curvature when the length of arc MN tends to zero:

$$k = \lim_{\Delta s \to 0} \frac{\Delta\alpha}{\Delta s},$$

where Δs is the length of a (small) arc MM_1 of curve Γ, and $\Delta\alpha$ is the increment of angle α corresponding to this arc (α is the angle between the tangent to the curve at point M and the x axis), or the angle of rotation of the tangent to the curve (the angle between the tangents t and t_1 to Γ at points M and M_1; Figure 7.10.3). But by virtue of the definition of a derivative (see Section 2.1), we can rewrite the last limit as

$$k = \frac{d\alpha}{ds}. \tag{7.10.2}$$

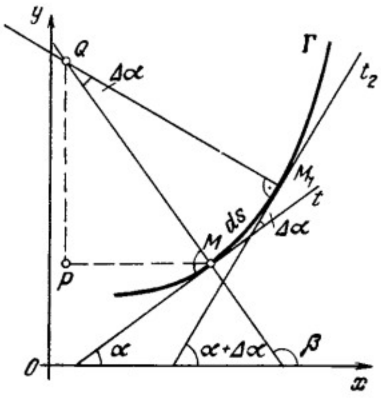

Figure 7.10.3

Thus, curvature k can be defined as the *rate of rotation of the tangent* to Γ as the point moves along the curve with a unit (linear) speed, that is, under conditions where point M travels the distance $MM_1 = ds$ in time $dt = ds$.

Now we need only recall that $\tan\alpha = y'$, so that $\alpha = \arctan y'$ and, hence,

$$d\alpha = d(\arctan y') = \frac{dy'}{1+(y')^2} = \frac{y''\,dx}{1+(y')^2};$$

moreover, $ds = \sqrt{1+(y')^2}\,ds$ (see Section 7.9). Thus, finally,

$$k = \frac{d\alpha}{ds} = \left[\frac{y''}{1+(y')^2}\,dx\right] \Big/ \left[\sqrt{1+(y')^2}\,dx\right] = \frac{y''}{[1+(y')^2]^{3/2}} \qquad (7.10.3)$$

and, hence,

$$R = \frac{1}{k} = \frac{[1+(y')^2]^{3/2}}{y''}. \qquad (7.10.3a)$$

If curve Γ is specified parametrically, $x = x(t)$ and $y = y(t)$ (see Section 1.8), then $dy/dx = y'/x'$ and $\frac{d^2y}{dx^2} = \frac{x'y''-x''y'}{(x')^3}$ (see formula (4.4.9)). Therefore, from (7.10.3) and (7.10.3a) it follows that

$$k = \left[\frac{x'y''-x''y'}{(x')^3}\right] \div \left[1+\frac{(y')^2}{(x')^2}\right]^{3/2} = \frac{x'y''-x''y'}{[(x')^2+(y')^2]^{3/2}},$$

$$R = \frac{1}{k} = \frac{[(x')^2+(y')^2]^{3/2}}{x'y''-x''y'}. \qquad (7.10.3b)$$

We note also that since α is a dimensionless quantity (we employ, as usual, radians for measuring angles) and s has the dimensions of length $[l]$, the curvature k of a curve has the dimensions $[l]^{-1}$ (say cm^{-1}) and the radius of curvature (as any radius), the dimensions of length $[l]$, say cm.

The notion of the radius of curvature (and hence the notion of curvature) of a curve may be introduced in a more geometrical manner. To this end we draw normals MQ and M_1Q (perpendicular lines) to the tangents to two close-lying points M and M_1 on Γ (by Q we have denoted the point of intersection of the normals; see Figure 7.10.3). The angle MQM_1 between the normals is equal to the angle $\Delta\alpha$ between the tangents to points M and M_1 (in accord with a familiar theorem of geometry on angles with mutually perpendicular sides). From this we can find the distance MQ from the curve to the point of intersection of the normals.

We regard the small portion of the curve as an arc of a circle. A normal to the circle is clearly a radius, and the point of intersection of normals is clearly the center of the circle. If the curve was a circle of radius R, then ds would be equal to $R\,d\alpha$, or $d\alpha/ds = 1/R$; this quantity, $d\alpha/ds$ (the curvature of the circle), is constant for any portion of an arc of the circle. Now we select the arc of a circle in such a manner that it is *as close as possible to* the arc MM_1 ("hugs" the arc). The words "as close as possible" are understood as a requirement that the first three terms in Taylor's expansion of the equation $y = y(x)$ of the curve,

$$y = y(a) + y'(a)(x-a) + \frac{1}{2}y''(a)(x-a)^2 + \frac{1}{6}y''(a)(x-a)^3 + \dots \qquad (7.10.4)$$

(we assume that the point M on the curve corresponds to the value $x = a$ of the abscissa), coincide with the first three terms in Taylor's expansion of the equation $y = Y(x)$ of the circle,

$$y = Y(a) + Y'(a)(x-a) + \\ + \frac{1}{2} Y''(a)(x-a)^2 \\ + \frac{1}{6} Y'''(a)(x-a)^3 + \dots \qquad (7.10.4a)$$

(see formula (6.1.18)).[7.29] In other words, we require that not only the values $y(a)$ and $Y(a)$ coincide but so do the first two derivatives of $y(x)$ and $Y(x)$ at point $x = a$:

$$y(a) = Y(a), \quad y'(a) = Y'(a), \\ y''(a) = Y''(a). \qquad (7.10.5)$$

But by virtue of (7.10.3), all this guarantees that at point M the curvatures of the curve Γ with equation $y = y(x)$ and of the circle Σ with equation $y = Y(x)$ coincide. This means that the radius $R = MQ$ of circle Σ is expressed by formula (7.10.3a).

The circle Σ that passes through point M of the curve Γ and is the closest to Γ is known as the ***osculating circle*** of the curve.[7.30] The radius R of this circle is the ***radius of curvature*** of the curve, and the center Q of circle Σ is said to be the center of curvature of the curve (at point M). Thus, the radius of curvature of a curve can be defined as the radius of the osculating circle; the curvature of the curve is the reciprocal of the radius of the osculating circle.

We note also that since by virtue of (7.10.4), (7.10.4a), and (7.10.5), the difference $Y(x) - y(x) = (1/6) \times [Y'''(a) - y'''(a)]\, dx + \dots$ changes sign as we pass through point M (i.e. as dx changes sign), the osculating circle Σ at point M of the curve Γ *intersects* the curve.[7.31] This makes it possible to describe the osculating circle thus.

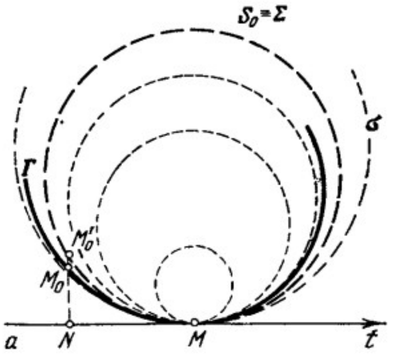

Figure 7.10.4

Let us consider various circles σ that touch point M of Γ and have at point M the same sense of convexity (the direction of bending), in other words, have the same tangent at point M as Γ and have centers that lie on the side of convexity of Γ (i.e. inside the curve) (Figure 7.10.4). Some of these circles lie completely inside Γ (i.e. on the side of convexity of Γ), and their curvature is *greater* than that of Γ. Others lie outside Γ, and their curvature is *smaller* than that of Γ. But there is only one circle that goes from one side of Γ to the other (this happens at point M), and this circle S_0 lies closest to Γ and is called the ***osculating circle*** Σ.

If conditions (7.10.5) are met for a straight line (the tangent t to Γ at point M), then the radius of curvature of Γ at this point (which is calculated via (7.10.3a)) becomes infinite and the curvature k vanishes. Such points M are sometimes called the ***rectifying points*** of curve Γ. It is clear that at

---

[7.29] A circle in a plane is defined by three numbers (parameters); these may be the coefficients a, b, and r in the equation of the circle $(x-a)^2 + (y-b)^2 - r^2 = 0$. To find these numbers (i.e. to define the circle) we must have *three* conditions, which may be the conditions in (7.10.5).

[7.30] An osculating circle Σ of a curve Γ can also be defined as follows. Consider the circle S that passes through three points M_1, M_2, and M_3 of curve Γ that lie close to point M. When all three points move toward M, circle S tends to the osculating circle Σ of curve Γ at point M.

[7.31] Exceptions in this case are only points where, in addition to conditions (7.10.5), we have $Y'''(a) = y'''(a)$. Examples are the vertices of an ellipse (points where the ellipse intersects the axes of coordinates); at such points, as symmetry considerations suggest, the osculating circle cannot interesct the ellipse (by analogy, all points of a curve Γ that possess this property are called the ***vertices*** of Γ).

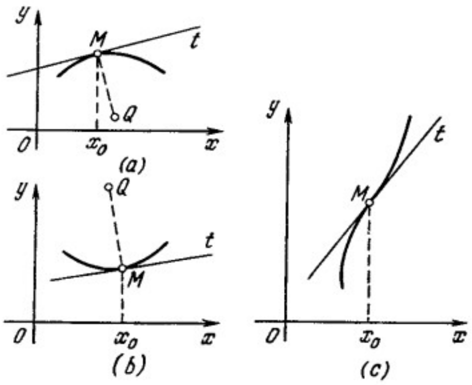

Figure 7.10.5

a rectifying point the curve Γ has no center of curvature Q (this center lies at infinity).

From (7.10.3) it follows that the signs of k and R (up till now we spoke only of the absolute values of k and R and ignored their signs) coincide with the sign of the second derivative y'', that is, characterize the sense of *convexity* of the curve (see Section 2.7). If the curvature is negative, that is, at point M we have a negative y'', the curve at this point lies below the tangent at point M, that is, the curve is *convex* (or *convex upward*; Figure 7.10.5*a*); the center of curvature Q then lies *below* point M. If the curvature is positive, that is, $y'' > 0$, the curve lies above the tangent and is said to be *concave* (*convex downward*; Figure 7.10.5*b*); in this case the center of curvature Q lies above point M. Finally, if the curvature at point M vanishes, that is, $y'' = 0$, then, as we already know, the curve at point M changes its sense of convexity; to one side of M the curve is convex upward and to the other it is convex downward (Figure 7.10.5*c*). At such a point the curve passes from one side of the tangent to the other, changes its sense of convexity (the direction of bending), and the point is called a ***point of inflection.*** At points of inflection, not only the first derivatives of the equation $y = y(x)$ of curve Γ and of the equation $y = Y(x)$ of tangent t coincide, but so do the second derivatives, $y'' = Y'' = 0$, that is, at such points the tangent t obeys the conditions (7.10.5); in other words, at a point of inflection M the *tangent* t acts as the osculating circle Σ, or M is a rectifying point of Γ.

For a straight line l, which of course can also be considered as a special case of a curve, the angle α between the tangent to l (which is simply l) and the x axis does not vary; this means that the curvature k of a straight line is identically zero (l is simply not curved in any way). For a circle S, the angle α changes, but the rate $k = d\alpha/ds$ at which α changes along the circle remains constant; in other words, we may say that circles (and straight lines, for that matter) are curves of constant curvature. It can be shown that these are the only types of such curves.

Suppose that M $(x, y, (x))$ is a point of a curve Γ. The tangent t to the curve at point M has a slope y' ($=\tan\alpha$), and the normal n is perpendicular to t, that is, forms an angle $\beta = \alpha + 90°$ with the x axis (see Figure 7.10.3); the slope of the normal is $\tan\beta = -\cot\alpha = -1/y'$. Therefore, the (directed) projections MP and PQ of the axes of coordinates of the line segment MQ of length R are, respectively, $p = R\cos\beta = -R\sin\alpha$ and $q = R\sin\beta = R\cos\alpha$, which means that the coordinates of the center of curvature Q are

$$\begin{aligned}\xi &= x + p = x - R\sin\alpha,\\ \eta &= y + q = y + R\cos\alpha.\end{aligned} \qquad (7.10.6)$$

If now we take into account formula (7.10.3a) for R and the obvious fact that

$$\cos\alpha = \frac{1}{\sqrt{1+\tan^2\alpha}} = \frac{1}{\sqrt{1+(y')^2}},$$

$$\sin\alpha = \frac{\tan\alpha}{\sqrt{1+\tan^2\alpha}} = \frac{y'}{\sqrt{1+(y')^2}},$$

we finally get

$$\xi = x - \frac{\sqrt{[1+(y')^2]^3}}{y''}\,\frac{y'}{\sqrt{1+(y')^2}},$$

$$\eta = y + \frac{\sqrt{[1+(y')^2]^3}}{y''}\,\frac{1}{\sqrt{1+(y')^2}},$$

that is,

$$\xi = x - \frac{1+(y')^2}{y''}\, y', \quad \eta = y + \frac{1+(y')^2}{y''}. \tag{7.10.7}$$

(This agrees with the condition that $\eta > y$ for $k > 0$, or for $y'' > 0$, or the condition that $\eta < y$ for $k < 0$, or for $y'' < 0$.)

If the curve is specified parametrically, $x = x(t)$ and $y = y(t)$, we can write (see (7.10.3b))

$$\begin{aligned} \xi &= x - \frac{(x')^2+(y')^2}{x'y''-x''y'}\, y', \\ \eta &= y + \frac{(x')^2+(y')^2}{x'y''-x''y'}\, x' \end{aligned} \tag{7.10.7a}$$

(see Exercise 7.10.4).

The locus of the centers of curvature $Q(\xi, \eta)$ of a curve Γ constitutes a new curve γ known as the ***evolute*** of curve Γ. The curve Γ with respect to its own evolute γ is called the ***involute***.[7.32]

Example 1. The parabola $y = x^2$. Here $y' = 2x$ and $y'' = 2$ (a constant), whereby the curvature k and the radius of curvature R of the parabola at point $M(x, y)$ $(=M(x, x^2))$ are

$$k = \frac{2}{\sqrt{(1+4x^2)^3}}, \quad R = \frac{\sqrt{(1+4x^2)^3}}{2}.$$

The center of curvature $Q(\xi, \eta)$ of the parabola with respect to point $M(x, x^2)$ has coordinates

$$\xi = x - \frac{1+4x^2}{2}\cdot 2x = -4x^3,$$

$$\eta = x^2 + \frac{1+4x^2}{2} = 3x^2 + \frac{1}{2},$$

that is,

$$\xi = -4\sqrt{\left(\frac{\eta - 1/2}{3}\right)^3}$$

$$= -\frac{4}{3\sqrt{3}}\sqrt{(\eta - 1/2)^3}, \text{ or } \xi = c\eta_1^{3/2}, \tag{7.10.8}$$

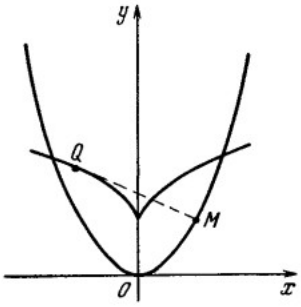

Figure 7.10.6

where $c = -4/3\sqrt{3}$ and $\eta_1 = \eta - 1/2$.

Thus, the evolute of $y = x^2$ is the *semicubical parabola* (7.10.8) whose cusp coincides with point (0, 1/2) and whose axis of symmetry is the axis of ordinates (Figure 7.10.6).

Example 2. The cycloid $x = a(t - \sin t)$, $y = a(1 - \cos t)$. We have $x' = a(1 - \cos t)$, $y' = a \sin t$, $x'' = a \sin t$, and $y'' = a \cos t$ (the primes denote derivatives with respect to parameter t). Whence,

$$\begin{aligned} (x')^2 + (y')^2 &= a^2(1-\cos t)^2 + a^2 \sin^2 t \\ &= a^2(2 - 2\cos t) = 4a^2 \sin^2 \frac{t}{2}, \\ y''x' - x''y' &= a\cos t \cdot a(1-\cos t) \\ &\quad - (a \sin t)^2 = a^2(\cos t - 1) \\ &= -2a^2 \sin^2 \frac{t}{2}. \end{aligned}$$

Thus, in view of (7.10.7a) we have

$$\begin{aligned} \xi &= a(t - \sin t) + 2a \sin t \\ &= a(t + \sin t), \\ \eta &= a(1 - \cos t) - 2a(1 - \cos t) \\ &= -a + a \cos t. \end{aligned} \tag{7.10.9}$$

To understand what curve is represented by these equations, we introduce a new parameter, $t_1 = t + \pi$ (or $t = t_1 - \pi$); since $\sin t = -\sin t$ and $\cos t = -\cos t_1$, we have

$$\begin{aligned} \xi &= a(t_1 - \sin t_1) - a\pi, \\ \eta &= a(1 - \cos t_1) - 2a. \end{aligned} \tag{7.10.10}$$

[7.32] The word "involute" is the Latin for "unwinding", while the word "evolute" is the Latin for "unwound," that is the curve that is being unwound; these names are related to the properties of evolutes and involutes discussed at the end of this section (see the text in small print).

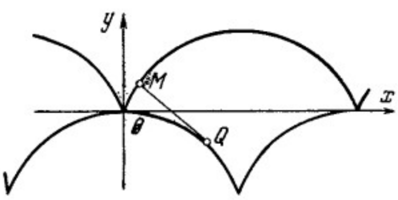

Figure 7.10.7

Thus, the evolute (7.10.9) (or (7.10.10)) of a cycloid is also a *cycloid*, $\xi_1 = a(t_1 - \sin t_1)$ and $\eta_1 = a(1 - \cos t_1)$, where $\xi_1 = \xi + a\pi$ and $\eta_1 = \eta + 2a$, only shifted in relation to the initial cycloid by $2a$ units downward ($2a$ is the diameter of the generating cirle) and πa units to be left (πa is the half-width of the arch of the initial cycloid) (Figure 7.10.7).

To discuss the properties of evolutes and involutes in detail, we must first differentiate in (7.10.6):

$$d\xi = dx - R\cos\alpha\, d\alpha - \sin\alpha\, dR,$$

$$d\eta = dy - R\sin\alpha\, d\alpha + \cos\alpha\, dR.$$

But since (see (7.9.2b))

$$dx = \cos\alpha\, ds = \cos\alpha\,\frac{ds}{d\alpha}\,d\alpha = R\cos\alpha\, d\alpha,$$

$$dy = \sin\alpha\, ds = \sin\alpha\,\frac{ds}{d\alpha}\,d\alpha = R\sin\alpha\, d\alpha,$$

we have

$$d\xi = -\sin\alpha\, dR, \quad d\eta = \cos\alpha\, dR. \tag{7.10.11}$$

Dividing one by the other, we get

$$\frac{d\eta}{d\xi} = -\cot\alpha = \tan(\alpha + 90°). \tag{7.10.12}$$

From this it follows that a tangent to evolute γ of a curve Γ (i.e. to the locus of the centers of curvature $Q(\xi, \eta)$) forms an angle $\beta = \alpha + 90°$ with the x axis, that is, coincides with the *normal* to Γ. And since point Q belongs to the normal n to curve Γ at point M, the respective tangent to γ coincides with n, that is, *tangents to the evolute γ of a curve Γ coincide with the normals to* Γ (Figure 7.10.8).[7.33]

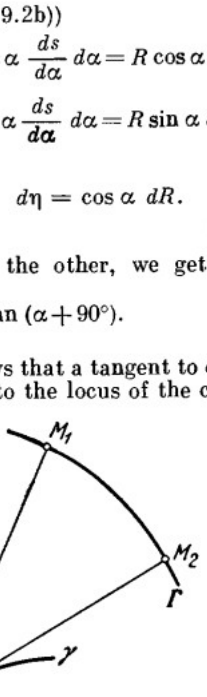

Figure 7.10.8

On the other hand, from (7.10.11) it follows that

$$d\xi^2 + d\eta^2 = \sin^2\alpha\, dR^2 + \cos^2\alpha\, dR^2 = dR^2,$$

$$\text{i.e.} \quad d\sigma = dR, \tag{7.10.12a}$$

where σ is the length of the arc of evolute γ of curve Γ (both $d\sigma$ and dR are assumed positive).

The last remark has the following meaning. Let us consider an arc M_1M_2 of curve Γ such that on it the derivative $R' = dR/ds$ retains its sign. We will agree to reckon the arc length along Γ in such a manner that the derivative of R is *positive*; in other words, we assume that the arc length is reckoned along Γ in the direction in which the radius of curvature R *grows*. Then the increment $M_2Q_2 - M_1Q_1 = R_2 - R_1 = \Delta R$ of the radius of curvature along arc M_1M_2 is equal to the length $\Delta\sigma$ of the evolute arc. And since the line segments M_1Q_1 $(=R_1)$ and M_2Q_2 $(=R_2)$ are tangents to evolute γ of curve Γ (see Figure 7.10.8), the process of reconstructing the involute Γ from its evolute γ resembles the unwinding under tension of a nonexpandable string from a spool shaped like γ; the end M of the string describes curve Γ. That is the origin of the names *evolute* and *involute* (see footnote 7.32).

By way of an example, let us construct the (parametric) equation of the *involute of a circle* of radius r and equation $x^2 + y^2 = r^2$, or $x = r\cos t$ and $y = r\sin t$, where t is the parameter (angle). Let us assume that the involute passes through point $A(r, 0)$ and that the unwinding of the string wound on the round spool occurs counterclockwise (Figure 7.10.9). The tangent MT to the circle at point $M(r\cos t, r\sin t)$ forms an angle $\alpha = t + 90°$ with the x axis, and the line segment MT of length rt along the tangent (rt is the length of arc AM of the circle) has projections $rt\cos\alpha = -rt\sin t$ and $rt\sin\alpha = rt\cos t$ on the axes of coordinates. This readily yields the following parametric expressions for the coordinates X, Y of point $T(X, Y)$ (i.e. the equation of the involute of the circle):

$$X = r\cos t - rt\sin t,$$

$$Y = r\sin t + rt\cos t. \tag{7.10.13}$$

The theory of evolutes and involutes was first developed by Christian Huygens in his

---

[7.33] In this connection it is often said that evolute γ of curve Γ is the *envelope of the normals* to Γ.

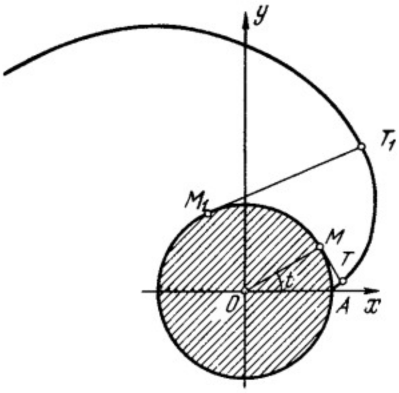

Figure 7.10.9

Horologium Oscillatorium (1673) in connection with the following problem. We wish to construct the equation of motion of a pendulum, that is, a material particle of mass m (the bob) moving along a curve γ:

$$m\,\frac{d^2s}{dt^2}=mg\sin\alpha, \tag{7.10.14}$$

where s is the arc length of curve γ and t is time, so that d^2s/dt^2 is the (*tangenrtial*, i.e. directed along the tangent to γ) *acceleration* of the particle, g is the acceleration of gravity, α is formed by the tangent l to curve γ and the horizontal, and $mg\sin\alpha$ is the (vertical) projection of the force of gravity mg on l (Figure 7.10.10; see Chapters 9 and 10). The period of oscillations of the pendulum is, strictly speaking, dependent on the swing (i.e. on the uppermost point on curve γ at which the pendulum starts oscillating). Huygens posed the question of what shape should curve γ have so that the pendulum bob swinging along this curve would take exactly the *same* time to complete swings of large and of small amplitude. By analyzing the differential equation (7.10.14) (which was not a simple task because at that time there was no differential and integral calculus) Huygens found that γ must be a *cycloid*. But how do we make a pendulum move along a cycloid? It was in this connection that Huygens developed the general theory of involutes and found that the evolute of a cycloid is also a cycloid (see Figure 7.10.7 and Eq. (7.10.10)). He also demonstrated that if at the point of suspension of the string of the pendulum certain "lips" in the form of a cycloid are attached, so that in the process of oscillations the string winds about them, then the end of the string (with the bob) of constant length describes a cycloid (Figure 7.10.11). The first pendulum clock constructed by Huygens had just such "lips"; however, later he dropped this idea because he found that the "lips" had practically no effect on the precision of the clock, since in view of the smallness of angles α in Eq. (7.10.14) we can always replace $\sin\alpha$ with α and the equation $m\,(d^2s/dt^2)=mg\,\alpha$ implies that the period of oscillations of a pendulum of *constant length* l is constant (see Section 10.3).

Exercises

7.10.1. Calculate the curvature (in an arbitrary point of the curve) of (a) an ellipse $x=a\cos t$ and $y=b\sin t$, (b) a hyperbola $y=1/x$, and (c) a fourth-order parabola $y=ax^4$.

7.10.2. Find the evolutes of (a) an ellipse $x=a\cos t$ and $y=b\sin t$, and (b) a hyperbola $y=1/x$.

7.10.3. Prove that the points of maxima or minima in the curvature of a curve correspond to the cuspidal points of the evolute of this point (see Figures 7.10.6 and 7.10.7).

7.10.4. Prove the validity of formulas (7.10.7a).

7.11 Solid Geometry Applications of Integral Calculus

In Section 3.6 we obtained the formula

$$V=\int_a^b S(x)\,dx, \tag{7.11.1}$$

where $S(x)$ is the area of a section of a solid by a plane $x=$ constant perpendicular to the x axis (we advise the reader to repeat the derivation of this formula). This formula was used to obtain an expression for the volume of a *pyramid*. The volume of a *cone* was obtained in exactly the same manner. Place the origin of the system of coordinates at the center of the circle of the

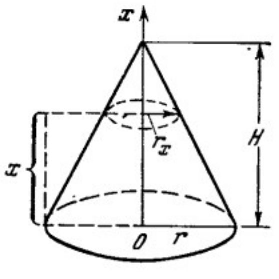

Figure 7.11.1

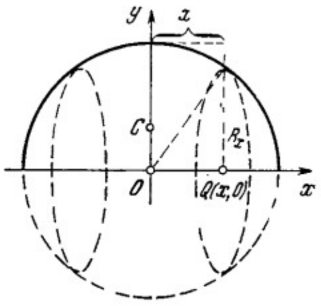

Figure 7.11.2

cone base and send the x axis along the altitude of the cone upward (Figure 7.11.1). Let $S(x)$ be the area of the section of the cone by a plane perpendicular to the altitude and distant x from the base. This section is a circle of radius r_x. From the similarity of triangles we have $r_x/r = (H - x)/H$, where r is the radius of the base and H is the altitude of the cone. Whence, $r_x = (r/H)(H - x)$ and $S(x) = \pi r_x^2 = \pi r^2 (H - x)^2/H^2$ and, consequently,

$$V = \int_0^H \pi \frac{r^2}{H^2}(H-x)^2\,dx$$

$$= -\frac{\pi r^2}{H^2}\,\frac{(H-x)^3}{3}\Big|_0^H = \frac{\pi r^2 H^3}{3H^2} = \frac{\pi r^2 H}{3}.$$

To obtain the volume of a *sphere* of radius R, we place the origin at the center of the sphere (Figure 7.11.2). The section cut by a plane perpendicular to the x axis and distant x from the origin is a circle of radius R_x. By the Pythagorean theorem $R_x = \sqrt{R^2 - x^2}$ and so $S(x) = \pi R_x^2 = \pi (R^2 - x^2)$, whence

$$V = \int_{-R}^{R} \pi (R^2 - x^2)\,dx$$

$$= \pi\left(R^2 x - \frac{x^3}{3}\right)\Big|_{-R}^{R} = \frac{4}{3}\pi R^3.$$

Formula (7.11.1) results in ***Cavalieri's theorem***,[7.34] which says that *if two solids have equal altitudes and if sections made by planes P and Q parallel to the bases and at equal distances to them always have a given ratio, the volumes of the two solids have this given ratio to each other*. Indeed, in calculating the volumes of such solids using formula (7.11.1), where the x axis is perpendicular to planes P and Q, we see that the ratio of the volumes is the same as the ratio of the integrands $S(x)$.

Let a solid be generated by revolving the curvilinear trapezoid depicted in Figure 7.11.3 about the x axis. In this case, the section is a circle of radius $y = f(x)$ and $S(x) = \pi y^2$. Using (7.11.1), we find the well-known formula for the *volume of a solid of revolution*:

$$V = \pi \int_a^b y^2\,dx. \qquad (7.11.2)$$

Let us find, say, the volume of a solid generated by the revolution of the upper half of the ellipse $x^2/a^2 + y^2/b^2 = 1$ about the x axis (make a drawing). This solid is called an ***ellipsoid of revolution***. Since for an ellipse $y =$

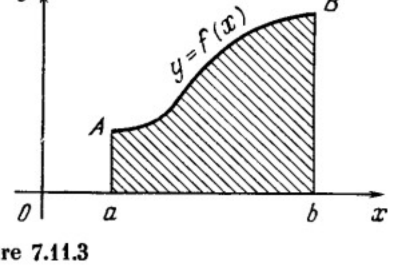

Figure 7.11.3

[7.34] This theorem played an important role in formulating the concept of the integral. Bonaventura ***Cavalieri*** (1598-1647), a pupil of Galileo, gave this theorem (without proof) in his *Geometria Indivisibilibus* (The Geometry of Indivisibles) (1635).

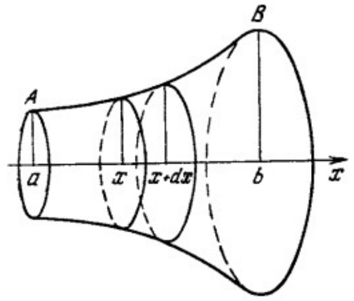

Figure 7.11.4

$(b/a)\sqrt{a^2-x^2}$, formula (7.11.2) yields

$$V=\pi\int_{-a}^{a}\frac{b^2}{a^2}(a^2-x^2)\,dx$$

$$=\frac{\pi b^2}{a^2}\left(a^2x-\frac{x^3}{3}\right)\Big|_{-a}^{a}=\frac{4}{3}\pi ab^2.$$

For $a=b=R$ we obtain, as expected the volume $(4/3)\,\pi R^3$ of a sphere of radius R.

Now let us derive the formula for the *surface area of a solid of revolution* (Figure 7.11.4). We consider a solid bounded by sections passing through the points x and $x+dx$. Denote by dF the lateral surface area of this solid. Regarding it as the frustrum of a cone, we get

$$dF\simeq\pi\,[y\,(x)+y\,(x+dx)]\,ds,$$

where ds is the length of the small portion of the curve by revolving which we get the surface of the solid; $ds=\sqrt{1+(y'\,(x))^2}\,dx$ (see Section 7.9). The sum $y\,(x)+y\,(x+dx)$ can be replaced with $2y\,(x)$, disregarding the quantity $y'\,(x)\,dx$ as compared with $y\,(x)$.[7.35] Therefore

$$dF\simeq 2\pi y\,(x)\sqrt{1+(y'\,(x))^2}\,dx.$$

The entire surface area of the initial solid of revolution is

$$F=2\pi\int_a^b y\,(x)\sqrt{1+(y'\,(x))^2}\,dx.\quad(7.11.3)$$

The surface area of a *sphere* is readily found by means of this formula. Indeed, a sphere is generated by the revolution of the upper semicircle about the x axis. The equation of a circle is $x^2+y^2=R^2$, whence

$$y=\sqrt{R^2-x^2},\quad y'=-\frac{x}{\sqrt{R^2-x^2}}.\quad(7.11.4)$$

Substituting into (7.11.3) yields

$$F=2\pi\int_{-R}^{R}\sqrt{R^2-x^2}\,\frac{R}{\sqrt{R^2-x^2}}\,dx$$

$$=2\pi Rx\Big|_{-R}^{R}=4\pi R^2.$$

Moreover, from (7.11.3) and (7.11.4) we can easily find the surface of a *spherical layer* (*spherical zone*) cut out of a sphere by two parallel planes $x=a$ and $x=b>a$ (see Figure 7.11.2 if, say, $b=R$, the layer becomes a *spherical segment* or *spherical cap*). Indeed, we have

$$F=2\pi\int_a^b\sqrt{R^2-x^2}\,\frac{R\,dx}{\sqrt{R^2-x^2}}$$

$$=2\pi Rx\Big|_a^b=2\pi R\,(b-a).$$

Thus, the sought-for surface area depends only on the altitude $b-a$ of the layer (segment) and the radius R of the sphere, which is really a remarkable and beautiful result.

Formulas (7.11.2) and (7.11.3) can be written also in a different way. Suppose the object depicted in Figure 7.11.3 is a metal plate of constant thickness. In this case the mass M of this plate is

$$M=\mu\int_a^b y\,dx=\mu S,\quad(7.11.5)$$

where μ is the density of the material of the plate (density per unit surface area; see Section 9.13), and $S=\int_a^b y\,dx$ is the surface area of the plate. The distance y_C from the center

---

[7.35] Note that in the expression dF of the sum $y\,(x)+y\,(x+dx)$ is multiplied by ds, so that the quantity we ignore is of the order of $dx\,ds\simeq dx^2$.

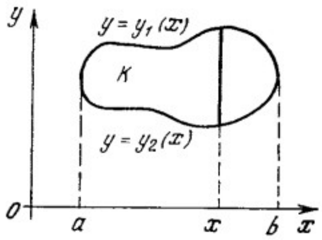

Figure 7.11.5

of gravity to the x axis is expressed by the formula

$$y_C=\frac{1}{2M}\int_a^b \mu y^2\,dx=\frac{1}{2S}\int_a^b y^2\,dx \qquad (7.11.6)$$

(see (9.13.12)). Comparing (7.11.2) and (7.11.6), we see that

$$V=2\pi\, Sy_C=2\pi y_C S, \qquad (7.11.7)$$

or that *the volume V of a solid revolution is equal to the area S of the figure whose rotation generates the solid multiplied by the circumference $2\pi y_C$ of the circle described in the process of rotation by the center of gravity of the figure.* (Here the center of gravity, or centroid, of a flat figure is assumed to coincide with the center of gravity of a homogeneous plate whose shape would be that of the figure.) This theorem is known as the ***(first) theorem of Pappus***.[7.36]

Formula (7.11.7) and the theorem of Pappus can be modified so that they incorporate the case of a solid generated by the rotation of a figure of arbitrary shape, and not only a curvilinear trapezoid.

Take, for example, the solid generated by the rotation about the x axis of the figure depicted in Figure 7.11.5. In this case the section of the solid by a plane perpendicular to the x axis is a circular ring (annulus) bounded by the circles of radii $y_1(x)$ and $y_2(x)$. Hence

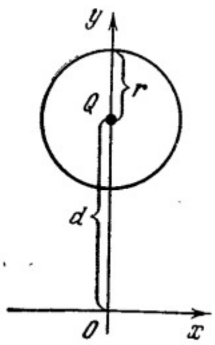

Figure 7.11.6

$$S(x)=\pi\,[y_1(x)]^2-\pi\,[y_2(x)]^2$$
$$=\pi\,(y_1^2-y_2^2)$$

and, therefore, the volume of the solid of revolution is

$$V=\pi\int_a^b (y_1^2-y_2^2)\,dx. \qquad (7.11.8)$$

On the other hand, the distance y_C from the x axis to the center of gravity (centroid) C of a homogeneous plate shaped as K in Figure 7.11.5 is

$$y_C=\frac{1}{2S}\int_a^b (y_1^2-y_2^2)\,dx=\frac{\int_a^b (y_1^2-y_2^2)\,dx}{2\int_a^b (y_1-y_2)\,dx} \qquad (7.11.9)$$

(see 9.13.11)). Hence here also $V=2\pi y_C S$.

Formula 7.11.3) can be interpreted in a similar manner. Suppose that the surface of a solid of revolution is generated by the rotation of an arc AB (see Figure 7.11.4) and imagine that the arc is a homogeneous heavy string with a constant density σ (mass per unit length; see the text between formulas (9.12.1) and (9.12.2)). In this case the distance y_C from the center of gravity of the string C to the x axis is given by the following formula:

$$y_C=\frac{1}{M}\int_{s_0}^{s_1}\sigma y(x)\,ds=\frac{1}{L}\int_{s_0}^{s_1} y(x)\,ds$$

$$=\frac{1}{L}\int_a^b y(x)\sqrt{1+(y'(x))^2}\,dx; \qquad (7.11.10)$$

here $x(s_0)=a$, $x(s_1)=b$, ds is the element of length of arc AB, $L=\int_{s_0}^{s_1} ds=\int_a^b \sqrt{1+(y'(x))^2}\,dx$

[7.36] ***Pappus*** of Alexandria (end of 3rd century A.D.) was the last of the great Greek mathematicians; in his works he set forth (usually without any proof) many results obtained by his predecessors and also by himself. The fact that the theorems of Pappus are often called the ***Pappus-Guldin theorems*** or even simply ***Guldin's theorems*** in the literature is completely groundless. Both theorems were formulated by Pappus, while their proofs, put forward by Paul ***Guldin*** (1577-1643), a Swiss monk and an amateur mathematician, were highly doubtful and substantially weaker than the proofs of the theorems given by B. Cavalieri and the famous Johann Kepler (1571-1630) (the latter proofs were harshly, but unjustly, criticized by Guldin).

$$V = 2\pi\, Sy_C = 2\pi y_C S, \qquad (7.11.7)$$

or that *the volume V of a solid revolution is equal to the area S of the figure whose rotation generates the solid multiplied by the circumference $2\pi y_C$ of the circle described in the process of rotation by the center of gravity of the figure.* (Here the center of gravity, or centroid, of a flat figure is assumed to coincide with the center of gravity of a homogeneous plate whose shape would be that of the figure.) This theorem is known as the ***(first) theorem of Pappus***.[7.36]

Formula (7.11.7) and the theorem of Pappus can be modified so that they incorporate the case of a solid generated by the rotation of a figure of arbitrary shape, and not only a curvilinear trapezoid.

Take, for example, the solid generated by the rotation about the x axis of the figure depicted in Figure 7.11.5. In this case the section of the solid by a plane perpendicular to the x axis is a circular ring (annulus) bounded by the circles of radii $y_1(x)$ and $y_2(x)$. Hence

---

[7.36] ***Pappus*** of Alexandria (end of 3rd century A.D.) was the last of the great Greek mathematicians; in his works he set forth (usually without any proof) many results obtained by his predecessors and also by himself. The fact that the theorems of Pappus are often called the ***Pappus-Guldin theorems*** or even simply ***Guldin's theorems*** in the literature is completely groundless. Both theorems were formulated by Pappus, while their proofs, put forward by Paul ***Guldin*** (1577-1643), a Swiss monk and an amateur mathematician, were highly doubtful and substantially weaker than the proofs of the theorems given by B. Cavalieri and the famous Johann Kepler (1571-1630) (the latter proofs were harshly, but unjustly, criticized by Guldin).

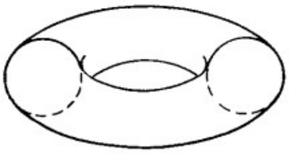

Figure 7.11.7

is the length of the string, and $M = \sigma L$ is the mass of string (see formulas (9.13.4) and (9.13.5b)).

Comparing (7.11.3) and (7.11.10), we get

$$F = 2\pi\ Ly_C = 2\pi y_C L, \qquad (7.11.11)$$

which means that *the surface area of a solid of revolution is the product of the length L of the arc whose rotation generates the surface by the circumference $2\pi y_C$ of the circle described by the centroid of the curve in the process of rotation.* This result (known as the ***second theorem of Pappus***) can be generalized so as to incorporate the case of a curve of arbitrary shape (say the one that is the boundary of figure K in Figure 7.11.5) and not only arc AB (see Figure re 7.11.3), which is the boundary of a curvilinear trapezoid.

The theorems of Pappus (7.11.7) and (7.11.11) often prove very useful. For instance, let us find the *volume* and *surface area of a torus* (*anchor ring*), which is generated by the rotation about the x axis of a circle of radius r whose center is d distant from the axis of rotation (Figure 7.11.6). Here, obviously, the center of gravity C of the circle (and of the circumference of the circle) coincides with the (geometrical) center Q of the circle. Hence, the volume of the torus in Figure 7.11.7 is

$$V = 2\pi d \times \pi r^2 = 2\pi^2 r^2 d, \qquad (7.11.12)$$

and the surface area is

$$F = 2\pi d \times 2\pi r = 4\pi^2 rd. \qquad (7.11.13)$$

The theorems of Pappus can be used in the reverse direction, so to say. The sphere in Figure 7.11.2 can be obtained by rotating a semicircle about the diameter that is part of the boundary of this semicircle. Then, if the radius of the sphere is R, the volume will be

$$V = 2\pi y_C \frac{\pi R^2}{2} = \pi^2 R^2 y_C.$$

Since we know that the volume V of a sphere is $(4/3)\,\pi R^3$, we can find the distance y_C from the *center of gravity of a semicircle* to the diameter:

$$y_C = \frac{4}{3}\pi R^3/(\pi^2 R^2) = \frac{4R}{3\pi} \simeq 0.4R.$$

Similarly, using the second theorem of Pappus, we can find the *center of gravity of a semicircumference* (see Exercise 7.11.3).

Exercises

7.11.1. Find the volume of a cone using the fact that the cone is a solid generated by rotating a right triangle about one of its legs.

7.11.2. Find the volume of a solid generated by rotating a figure bounded from above by the curve $y = \sqrt{x}$, from below by the x axis, and on the right by the vertical $x = 2$ about the x axis.

7.11.3. Using the second theorem of Pappus, find the center of gravity of a semicircumference.

7.12 Curve Sketching

The most primitive method of constructing the graph of a function $f(x)$ is to compute the value of $f(x_n)$ for a large number of points x_n. The usual procedure is to choose points x_n in the form $x_n = x_0 + na$, with $n = 0, \pm 1, \pm 2, \ldots$. This, clearly, is quite an extravagant method. In order to see the variation of the function on an interval Δx, we have to choose a step a much less than Δx, or $a \ll \Delta x$. And if the step (subinterval) is small, a very large number of points are required to embrace the whole range we are interested in. And yet we encounter the problem of constructing curves very often, since knowing the graph of a function provides extensive information about the properties of the function; for one, it immediately gives the number of real roots of the equation $f(x) = 0$, gives the intervals within which these roots lie, shows the maxima and minima of the function.

The techniques considered in Sections 7.1 and 7.2 make it possible to construct graphs much faster and more reliably and to gain a general picture of the shape of the curve. This requires, first of all, that we find the characteristic points of the graph—maxima, minima, discontinuities, salient points, points of inflection, etc.

Let us illustrate this fact by using the example of the graph of a third-degree *polynomial*,

$$y = ax^3 + bx^2 + cx + d. \qquad (7.12.1)$$

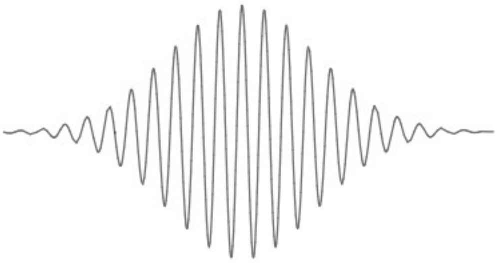

FIGURE 1.2.1 Schematic of a Gaussian wavepacket. The envelope of the wavepacket propagates with group velocity $u(\omega_0)$. Under the envelope is the carrier wave of frequency ω_0. The carrier propagates with phase velocity $\omega_0/k(\omega_0)$. The wavepacket is centered at space-time point $\tau = t - r/u(\omega_0) = 0$. At $\tau = 0$, all of its "Fourier-modes" superpose coherently and constructively due to their common initial phase $\varphi(\omega) = \varphi_0$.

Chapter 14

Projection slice theorem and computed tomography

As remarked previously in chapter 10, the goal of inverse scattering is to determine the object shape and its constitution from measurements of transmitted field quantities (or field derived quantities) when the object is irradiated by an electromagnetic wave. The Radon transform and the projection slice theorem find extensive use in inverse scattering by x-ray irradiation [1]. Object features imaged with x-rays are often very large compared to the wavelength and as such the phase of the wave becomes less important, particularly when the detectors used are non-coherent. In such cases one relies on the measurement of the intensity of the transmitted radiation. Recall from equation (9.81) that the intensity ratio under geometrical optics considerations is proportional to the exponent of the integral of the optical ray path through the medium. The Radon transform and the projection slice theorem apply in such circumstances. Practical applications of the Radon transform and the projection slice theorem are in computed tomography (CT scans) and all of these topics will be considered in the present chapter. An example imaging problem is considered at the end of the chapter to illustrate the various steps.

14.1 Radon transform and projection slice theorem

The Radon transform is an integral transform which maps a continuous function $f(x, y)$ defined on a plane to another function $\mathscr{R}[f]$ defined on the two-dimensional space of parallel straight lines in the plane, whose value on a particular line is equal to the line integral of $f(x, y)$ over that line. With the reference to figure 14.1, consider a tilted straight line L whose normal distance from the origin is ξ and on which the arc length is denoted by η. The tilt of the straight line is governed by α ($\alpha = 0$ for a vertical line and $\alpha = \pi/2$ for a horizontal line). The normal to the straight line is $\hat{\boldsymbol{\xi}} = \hat{\mathbf{x}} \cos\alpha + \hat{\mathbf{y}} \sin\alpha$. For a fixed ξ, the Cartesian coordinates on the straight line are $\mathbf{r} = (x(\eta; \xi), y(\eta; \xi)) = (\xi \cos\alpha - \eta \sin\alpha, \xi \sin\alpha + \eta \cos\alpha)$. This

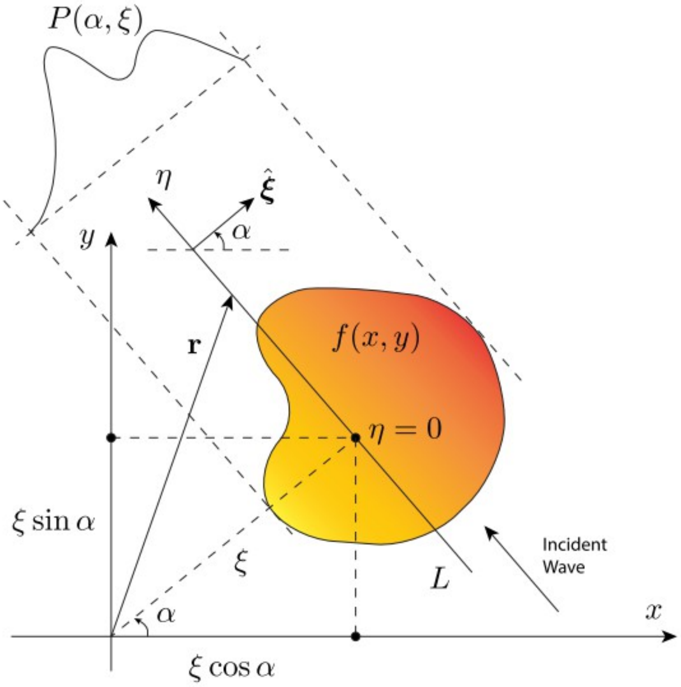

Figure 14.1. Transformation of an object with density $f(x, y)$ to a projection $P(\alpha, \xi)$ through the Radon transform. The color and shade denote the value of density.

simply corresponds to rotation of the xy-coordinate system through an angle α with respect to the x-axis. The inverse transformation yields $\xi = x\cos\alpha + y\sin\alpha = \mathbf{r}\cdot\hat{\boldsymbol{\xi}}$, $y = -x\sin\alpha + y\cos\alpha$. The Jacobian of the transformation is equal to one and $\mathrm{d}x\mathrm{d}y = \mathrm{d}\xi\mathrm{d}\eta$. Then the Radon transform $\mathscr{R}[f](\alpha, \xi)$ is defined in any of the three equivalent mathematical forms

$$\mathscr{R}[f](\alpha, \xi) =: P(\alpha, \xi) = \int\limits_{\eta=-\infty}^{\infty} f(x(\eta; \xi), y(\eta; \xi))\, \mathrm{d}\eta, \tag{14.1}$$

$$\begin{aligned} &= \iint\limits_{\xi,\eta} f(x(\eta; \xi), y(\eta; \xi))\delta(\xi - \mathbf{r}\cdot\hat{\boldsymbol{\xi}})\, \mathrm{d}\xi\mathrm{d}\eta \\ &= \iint\limits_{x,y} f(x, y)\delta(\xi - \mathbf{r}\cdot\hat{\boldsymbol{\xi}})\, \mathrm{d}x\mathrm{d}y. \end{aligned} \tag{14.2}$$

For a fixed α, the straight line is translated back and forth, which is represented by the value of the coordinate ξ, and each line gives rise to one value of $\mathscr{R}[f](\alpha, \xi)$ over $\infty < \xi < \infty$. To exhaust all points in the xy-plane it is clear that the angle $\alpha \in (0, \pi)$.

In applications, the function $f(x, y) > 0$ may represent attenuation (scattering plus absorption) of a high-frequency wave as it passes through a physical object and α may represent the direction of the incident wave. The Radon transform will then correspond to the normalized intensity at scan angle α after transmission through the object. If object is of finite support, then $P(\alpha, \xi)$ will also be of finite extent in ξ and will be zero beyond the confines of the object.

The 1D Fourier transform, $\widetilde{P}(\alpha, \kappa)$, of the projection $P(\alpha, \xi)$ w.r.t. ξ is[1]

$$\begin{aligned}\widetilde{P}(\alpha, \kappa) &= \frac{1}{2\pi}\int_{\xi=-\infty}^{\infty} P(\alpha, \kappa)\mathrm{e}^{-j\kappa\xi}\,\mathrm{d}\xi,\ -\infty < \kappa < \infty \\ &= \frac{1}{2\pi}\iint_{x,y} f(x, y)\int_{\xi=-\infty}^{\infty}\delta(\xi - \mathbf{r}\cdot\hat{\boldsymbol{\xi}})\mathrm{e}^{-j\kappa\xi}\,\mathrm{d}\xi\,\mathrm{d}x\mathrm{d}y \\ &= \frac{1}{2\pi}\iint_{x,y} f(x, y)\mathrm{e}^{-j\kappa\hat{\boldsymbol{\xi}}\cdot\mathbf{r}}\,\mathrm{d}x\mathrm{d}y = F(\boldsymbol{\kappa} = \hat{\boldsymbol{\xi}}\kappa),\end{aligned} \tag{14.3}$$

where

$$F(\boldsymbol{\kappa}) = \frac{1}{2\pi}\iint_{x,y} f(x, y)\mathrm{e}^{-j\boldsymbol{\kappa}\cdot\mathbf{r}}\,\mathrm{d}x\mathrm{d}y \tag{14.4}$$

is the 2D Fourier transform of $f(x, y)$ in the transform variables $\boldsymbol{\kappa} = \hat{\mathbf{x}}\kappa_x + \hat{\mathbf{y}}\kappa_y = \kappa_r(\hat{\mathbf{x}}\cos\beta + \hat{\mathbf{y}}\sin\beta)$, $-\infty < \kappa_x, \kappa_y, \kappa < \infty$, $0 \leqslant \kappa_r < \infty$, $0 \leqslant \beta \leqslant 2\pi$. It may be noted that since κ ranges over $(-\infty, \infty)$, it is not the same as the radial wavenumber, κ_r, that one associates with a 2D Fourier transform. In particular, $\kappa_r = \sqrt{\kappa_x^2 + \kappa_y^2} \neq \kappa$, but $\kappa_r = |\kappa|$. However, with $\kappa_x = \kappa\cos\alpha$ and $\kappa_y = \kappa\sin\alpha$, $0 \leqslant \alpha \leqslant \pi$, $-\infty < \kappa < \infty$, all points in the $\boldsymbol{\kappa}$-space are exhausted, but $\alpha \neq \beta$. Equation (14.3) states that *the 1D Fourier transform, $\widetilde{P}(\alpha, \kappa)$, of the projection, $P(\alpha, \xi)$, of a function, $f(x, y)$, at an angle α obtained through the Radon transform is the slice at angle α of the 2D Fourier transform $F(\boldsymbol{\kappa})$ of $f(x, y)$*. This is known as the *projection slice theorem*. This theorem allows us to retrieve the function $f(x, y)$ through the inverse Fourier transform

$$f(x, y) = \frac{1}{2\pi}\iint_{\kappa_x,\kappa_y=-\infty}^{\infty} F(\boldsymbol{\kappa})\mathrm{e}^{j\boldsymbol{\kappa}\cdot\mathbf{r}}\,\mathrm{d}\boldsymbol{\kappa} = \frac{1}{2\pi}\int_{\kappa_r=0}^{\infty}\int_{\beta=0}^{2\pi}\kappa_r F(\boldsymbol{\kappa})\mathrm{e}^{j\kappa_r(x\cos\beta + y\sin\beta)}\,\mathrm{d}\beta\mathrm{d}\kappa_r. \tag{14.5}$$

Note that $\boldsymbol{\kappa} = \kappa_r(\hat{\mathbf{x}}\cos\beta + \hat{\mathbf{y}}\sin\beta) = (-\kappa_r)(\hat{\mathbf{x}}\cos(\beta - \pi) + \hat{\mathbf{y}}\sin(\beta - \pi))$. Therefore the integral in equation (14.5) may be rewritten as

---

[1] We put the factor $1/2\pi$ in the 1D forward transform here so that the eventual result involving 2D forward and inverse transforms will be symmetric in the factor $1/2\pi$.

$$
\begin{aligned}
f(x,\,y) &= \tfrac{1}{2\pi}\int\limits_{\kappa_r=0}^{\infty}\left[\int\limits_{\beta=0}^{\pi} + \int\limits_{\beta=\pi}^{2\pi}\right]\kappa_r F(\boldsymbol{\kappa})\mathrm{e}^{j\kappa_r(x\cos\beta+y\sin\beta)}\,\mathrm{d}\beta\mathrm{d}\kappa_r \\
&= \tfrac{1}{2\pi}\int\limits_{\kappa_r=0}^{\infty}\int\limits_{\beta=0}^{\pi}\kappa_r F(\boldsymbol{\kappa})\mathrm{e}^{j\kappa_r(x\cos\beta+y\sin\beta)}\,\mathrm{d}\beta\mathrm{d}\kappa_r + \\
&\quad + \tfrac{1}{2\pi}\int\limits_{\kappa_r=0}^{\infty}\int\limits_{\beta=\pi}^{2\pi}(-\kappa_r)F(\boldsymbol{\kappa})\mathrm{e}^{j(-\kappa_r)[x\cos(\beta-\pi)+y\sin(\beta-\pi)]}\,\mathrm{d}\beta(-\mathrm{d}\kappa_r) \\
&= \tfrac{1}{2\pi}\int\limits_{\kappa=-\infty}^{\infty}\int\limits_{\alpha=0}^{\pi}|\,\kappa\,|\,F(\boldsymbol{\kappa})\mathrm{e}^{j\kappa(x\cos\alpha+y\sin\alpha)}\mathrm{d}\alpha\mathrm{d}\kappa \\
&= \tfrac{1}{2\pi}\int\limits_{-\infty}^{\infty}\int\limits_{\alpha=0}^{\pi}|\,\kappa\,|\,F(\boldsymbol{\kappa})\mathrm{e}^{j\kappa\hat{\boldsymbol{\xi}}\cdot\mathbf{r}}\,\mathrm{d}\alpha\mathrm{d}\kappa,
\end{aligned}
$$

where $\kappa_r = \kappa$, $\beta = \alpha$ was used in the first integral and $-\kappa_r = \kappa$, $\beta - \pi = \alpha$ was used in the second integral in the middle step to arrive at the end result. Combining this with the fact that $\widetilde{P}(\alpha,\,\kappa) = F(\boldsymbol{\kappa} = \hat{\boldsymbol{\xi}}\kappa)$ we finally obtain the inversion formula

$$
f(x,\,y) = \frac{1}{2\pi}\int\limits_{\alpha=0}^{\pi}\int\limits_{\kappa=-\infty}^{\infty}|\,\kappa\,|\,\widetilde{P}(\alpha,\,\kappa)\mathrm{e}^{j\kappa\hat{\boldsymbol{\xi}}\cdot\mathbf{r}}\,\mathrm{d}\kappa\mathrm{d}\alpha. \tag{14.6}
$$

14.2 Computed tomography

In x-ray tomography, $f(x,\,y)$ represents the attenuation function presented by the object being scanned such that the intensity at the exit plane, $I_t(\alpha,\,\xi)$, for illumination at the angle α is related to the incident intensity I_0 via

$$
\frac{I_t(\alpha,\,\xi)}{I_0} = \mathrm{e}^{-\left[\int f(x,\,y)\,d\eta\right]} = \mathrm{e}^{-P(\alpha,\,\xi)} \Longrightarrow P(\alpha,\,\xi) = -\ln\frac{I_t(\alpha,\,\xi)}{I_0}. \tag{14.7}
$$

If measurements of intensity are only available over some finite bandwidth $-W \leqslant \kappa \leqslant W$ through a filter with transfer function $H(\kappa)$, then the reconstructed attenuation function will be smeared by the filter response. The reconstructed attenuation function, $\hat{f}(x,\,y)$, is

$$
\hat{f}(x,\,y) = \frac{1}{2\pi}\int\limits_{0}^{\pi}\int\limits_{-W}^{W}|\,\kappa\,|\,H(\kappa)\widetilde{P}(\alpha,\,\kappa)\mathrm{e}^{j\kappa\hat{\boldsymbol{\xi}}\cdot\mathbf{r}}\,\mathrm{d}\kappa\mathrm{d}\alpha. \tag{14.8}
$$

Equation (14.8) is suitable for practical implementations once measurements of intensity at the exit plane are recorded. The Fourier transform of $P(\alpha,\,\xi)$ as well as the inverse transform in equation (14.8) can be conveniently evaluated using FFTs and inverse FFTs.

Substituting for $\widetilde{P}(\alpha, \xi)$ from equation (14.3), defining $R = \sqrt{(x - x')^2 + (y - y')^2}$, $(x - x') = R\cos\zeta$, $(y - y') = R\sin\zeta$, $\hat{\boldsymbol{\xi}} \cdot (\mathbf{r} - \mathbf{r}') = R\cos(\alpha - \zeta)$, utilizing the series expansion (C.71) and evaluating the integral w.r.t. α, the reconstructed attenuation function can be recast as

$$\begin{aligned}\hat{f}(x, y) &= \frac{1}{(2\pi)^2} \iint\limits_{x',y'} dx'dy' f(x', y') \int_{-W}^{W} |\kappa|\, H(\kappa) \int_{0}^{\pi} e^{j\kappa\hat{\boldsymbol{\xi}}\cdot(\mathbf{r}-\mathbf{r}')}\, d\alpha d\kappa \\ &= \frac{1}{(2\pi)^2} \iint\limits_{x',y'} dx'dy' f(x', y') \int_{-W}^{W} \left[\pi J_0(\kappa R) + 4 \sum_{m=0}^{\infty} \frac{J_{2m+1}(\kappa R)}{2m + 1} \sin(2m + 1)\zeta\right] \\ &\quad \times |\kappa|\, H(\kappa)\, d\kappa. \end{aligned} \tag{14.9}$$

If the filter function is symmetric in κ such that $H(-\kappa) = H(\kappa)$, then the series terms drops out on recalling that Bessel functions with odd order are odd functions of the argument. In that case

$$\hat{f}(x, y) = \frac{1}{4\pi} \iint\limits_{x',y'} f(x', y') \left[\int_{-W}^{W} |\kappa|\, H(\kappa) J_0(\kappa R)\, \mathrm{d}\kappa\right] \mathrm{d}x'\mathrm{d}y'. \tag{14.10}$$

The quantity within the square brackets in equation (14.10) is a function of $R = |\mathbf{r} - \mathbf{r}'|$. Thus the spatial integral in equation (14.10) is of convolutional type. For an ideal low-pass filter $H(\kappa) = 1, |\kappa| < W$. The integral involving Bessel function can then be evaluated using identity (C.61) with the result

$$\hat{f}(x, y) = \frac{W}{2\pi} \iint\limits_{x',y'} \frac{J_1(WR)}{R} f(x', y')\, \mathrm{d}x'\mathrm{d}y'. \tag{14.11}$$

Equation (14.11) gives $\hat{f}(x, y) = WJ_1(Wr)/2\pi r$ for a point attenuation function $f(x, y) = \delta(\mathbf{r})$. Note that $\lim\limits_{W\to\infty} WJ_1(Wr) = \delta(r)$, so that one recovers the exact point for infinite bandwidth.

Example 14.2.0.1. Circular object with uniform attenuation.
Determine the reconstructed object if the attenuation within a circular object of radius a is constant and an ideal low-pass filter is used in measurements.

Let us assume the constant attenuation to be unity. The most convenient form to proceed here is that given in equation (14.10). Using cylindrical coordinates, we have $f(x', y') = 1$, $\mathrm{d}x'\mathrm{d}y' = \rho'\mathrm{d}\rho'\mathrm{d}\phi'$, $R = [\rho^2 + \rho'^2 - 2\rho\rho'\cos(\phi' - \phi)]^{1/2}$. We next employ the addition theorem for Bessel functions (C.39), interchange the orders of integration in equation (14.10), evaluate the integral w.r.t. ϕ' and use the identity (C.61) to obtain the following expression for the reconstructed object

$$
\begin{aligned}
\hat{f}(\rho, \phi) &= \frac{1}{2\pi} \int_0^W \kappa d\kappa \int_0^a \rho' d\rho' \int_0^{2\pi} \Big[J_0(\kappa\rho) J_0(\kappa\rho') \\
&\qquad + 2 \sum_{n=1}^{\infty} J_n(\kappa\rho) J_n(\kappa\rho') \cos n(\phi - \phi') \Big] d\phi' \\
&= \int_0^W \kappa J_0(\kappa\rho) d\kappa \int_0^a \rho' J_0(\kappa\rho')\, d\rho' \qquad (14.12) \\
&= a \int_0^W J_1(\kappa a) J_0(\kappa\rho)\, d\kappa = \int_0^{Wa} J_1(x) J_0(xr)\, dx \\
&= \Theta(1 - r) - \int_{Wa}^{\infty} J_1(x) J_0(xr)\, dx,
\end{aligned}
$$

where the final expression in the last step follows from the identity [2, 6.512–3], $r = \rho/a$ and $\Theta(\cdot)$ is the unit step function. Clearly, for $Wa \to \infty$ the asymptotic integral on the rhs of equation (14.12) vanishes and one recovers the exact shape. Figure 14.2 shows the reconstructed object as a function of $r = \rho/a$ for two different filter bandwidths of $Wa = 2\pi$ and $Wa = 4\pi$ after carrying out the integral in equation (14.12) numerically. The smearing of the object shape due to band-limited

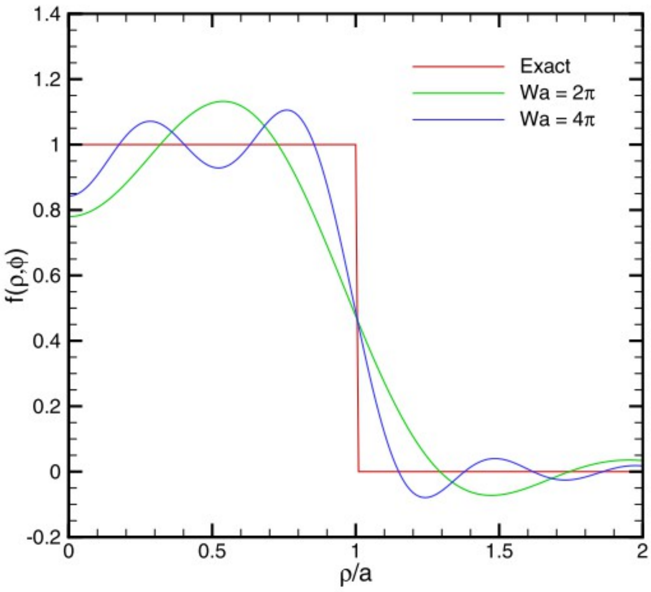

Figure 14.2. Exact object shape and reconstructed ones with $Wa = 2\pi$ and $Wa = 4\pi$ for a circular cylinder of radius a.

data is clearly evident. There is ringing as well as softening of edges in the reconstructed image with better results appearing for larger bandwidth of $Wa = 4\pi$ than for $Wa = 2\pi$. ■■

Chapter 9

Geometrical optics and Fermat's principle

Maxwell's equations can only be solved exactly in the presence of material objects for a few well-defined geometries. For complicated and irregularly shaped objects one often resorts to numerical approaches. When the principal radii of curvature on an object size are large compared to wavelength, reasonably approximate solutions to Maxwell's equations can be obtained by the geometrical optics technique [1], which has been in existence for a number of centuries. Geometrical optics also provides a basis and bridge to diffraction optics, wherein one describes waves reaching regions in the shadow portion of a lit object by means of diffraction by geometric singularities and curvature [2].

The rigorous derivation of a geometrical optics field comprised of wavefronts and rays and the various laws, such as the eikonal equation, Sommerfeld–Runge law, Snell's law, intensity law, are all discussed in the present chapter. A widely occurring variational principle known as Fermat's principle, which has its origin in geometrical optics, is derived. With the recent emergence of electromagnetic metasurfaces for the control of reflected and transmitted electromagnetic energies, there has been a renewed interest in geometrical optics that witnessed some generalizations to the classical laws. The related topics of gradient metasurfaces and generalized Snell's law are also treated in this chapter.

9.1 Geometrical optics and Fermat's principle

The most rigorous and useful definition of geometrical optics is provided by Kline and Kay [3, pp 14–16] and involves the time-domain Maxwell's equations. The geometrical optics field at any point (x, y, z) of space is that field that corresponds to finite discontinuities[1] of the electric and magnetic fields, $\mathscr{E}$ and $\mathscr{H}$, on some hypersurface $\Phi(x, y, z; t) = \psi(x, y, z) - ct = 0$, where c is the speed of light in

---

[1] By finite discontinuities we mean singularities which are finite discontinuities with respect to the time variable of $\mathscr{E}$ and $\mathscr{H}$ and their successive time derivatives.

doi:10.1088/978-0-7503-1716-0ch9

© IOP Publishing Ltd 2020

free space. The family of surfaces $\psi(x, y, z) = ct$ are known as *wavefronts* and the normals erected on the wavefronts are termed *rays*, see figure 9.1. In the above representation, the hypersurface $\Phi(x, y, z; t) = 0$ is solved explicitly for t and cast in the form $\Phi(x, y, z; t) = \psi(x, y, z) - ct$ and the speed of light in free space is merely used to scale the time variable. In particular, c is *not* the speed of the wavefront.

9.1.1 Field discontinuities, wavefronts, and the eikonal equation

Consider a family of wavefronts $\psi = ct$ emanating from some source. At any specific time $t = t_0$, there is a point (x_0, y_0, z_0) on the wavefront such that the electric field $\mathscr{E}$ (and $\mathscr{H}$) is zero for $t < t_0$; at $t = t_0$, $\mathscr{E}$ jumps from zero to some non-zero value, and for $t > t_0$, $\mathscr{E}$ is non-zero. The geometrical optics field $(\tilde{\mathscr{E}}, \tilde{\mathscr{H}})$ exists at (x_0, y_0, z_0) *only* at the instant t_0. In particular, the values of $\mathscr{E}$ and $\mathscr{H}$ for $t > t_0$ at (x_0, y_0, z_0) belong to the time-dependent field satisfying Maxwell's equations, but not to the geometrical optics field. If we follow the geometrical optics field along a ray, that is, let x, y, and z take on values along a ray, then the corresponding value of t at which the geometrical optics field exists is given by $t = \psi(x, y, z)/c$. Hence

$$\tilde{\mathscr{E}}(x, y, z) = \mathscr{E}(x, y, z; \psi/c); \quad \tilde{\mathscr{H}}(x, y, z) = \mathscr{H}(x, y, z; \psi/c). \tag{9.1}$$

In the following we show that such a definition of a geometrical optics field follows rigorously from Maxwell's equations [3]. We would like to know what the wavefronts are and how the values of $(\widetilde{\mathbf{E}}, \widetilde{\mathbf{H}})$ vary along a ray. In this regard the generalizations of divergence and the curl theorems to four-dimensional spacetime are useful. Let G be a region in spacetime and let the hypersurface Γ be its boundary,

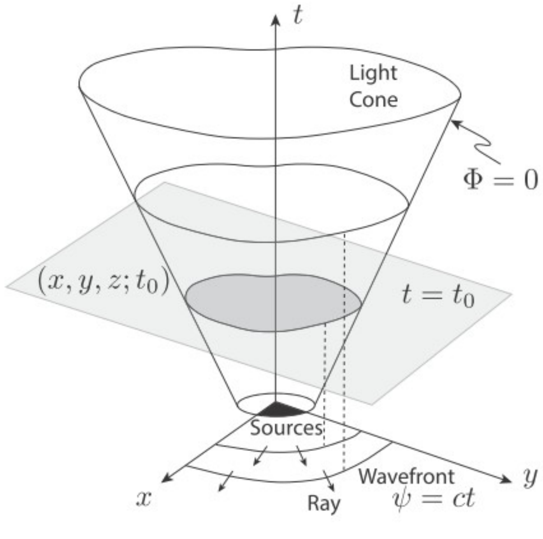

Figure 9.1. Wavefronts emanating from a finite-support source. Fields are zero outside the light cone and non-zero inside the light cone. The front across which the fields are discontinuous is described by $\Phi = 0$.

assumed to be continuous with piece-wise continuous derivatives, figure 9.2. The surface Γ is defined by $\chi(x, y, z; t) = 0$ and an outward unit normal $\hat{\mathbf{n}}$ has components

$$n_x = \lambda\hat{\mathbf{x}} \cdot \nabla\chi,\ n_y = \lambda\hat{\mathbf{y}} \cdot \nabla\chi,\ n_z = \lambda\hat{\mathbf{z}} \cdot \nabla\chi,\ n_t = \lambda\dot{\chi}, \tag{9.2}$$

where

$$\lambda = \pm[|\nabla\chi|^2 + \dot{\chi}^2]^{-1/2}, \tag{9.3}$$

and an over-dot represents a partial derivative w.r.t. t. The sign is λ is chosen to fit the requirement that the normal be directed outward from G. Let $\mathbf{m} = n_x\hat{\mathbf{x}} + n_y\hat{\mathbf{y}} + n_z\hat{\mathbf{z}} = \lambda\nabla\chi$ be the projection of $\hat{\mathbf{n}}$ onto the (x, y, z)-space. Note that $\mathbf{m}$ is not a unit vector in space coordinates. Let $\mathrm{d}w$ be an elemental volume of spacetime G and let $\mathrm{d}v$ be the elemental surface of the hypersurface Γ. Consider a vector field $\mathbf{A}(x, y, z; t) = \hat{\mathbf{x}}A_1(x, y, z; t) + \hat{\mathbf{y}}A_2(x, y, z; t) + \hat{\mathbf{z}}A_3(x, y, z; t)$ defined over G. Then [3, p 41]

$$\iiiint_G \nabla \times \mathbf{A}\, \mathrm{d}w = \iiint_\Gamma \mathbf{m} \times \mathbf{A}\, \mathrm{d}v, \tag{9.4}$$

$$\iiiint_G \nabla \cdot \mathbf{A}\, \mathrm{d}w = \iiint_\Gamma \mathbf{m} \cdot \mathbf{A}\, \mathrm{d}v, \tag{9.5}$$

where the curl and divergence operations are the usual three-dimensional curl and divergence.

Consider now the time-domain Maxwell's equations in an isotropic medium with electrical parameters $\varepsilon = \varepsilon_0\varepsilon_\mathrm{r}$, $\mu = \mu_0\mu_\mathrm{r}$, σ (non-dispersive) and with no magnetic sources

$$\nabla \times \mathscr{E} = -\dot{\mathscr{B}}; \quad \mathscr{B} = \mu\mathscr{H}, \quad \mathscr{D} = \varepsilon\mathscr{E}, \quad \mathscr{J}_\mathrm{c} = \sigma\mathscr{E}, \tag{9.6}$$

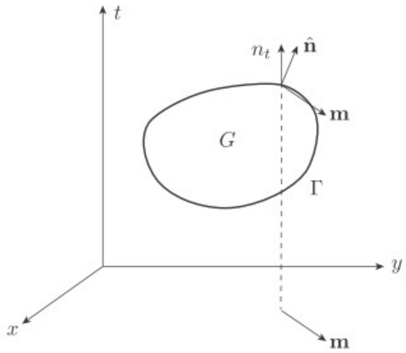

Figure 9.2. A four-dimensional domain G bounded by a surface Γ. The normal unit normal $\hat{\mathbf{n}}$ has a component n_t along the time-axis. The projection of $\hat{\mathbf{n}}$ onto space is the vector $\mathbf{m}$.

$$\nabla \times \mathscr{H} = \dot{\mathscr{D}} + \mathscr{J}_\mathrm{c} + \mathscr{J}_\mathrm{i}; \quad \mathscr{J}_\mathrm{i} = \dot{\mathscr{Q}}_\mathrm{e}, \quad \nabla \cdot \mathscr{Q}_\mathrm{e} = -q_\mathrm{ev}, \tag{9.7}$$

$$\nabla \cdot \mathscr{B} = 0; \quad \nabla \cdot (\mathscr{J}_\mathrm{i} + \mathscr{J}_\mathrm{c} + \dot{\mathscr{D}}) = 0, \tag{9.8}$$

where $\mathscr{Q}_\mathrm{e}$ is the electric steam potential introduced in equation (3.1) and we have chosen the magnetic stream potential $\mathscr{Q}_\mathrm{m} = 0$. The quantities $\mathscr{J}_\mathrm{i}$ and $\mathscr{J}_\mathrm{c}$ are, respectively, the impressed current density and the conduction current density. These equations can be cast in an integral form by making use of the above four-dimensional curl and divergence theorems. Applying equation (9.4) to the two Maxwell's curl equations and evaluating the integral with respect to time for time-derivative quantities yields

$$\iiint\limits_\Gamma [\mathbf{m} \times \mathscr{H} - n_t\mathscr{D} - n_t\mathscr{Q}_\mathrm{e}]\,\mathrm{d}v = \iiiint\limits_G \mathscr{J}_\mathrm{c}\,\mathrm{d}w, \tag{9.9}$$

$$\iiint\limits_\Gamma [\mathbf{m} \times \mathscr{E} + n_t\mathscr{B}]\,\mathrm{d}v = 0. \tag{9.10}$$

Applying equation (9.5) to the two Maxwell's divergence equations (9.8) leads to

$$\iiint\limits_\Gamma \mathbf{m} \cdot (\mathscr{J}_\mathrm{i} + \mathscr{J}_\mathrm{c} + \dot{\mathscr{D}})\,\mathrm{d}v = 0, \tag{9.11}$$

$$\iiint\limits_\Gamma \mathbf{m} \cdot \mathscr{B}\,\mathrm{d}v = 0. \tag{9.12}$$

Consider now a hypersurface $\Phi = 0$ that divides the region G into two subregions G_1 and G_2 as shown in figure 9.3. The boundary Γ is also subdivided into two parts Γ_1

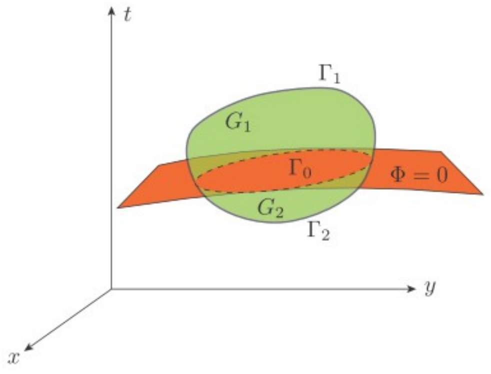

Figure 9.3. The spacetime domain G divided into a part G_1 with boundary $\Gamma_1 + \Gamma_0$ and a part G_2 with boundary $\Gamma_2 + \Gamma_0$ by the hypersurface $\Phi(x, y, z; t) = 0$. The normal on the common boundary Γ_0 points out of region G_i, $i = 1, 2$.

and Γ_2 such that $\Gamma_1 \cup \Gamma_2 = \Gamma$. The boundary of G_1 is the portion Γ_1 of Γ and the portion Γ_0 of $\Phi = 0$ which lies in G. Likewise the boundary of G_2 is Γ_2 and Γ_0. Note that if the vector $\mathbf{m} = \mathbf{m}_0$ associated with Γ_0 is taken as $+\lambda_0 \nabla\Phi$ for G_1, it will be $-\lambda_0 \nabla\Phi$ for G_2, where $\lambda_0 = [|\nabla\Phi|^2 + \dot{\Phi}^2]^{-1/2}$ and $n_t = \lambda_0 \dot{\Phi}$. We assume that the field vectors are discontinuous on Γ_0. Let $(\mathscr{E}_i, \mathscr{H}_i, \mathscr{D}_i, \mathscr{B}_i, \mathscr{Q}_{ei})$ denote the values of the various field components when approaching Γ_0 through G_i, $i = 1, 2$.

We now apply the integral relations (9.9)–(9.12) to (i) the domain G bounded by $\Gamma_1 \cup \Gamma_2$, both associated with $\mathbf{m} = \lambda \nabla\chi$, $\lambda = [|\nabla\chi|^2 + \dot{\chi}^2]^{-1/2}$, (ii) the domain G_1 bounded by $\Gamma_1 \cup \Gamma_0$, and (iii) the domain G_2 bounded by $\Gamma_2 \cup \Gamma_0$. Application to equation (9.9) yields

$$\iiint\limits_{\Gamma_1+\Gamma_2} [\mathbf{m} \times \mathscr{H} - n_t \mathscr{D} - n_t \mathscr{Q}_\mathrm{e}]\, \mathrm{d}v = \iiiint\limits_{G} \mathscr{J}_\mathrm{c}\, \mathrm{d}w, \tag{9.13}$$

$$\begin{aligned} &\iiint\limits_{\Gamma_1} [\mathbf{m} \times \mathscr{H} - n_t \mathscr{D} - n_t \mathscr{Q}_\mathrm{e}]\, \mathrm{d}v \\ &\quad + \iiint\limits_{\Gamma_0} [\nabla\Phi \times \mathscr{H}_1 - \dot{\Phi}\mathscr{D}_1 - \dot{\Phi}\mathscr{Q}_{\mathrm{e}1}]\lambda_0\, \mathrm{d}v = \iiiint\limits_{G_1} \mathscr{J}_\mathrm{c}\, \mathrm{d}w, \end{aligned} \tag{9.14}$$

$$\begin{aligned} &\iiint\limits_{\Gamma_2} [\mathbf{m} \times \mathscr{H} - n_t \mathscr{D} - n_t \mathscr{Q}_\mathrm{e}]\, \mathrm{d}v \\ &\quad - \iiint\limits_{\Gamma_0} [\nabla\Phi \times \mathscr{H}_2 - \dot{\Phi}\mathscr{D}_2 - \dot{\Phi}\mathscr{Q}_{\mathrm{e}2}]\lambda_0\, \mathrm{d}v = \iiiint\limits_{G_2} \mathscr{J}_\mathrm{c}\, \mathrm{d}w. \end{aligned} \tag{9.15}$$

Subtracting equation (9.13) from the sum of equations (9.14) and (9.15) results in

$$\iiint\limits_{\Gamma_0} \left\{\nabla\Phi \times \Delta[\mathscr{H}] - \dot{\Phi}\, \Delta[\mathscr{D}] - \dot{\Phi}\Delta[\mathscr{Q}_\mathrm{e}]\right\}\lambda_0\, \mathrm{d}v = 0, \tag{9.16}$$

where $\Delta[\mathscr{H}] = \mathscr{H}_1 - \mathscr{H}_2$ is the discontinuity in $\mathscr{H}$ across the hypersurface $\Phi = 0$ and similarly the other quantities. Since G can be taken arbitrarily small to enclose an arbitrary small section of Γ_0, the integrand of equation (9.16) must be zero. Thus

$$\nabla\Phi \times \Delta[\mathscr{H}] - \dot{\Phi}\Delta[\mathscr{D}] - \dot{\Phi}\Delta[\mathscr{Q}_\mathrm{e}] = 0 \quad \text{on } \Phi = 0. \tag{9.17}$$

Repeating the process for equations (9.10)–(9.12) we obtain the additional discontinuity relations

$$\nabla\Phi \times \Delta[\mathscr{E}] + \dot{\Phi}\Delta[\mathscr{B}] = 0 \quad \text{on } \Phi = 0, \tag{9.18}$$

$$\nabla\Phi \cdot \left\{\Delta[\mathscr{J}_\mathrm{i}] + \Delta[\mathscr{J}_\mathrm{c}] + \Delta[\dot{\mathscr{D}}]\right\} = 0 \quad \text{on } \Phi = 0, \tag{9.19}$$

$$\nabla\Phi \cdot \Delta[\mathscr{B}] = 0 \quad \text{on } \Phi = 0. \tag{9.20}$$

When these discontinuity equations are applied to a static boundary separating two material media, one obtains the usual boundary conditions on the tangential components of $(\mathscr{E}, \mathscr{H})$ and the normal components of $(\mathscr{D}, \mathscr{B}, \mathscr{J})$. When they are applied to a special hypersurface $\Phi = t = 0$ $(\Longrightarrow \nabla\Phi = 0, \dot{\Phi} = 1)$ assuming that the source function $\mathscr{Q}_\mathrm{e} = 0$ for $t < 0$ (which implies that the fields $\mathscr{E}$ and $\mathscr{H}$ are also zero for $t < 0$) and not equal to 0 for $t \geqslant 0$, one obtains from these discontinuity relations the initial conditions

$$\mathscr{E}(x, y, z; 0+) = -\frac{1}{\varepsilon}\mathscr{Q}_\mathrm{e}(x, y, z, 0+), \tag{9.21}$$

$$\mathscr{H}(x, y, z; 0+) = 0. \tag{9.22}$$

Thus the electric field responds instantaneously, but the magnetic field continues to be zero after the electric source is switched on. The situation is similar to the voltage response across a capacitor and the current response through an inductor when the elements are excited by a step charge source.

The more interesting case of field discontinuities that exist even in the absence of material discontinuities arises when the fields spread out from the source into the $(x, y, z; t)$-spacetime at finite speed. As before the source is assumed to be located within a finite spatial domain and switched on at $t = 0$. Because of this finite speed the field at $(x, y, z; t)$ will be zero until t is greater than some t_0 which is determined by its distance to the nearest source point. Hence there is a region of spacetime in which the field is non-zero and outside this a region in which the field is zero. In an isotropic medium (even in an inhomogeneous medium), the surface $\Phi(x, y, z; t) = 0$ separating the two regions will be a truncated light cone as shown in figure 9.1. The fields are zero outside the light cone and non-zero inside. The stream potential $\mathscr{Q}_\mathrm{e} = 0$ for any $t > 0$ on this light cone. The discontinuity relations (9.17) and (9.18) then yield the two homogeneous, linear vector equations for the quantities $\Delta[\mathscr{E}]$ and $\Delta[\mathscr{H}]$

$$\nabla\Phi \times \Delta[\mathscr{H}] - \varepsilon\dot{\Phi}\Delta[\mathscr{E}] = 0, \tag{9.23}$$

$$\nabla\Phi \times \Delta[\mathscr{E}] + \mu\dot{\Phi}\Delta[\mathscr{H}] = 0. \tag{9.24}$$

Taking a scalar product of these equations with $\nabla\Phi$ gives[2]

$$\nabla\Phi \cdot \Delta[\mathscr{E}] = 0 = \nabla\Phi \cdot \Delta[\mathscr{H}], \tag{9.25}$$

implying that $\Delta[\mathscr{E}] \perp \nabla\Phi$ and $\Delta[\mathscr{H}] \perp \nabla\Phi$. In addition taking a scalar product of equation (9.23) with $\Delta[\mathscr{H}]$ gives $\Delta[\mathscr{E}] \cdot \Delta[\mathscr{H}] = 0$, which implies that $\Delta[\mathscr{E}] \perp \Delta[\mathscr{H}]$. Hence the vectors $\Delta[\mathscr{E}]$, $\Delta[\mathscr{H}]$ and $\nabla\Phi$ are mutually perpendicular at any point on the hypersurface $\Phi = 0$. Taking a vector product of equation (9.24) by $\nabla\Phi$ and utilizing equation (9.23) gives

---

[2] Note that $\dot{\Phi} \neq 0$ since we are dealing with a dynamic hypersurface here.

$$\begin{aligned}&\nabla\Phi \times (\nabla\Phi \times \Delta[\mathscr{E}]) + \mu\varepsilon\dot{\Phi}^2\Delta[\mathscr{E}] = 0\\ &\Longrightarrow (-|\nabla\Phi|^2 + \mu\varepsilon\dot{\Phi}^2)\Delta[\mathscr{E}] = 0.\end{aligned} \tag{9.26}$$

Since $\Delta[\mathscr{E}] \neq 0$ we arrive at

$$|\nabla\Phi|^2 - \mu\varepsilon\dot{\Phi}^2 = 0 \quad \text{on } \Phi = 0. \tag{9.27}$$

This is a condition of the characteristic for the hyperbolic system of Maxwell's equations [4] and $\Phi = 0$ are known as the *characteristics*. Writing the light cone as $\Phi(x, y, z; t) = \psi(x, y, z) - ct = 0$ and noting that $\nabla\Phi = \nabla\psi$, $\dot{\Phi} = -c$, we finally arrive at the *eikonal differential equation of geometrical optics*

$$|\nabla\psi|^2 - c^2\mu\varepsilon = 0. \tag{9.28}$$

It is interesting to note that the eikonal equation is governed only by the permittivity and permeability of the medium. In particular, it is independent of the conductivity of the medium. Note that the derivation of this eikonal equation is exact and no approximations concerning field behavior have been made. The only assumption that has been made is that the media constants $(\varepsilon_r, \mu_r, \sigma)$ are all frequency independent. Since the fields are zero outside the light cone and non-zero just inside the light cone, the field discontinuities may well be taken to be $\Delta[\mathscr{E}] = \tilde{\mathscr{E}}$ and $\Delta[\mathscr{H}] = \tilde{\mathscr{H}}$, where $\tilde{\mathscr{E}}$ and $\tilde{\mathscr{H}}$ are defined in equation (9.1). In this sense, geometrical optics is concerned with the field vectors on the wavefronts as the wavefront spreads out into the (x, y, z)-space as time progresses. These specific values of field are indeed termed as *signals* in the literature [5][3].

9.1.2 Ray equations

As remarked previously, the normals erected on the family of wavefronts $\psi = ct$ are the rays[4]. The rays will have a direction proportional to $\nabla\psi$. Let $\mathbf{r}(t) = (x = x(t), y = y(t), z = z(t))$ be the equation of one of the rays passing through a point P on the family of wavefronts, figure 9.4. The velocity $\mathbf{v}$ of the wavefront is defined as the velocity with which the point P moves along the ray as t increases. Let us write

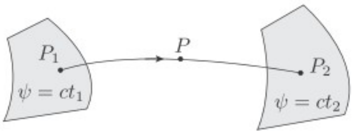

Figure 9.4. A ray emanating from a wavefront $\psi = ct_1$ at the point P_1, passing through an intermediate point P and terminating on the wavefront $\psi = ct_2$ at the point P_2.

---

[3] By considering a sinusoidal waveform modulated by a step function (a quasi time-periodic signal), Sommerfeld and Brillouin have shown that the signals travel with the velocity c even in a dispersive medium.

[4] Each value of t will generate a surface in ordinary space defined by $\psi = ct$.

$$\mathbf{v} = \frac{\mathrm{d}\mathbf{r}(t)}{\mathrm{d}t} =: v\frac{\nabla\psi}{|\nabla\psi|}, \tag{9.29}$$

where v is the speed to be determined. Along the ray we have

$$\psi(x(t), y(t), z(t)) = ct.$$

Differentiating this w.r.t. time we obtain upon using equations (9.28) and (9.29) that

$$\begin{aligned} c = \frac{\mathrm{d}\psi}{\mathrm{d}t} &= \frac{\partial\psi}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}t} + \frac{\partial\psi}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}t} + \frac{\partial\psi}{\partial z}\frac{\mathrm{d}z}{\mathrm{d}t} \\ &= \nabla\psi\cdot\mathbf{v} = v\,|\nabla\psi| = vc\sqrt{\mu\varepsilon} \implies v = 1/\sqrt{\mu\varepsilon}\,. \end{aligned} \tag{9.30}$$

Thus $v = 1/\sqrt{\mu\varepsilon}$ is a speed associated with the wavefront $\Phi = 0$ and it depends only on the permittivity and permeability of the medium and is true even in the case of perfect or lossy conductors. The refractive index of the medium is $n = c/v = \sqrt{\mu\varepsilon/\mu_0\varepsilon_0} = \sqrt{\mu_r\varepsilon_r}$. In terms of the refractive index, the eikonal equation may be rewritten as

$$|\nabla\psi|^2 - n^2 = 0, \tag{9.31}$$

which is a non-linear first order partial differential equation. We introduce a unit vector along the ray as $\hat{\mathbf{p}} = \nabla\psi/|\nabla\psi| = \nabla\psi/n$ and define the *wave normal*

$$\mathbf{p} = \nabla\psi = \hat{\mathbf{p}}\,|\nabla\psi| = n\hat{\mathbf{p}}. \tag{9.32}$$

Note that the wave normal (a.k.a. *ray vector*) is not a unit vector.

The directional derivative of the wavefront $\psi = ct$ ($\Longrightarrow \mathrm{d}\psi = c\mathrm{d}t$) with respect to distance ρ in any arbitrary direction with unit vector $\hat{\boldsymbol{\rho}}$ is

$$\frac{\mathrm{d}\psi}{\mathrm{d}\rho} = \frac{\partial\psi}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}\rho} + \frac{\partial\psi}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}\rho} + \frac{\partial\psi}{\partial z}\frac{\mathrm{d}z}{\mathrm{d}\rho} = c\frac{\mathrm{d}t}{\mathrm{d}\rho} = \frac{c}{v}v\frac{\mathrm{d}t}{\mathrm{d}\rho} = n\frac{\mathrm{d}s}{\mathrm{d}\rho}, \tag{9.33}$$

where $\mathrm{d}s/\mathrm{d}t = v = c/n$ is the speed of the wavefront and $\mathrm{d}s$ is the arclength along the orthogonal trajectory between two neighboring wavefronts. In general $\mathrm{d}s \leqslant \mathrm{d}\rho$ as clear geometrically from figure 9.5. The *optical path length* between P_1 and P_2 along this new curve is defined as

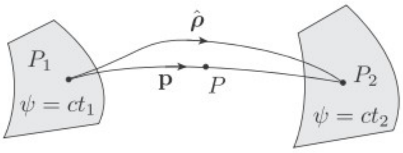

Figure 9.5. Any arbitrary path with a unit normal $\boldsymbol{\rho}$ between P_1 and P_2. The actual ray between P_1 and P_2 has a wave normal $\mathbf{p}$.

$$
\begin{aligned}
\psi(P_2) - \psi(P_1) &= \int_{P_1}^{P_2} \frac{\mathrm{d}\psi}{\mathrm{d}\rho}\,\mathrm{d}\rho = \int_{P_1}^{P_2} n(x,\, y,\, z)\mathrm{d}s = c\int_{P_1}^{P_2} \mathrm{d}t, \\
&= \int_{\rho_1}^{\rho_2} n(x(\rho),\, y(\rho),\, z(\rho))\sqrt{\dot{x}^2(\rho) + \dot{y}^2(\rho) + \dot{z}^2(\rho)}\,\mathrm{d}\rho,
\end{aligned}
\tag{9.34}
$$

where an overhead dot represents derivative with respect to argument, $\mathrm{d}s$ is the elemental arclength along the arbitrary curve with parameter ρ and $n\mathrm{d}s = c\mathrm{d}t$. The geometrical optics energy flux density vector is defined from the Poynting vector on the wavefront as

$$\tilde{\mathscr{S}} = \tilde{\mathscr{E}} \times \tilde{\mathscr{H}}.$$

From the discussion above $\tilde{\mathscr{S}}$ points along $\nabla\psi$ so that flux density vector can be written as $\tilde{\mathscr{S}} = \hat{\mathbf{p}}\widetilde{\mathcal{S}}$. Now carrying out (9.23) $\times\, \tilde{\mathscr{E}}$ − (9.24) $\times\, \tilde{\mathscr{H}}$ and making use of the following facts that (i) $\tilde{\mathscr{E}}$, $\tilde{\mathscr{H}}$, and $\nabla\psi$ are mutually perpendicular, (ii) the field energy density is $\widetilde{W} = \frac{1}{2}(\tilde{\mathscr{E}} \cdot \tilde{\mathscr{D}} + \tilde{\mathscr{H}} \cdot \tilde{\mathscr{B}})$ from the definition in theorem 5.2.1, (iii) $\nabla\Phi = \nabla\psi$, $\dot{\Phi} = -c$, and (iv) the interchange of the dot and cross in a vector triple product is valid, we obtain

$$\nabla\psi \cdot \tilde{\mathscr{S}} = c\widetilde{W} \Longrightarrow \tilde{\mathscr{S}} = \hat{\mathbf{p}}\frac{c}{|\nabla\psi|}\widetilde{W} = \hat{\mathbf{p}}v\widetilde{W}; \quad \widetilde{\mathcal{S}} = v\widetilde{W}. \tag{9.35}$$

The geometrical optics energy density vector $\widetilde{\mathcal{S}}$ carries energy along the rays together with $\tilde{\mathscr{E}}$, $\tilde{\mathscr{H}}$.

9.1.3 Ray tracing

It is possible to obtain differential equations satisfied by the rays from the eikonal equation. The evolution parameter along a ray could be time t or arclength s or a particular spatial coordinate or any other quantity τ. Different initial points $\mathbf{r}_0$ on a wavefront will generate different rays. Thus there will be a two-parameter (two initial coordinates contained in $\mathbf{r}_0$) family of rays belonging to the family of wavefronts $\psi = ct$. Let us represent the spatial coordinates of a ray by

$$x = x(\tau), \quad y = y(\tau), \quad z = z(\tau).$$

Since the path of the ray is orthogonal to the wavefront (i.e. along $\nabla\psi$) we have the dynamical equations

$$\frac{\mathrm{d}x}{\mathrm{d}\tau} = \lambda(\tau)\psi_x, \tag{9.36}$$

$$\frac{\mathrm{d}y}{\mathrm{d}\tau} = \lambda(\tau)\psi_y, \tag{9.37}$$

$$\frac{\mathrm{d}z}{\mathrm{d}\tau} = \lambda(\tau)\psi_z, \tag{9.38}$$

where $\psi_x = \partial\psi/\partial x$ and so on and $\lambda(\tau) \neq 0$ is a quantity that depends on the choice of τ (or vice versa). Indeed from the eikonal equation $\psi_x^2 + \psi_y^2 + \psi_z^2 = n^2$. Hence

$$\left(\frac{\mathrm{d}x}{\mathrm{d}\tau}\right)^2 + \left(\frac{\mathrm{d}y}{\mathrm{d}\tau}\right)^2 + \left(\frac{\mathrm{d}z}{\mathrm{d}\tau}\right)^2 = \left(\frac{\mathrm{d}s}{\mathrm{d}\tau}\right)^2 = \lambda^2 n^2 = c\frac{\mathrm{d}t}{\mathrm{d}\tau}, \tag{9.39}$$

where $\mathrm{d}s = \sqrt{\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2}$ is the elemental arclength and the last form follows from taking the derivative w.r.t. τ on the wavefront $\psi(x(\tau),\ y(\tau),\ z(\tau)) = ct$ and making use of the eikonal equation and equations (9.36)–(9.38). The last form also suggests that $\mathrm{d}^2\tau/\mathrm{d}t^2 = 0$ since n, λ are assumed to be independent of time. In other words, τ has to be a linear function of the time variable. For instance, if one chooses $\lambda = 1$, then the last form in equation (9.39) implies that the corresponding τ is $\tau = ct/n^2$. On the other hand, if one chooses τ to be the arclength parameter s, then the lhs of equation (9.39) is unity and the corresponding λ is $\lambda(s) = 1/n(s)$ that can vary arbitrarily with position.

Our goal now is to eliminate the wavefront ψ from the ray equations. Dividing both sides of equation (9.36) with λ and taking the derivative with respect to τ gives

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{1}{\lambda}\frac{\mathrm{d}x}{\mathrm{d}\tau}\right) &= \psi_{xx}\frac{\mathrm{d}x}{\mathrm{d}\tau} + \psi_{xy}\frac{\mathrm{d}y}{\mathrm{d}\tau} + \psi_{xz}\frac{\mathrm{d}z}{\mathrm{d}\tau}\\ &= \frac{\lambda}{2}\frac{\partial}{\partial x}\left(\psi_x^2 + \psi_y^2 + \psi_z^2\right) = \frac{\lambda}{2}\frac{\partial}{\partial x}n^2,\end{aligned}$$

where equations (9.36)–(9.38) are used in the top line on the rhs to obtain the bottom line. Similar equations are obtained for the y- and z-coordinates. Therefore the differential equations for the ray coordinates are

$$\frac{2}{\lambda}\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{1}{\lambda}\frac{\mathrm{d}x}{\mathrm{d}\tau}\right) = \frac{\partial}{\partial x}n^2, \tag{9.40}$$

$$\frac{2}{\lambda}\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{1}{\lambda}\frac{\mathrm{d}y}{\mathrm{d}\tau}\right) = \frac{\partial}{\partial y}n^2, \tag{9.41}$$

$$\frac{2}{\lambda}\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{1}{\lambda}\frac{\mathrm{d}z}{\mathrm{d}\tau}\right) = \frac{\partial}{\partial z}n^2. \tag{9.42}$$

These are non-homogeneous, linear, second order ordinary differential equations with non-constant coefficients. The ray is determined by the refractive index of the medium and the initial conditions. Equation (9.39) constrains the three ray velocity components and will eliminate one of the six constants of integration arising from the solution of the ray equations. Furthermore, since the parameter τ can be chosen rather arbitrarily without changing the geometric trajectory of the ray, an additional constant of integration can be eliminated by an appropriate transformation of the parameter τ.

Example 9.1.3.1. Ray equations in cylindrical coordinates.

It is possible to cast the ray equations given in equations (9.40)–(9.42) for Cartesian coordinates in any other coordinate system. In this example we demonstrate this for a cylindrical system with coordinates (ρ, ϕ, z). To this end the total and partial derivatives need to be expressed in terms of the new coordinates. The transformation relations facilitating the conversion are $\partial\rho/\partial x = \cos\phi$, $\partial\rho/\partial y = \sin\phi$, $\partial\phi/\partial x = -\sin\phi/\rho$, $\partial\phi/\partial y = \cos\phi/\rho$ and the inverse relations are $\partial x/\partial\rho = \cos\phi$, $\partial x/\partial\phi = -\rho\sin\phi$, $\partial y/\partial\rho = \sin\phi$, $\partial y/\partial\phi = \rho\cos\phi$. Using these it is straightforward to establish that

$$\frac{\mathrm{d}x}{\mathrm{d}\tau} = \cos\phi\frac{\mathrm{d}\rho}{\mathrm{d}\tau} - \rho\sin\phi\frac{\mathrm{d}\phi}{\mathrm{d}\tau}, \tag{9.43}$$

$$\frac{\mathrm{d}y}{\mathrm{d}\tau} = \sin\phi\frac{\mathrm{d}\rho}{\mathrm{d}\tau} + \rho\cos\phi\frac{\mathrm{d}\phi}{\mathrm{d}\tau}, \tag{9.44}$$

$$\frac{\partial}{\partial x} = \cos\phi\frac{\partial}{\partial\rho} - \frac{\sin\phi}{\rho}\frac{\partial}{\partial\phi}, \tag{9.45}$$

$$\frac{\partial}{\partial y} = \sin\phi\frac{\partial}{\partial\rho} + \frac{\cos\phi}{\rho}\frac{\partial}{\partial\phi}. \tag{9.46}$$

Substituting these into equations (9.40) and (9.41) results in

$$\frac{2}{\lambda}\frac{\mathrm{d}}{\mathrm{d}\tau}\left[\frac{1}{\lambda}\left(\cos\phi\frac{\mathrm{d}\rho}{\mathrm{d}\tau} - \rho\sin\phi\frac{\mathrm{d}\phi}{\mathrm{d}\tau}\right)\right] = \cos\phi\frac{\partial n^2}{\partial\rho} - \frac{\sin\phi}{\rho}\frac{\partial n^2}{\partial\phi}, \tag{9.47}$$

$$\frac{2}{\lambda}\frac{\mathrm{d}}{\mathrm{d}\tau}\left[\frac{1}{\lambda}\left(\sin\phi\frac{\mathrm{d}\rho}{\mathrm{d}\tau} + \rho\cos\phi\frac{\mathrm{d}\phi}{\mathrm{d}\tau}\right)\right] = \sin\phi\frac{\partial n^2}{\partial\rho} + \frac{\cos\phi}{\rho}\frac{\partial n^2}{\partial\phi}, \tag{9.48}$$

Taking the sum of equation (9.47) multiplied by $\cos\phi$ and equation (9.48) multiplied by $\sin\phi$ and carrying out some simplification gives

$$\frac{2}{\lambda}\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{1}{\lambda}\frac{\mathrm{d}\rho}{\mathrm{d}\tau}\right) - \frac{2\rho}{\lambda^2}\left(\frac{\mathrm{d}\phi}{\mathrm{d}\tau}\right)^2 = \frac{\partial n^2}{\partial\rho}. \tag{9.49}$$

Likewise (9.47) × $\sin\phi$ − (9.48) × $\cos\phi$ and simplifications give

$$\frac{2}{\lambda}\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{\rho}{\lambda}\frac{\mathrm{d}\phi}{\mathrm{d}\tau}\right) + \frac{2}{\lambda^2}\frac{\mathrm{d}\phi}{\mathrm{d}\tau}\frac{\mathrm{d}\rho}{\mathrm{d}\tau} = \frac{1}{\rho}\frac{\partial n^2}{\partial\phi}. \tag{9.50}$$

Note that new ray equations (9.49) and (9.50) in the ρ–ϕ-plane are now coupled, non-linear, second order ordinary differential equations. Simultaneously, equation (9.39) is modified to

$$\left(\frac{\mathrm{d}\rho}{\mathrm{d}\tau}\right)^2 + \left(\rho\frac{\mathrm{d}\phi}{\mathrm{d}\tau}\right)^2 + \left(\frac{\mathrm{d}z}{\mathrm{d}\tau}\right)^2 = \lambda^2 n^2, \tag{9.51}$$

at all points along the ray. ■■

Example 9.1.3.2 Ray tracing in a standard atmosphere.
Consider the propagation of rays in a standard atmosphere where the refractive index in a certain geographical region changes only along the vertical axis, which is taken here as the z-axis. In a standard atmosphere, the refractive index varies linearly with height as [6, p 203], [7, p 112] $n(z) = n_0 + n_1 z$, where n_0 and $n_1 \neq 0$ are constants. For example, over the continental USA, a refractive index commonly used after correcting for the Earth's curvature is $n_0 = 1 + 289 \times 10^{-6}$, $n_1 = 118 \times 10^{-6}\ \mathrm{km}^{-1}$.

Let the initial conditions in ϕ be $\phi(\tau = 0) = 0 = \mathrm{d}\phi(\tau = 0)/\mathrm{d}\tau$. A valid solution for ϕ satisfying equation (9.50) along the ray is $\phi(\tau) = 0$ so that a ray initially in the meridian plane $\phi = 0$ continues to remain in it along its entire trajectory. Inserting this solution into equation (9.49) determines the ratio $\mathrm{d}\rho/\mathrm{d}\tau$ as

$$\frac{1}{\lambda}\frac{\mathrm{d}\rho}{\mathrm{d}\tau} = \frac{1}{c_0}, \tag{9.52}$$

where $c_0 \neq 0$ is some constant. Let us choose $\tau = \rho$ along the ray. Then the function λ reduces to the constant c_0 from equation (9.52). The z coordinate as a function of ρ along the ray is determined from equation (9.42):

$$\frac{\mathrm{d}^2 z}{\mathrm{d}\rho^2} - (c_0 n_1)^2 z = n_0 n_1 c_0^2. \tag{9.53}$$

The general solution of this second order differential equation is

$$z(\rho) = A\cosh(c_0 n_1 \rho) + B\sinh(c_0 n_1 \rho) - \frac{n_0}{n_1}.$$

If $z(\rho = 0) = z_0$ and $\mathrm{d}z/\mathrm{d}\rho|_{\rho=0} = \tan\theta_0$ are specified, then upon substituting into the above equation we obtain $A = z_0 + n_0/n_1$ and $B = \tan\theta_0/c_0 n_1$. Therefore the ray path is given by the closed-form expression

$$z(\rho) = \left(z_0 + \frac{n_0}{n_1}\right)\cosh(c_0 n_1 \rho) + \frac{\tan\theta_0}{c_0 n_1}\sinh(c_0 n_1 \rho) - \frac{n_0}{n_1}. \tag{9.54}$$

The constant c_0 can be determined from equation (9.51) which now reads

$$1 + \left(\frac{\mathrm{d}z}{\mathrm{d}\rho}\right)^2 = c_0^2 (n_0 + n_1 z)^2. \tag{9.55}$$

Evaluating this at $\rho = 0$ gives $c_0 = \pm\sec\theta_0/(n_0 + n_1 z_0)$. Since $z(\rho)$ is an even function of c_0, the sign of c_0 is immaterial. The special case of $\theta_0 = 0$ gives $c_0 = (n_0 + n_1 z_0)^{-1}$. Figure 9.6 shows the path of the ray for two different values of θ_0. Note that the scale of the range axis (that is, the ρ-axis) is in kilometers, while that of the altitude axis (that is, the z-axis) is in meters. For $\theta_0 = -1$ mrad, the ray is initially launched with a negative slope, but it eventually turns back up. Thus in both cases rays have a non-zero curvature and they eventually travel towards regions of higher refractive index values. ■■

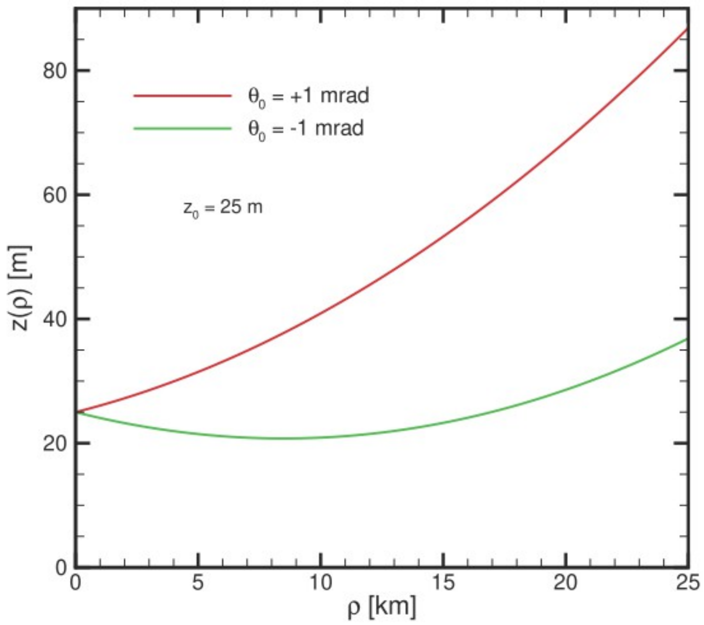

Figure 9.6. Ray tracing in a standard atmosphere with a refractive index $(n-1)\times 10^6 = 289 + 118z$.

Additional examples involving a geometrical optics interpretation of the solution of scattering by smooth convex bodies can be found in the books [8] and [2].

9.1.4 Mechanical interpretation of the ray path

Consider the special choice $\tau = ct/n^2$ (units of m), $\lambda = 1$ in the ray equations (9.39)–(9.40). Denoting the derivative w.r.t. τ with an overhead dot, the ray equations are

$$\ddot{x}(\tau) = \frac{\partial}{\partial x}\left(\frac{n^2}{2}\right), \quad \ddot{y}(\tau) = \frac{\partial}{\partial y}\left(\frac{n^2}{2}\right), \quad \ddot{z}(\tau) = \frac{\partial}{\partial z}\left(\frac{n^2}{2}\right). \tag{9.56}$$

The associated constraining equation (9.39) can be rewritten in the form

$$V = \frac{1}{2}(\dot{x}^2 + \dot{y}^2 + \dot{z}^2) = \frac{1}{2}n^2. \tag{9.57}$$

Equations (9.56) can be thought as the equations of motion of a particle ($m\mathbf{a} = \mathbf{F} = -\nabla U$, where m is the mass, $\mathbf{a}$ is the acceleration, $\mathbf{F}$ is the force, U is the potential energy) of unit mass subject to a potential energy $U = -\frac{1}{2}n^2$ (unitless). Then the kinetic energy of motion, V (unitless), is given by equation (9.57). The total energy of the particle $E = U + V = 0$. Thus electromagnetic rays in a medium of refractive index n can be thought of as the paths taken by particles which move with a total energy E in a potential field $U = -n^2/2$. The total energy of the particle is conserved at $E = 0$ as it moves along the path. Conversely, if a charged particle with a given energy C enters an electrostatic field with potential energy U then its kinetic energy $V = C - U$. We can then define a refractive index n from equation (9.57) as $n = \sqrt{2(C - U)}$ and consider ray paths by equation (9.56) whose trajectories will then mimic the actual paths taken by particles while conserving the total energy at C. ■■

9.1.5 Optical path length and Fermat's principle

With reference to figure 9.5, Fermat's principle states that [3, p 72], [1, p 128], [9, p 607]:

The rays between P_1 and P_2 are those curves along which the optical path length (9.34)

$$I = \int_{\sigma_1}^{\sigma_2} n(x(\sigma), y(\sigma), z(\sigma))\sqrt{\dot{x}^2(\sigma) + \dot{y}^2(\sigma) + \dot{z}^2(\sigma)}\; \mathrm{d}\sigma$$

is stationary with respect to infinitesimal variations in the path.

Proof. The integral I may be viewed as a cost function that depends not only on the 'particle' position (x, y, z) but also on its velocity $(\dot{x}, \dot{y}, \dot{z})$. The goal is to find the trajectory about which the cost function remains constant up to a first order in changes. Let us choose three functions $\xi(\sigma),\ \eta(\sigma),\ \zeta(\sigma)$ with continuous first order derivatives and which vanish at the end points

$$\xi(\sigma_1) = 0 = \xi(\sigma_2) = \eta(\sigma_1) = \eta(\sigma_2) = \zeta(\sigma_1) = \zeta(\sigma_2). \tag{9.58}$$

Let the extremal values we seek be x, y, z and the variations about the extremal values be $x + \varepsilon_1\xi,\ y + \varepsilon_2\eta,\ z + \varepsilon_3\zeta$, where $\varepsilon_1, \varepsilon_2, \varepsilon_3$ are small parameters. We can then view I as a function of $\varepsilon_i,\ i = 1, 2, 3$ on these varied paths:

$$I(\varepsilon_1, \varepsilon_2, \varepsilon_3) = \int_{\sigma_1}^{\sigma_2} F(x + \varepsilon_1\xi, y + \varepsilon_2\eta, z + \varepsilon_3\zeta; \dot{x} + \varepsilon_1\dot{\xi}, \dot{y} + \varepsilon_2\dot{\eta}, \dot{z} + \varepsilon_3\dot{\zeta})\, \mathrm{d}\sigma, \tag{9.59}$$

where $F(x, y, z; \dot{x}, \dot{y}, \dot{z}) = n(x, y, z)[\dot{x}^2 + \dot{y}^2 + \dot{z}^2]^{1/2}$. Note that all varied paths, including the extremal path, start and terminate at the same point owing to the boundary conditions in equation (9.58). The *first variation* of I w.r.t. x is defined as $(\delta I)_x = \partial I/\partial\varepsilon_1|_{\varepsilon_i=0, i=1,2,3}$ and is

$$\begin{aligned}(\delta I)_x &= \int_{\sigma_1}^{\sigma_2}\left(\xi\frac{\partial F}{\partial x} + \dot{\xi}\frac{\partial F}{\partial \dot{x}}\right)\mathrm{d}\sigma \\ &= \int_{\sigma_1}^{\sigma_2}\left(F_x - \frac{\mathrm{d}F_{\dot{x}}}{\mathrm{d}\sigma}\right)\xi\, \mathrm{d}\sigma,\end{aligned} \tag{9.60}$$

where integration by parts followed by the boundary conditions (9.58) were used in the second term on the rhs in the bottom row and we use the notation that $F_x = \partial F/\partial x$, $F_{\dot{x}} = \partial F/\partial \dot{x}$. Setting the first variation to zero for obtaining the extremum values and noting that ξ is arbitrary it follows that

$$\begin{aligned} F_x - \frac{\mathrm{d}F_{\dot{x}}}{\mathrm{d}\sigma} = 0 \Longrightarrow \frac{\partial n}{\partial x}\sqrt{\dot{x}^2 + \dot{y}^2 + \dot{z}^2} - \frac{\mathrm{d}}{\mathrm{d}\sigma}\left[\frac{n\dot{x}}{\sqrt{\dot{x}^2 + \dot{y}^2 + \dot{z}^2}}\right] = 0 \\ \Longrightarrow \frac{\partial n}{\partial x}\frac{\mathrm{d}s}{\mathrm{d}\sigma} = \frac{\mathrm{d}}{\mathrm{d}\sigma}\left[n\frac{\mathrm{d}x}{\mathrm{d}\sigma}\frac{\mathrm{d}\sigma}{\mathrm{d}s}\right] \\ \Longrightarrow \frac{\partial n}{\partial x} = \frac{\mathrm{d}}{\mathrm{d}s}\left[n\frac{\mathrm{d}x}{\mathrm{d}s}\right]. \end{aligned}$$

The left-hand side equation above is known as the *Euler equation* for the variational problem being studied here. We also know from equation (9.39) that $\lambda(s) = [n(s)]^{-1}$. Therefore the last equation above may be also be written as

$$\frac{2}{\lambda(s)}\frac{\mathrm{d}}{\mathrm{d}s}\left(\frac{1}{\lambda(s)}\frac{\mathrm{d}x}{\mathrm{d}s}\right) = \frac{\partial n^2}{\partial x}, \tag{9.61}$$

which is precisely the ray equation (9.40) expressed in terms of the arclength ray coordinate $\tau = s$. The other two ray equations (9.41) and (9.42) follow similarly from setting the first variation with respect to y and z also to zero. ■

9.1.6 Sommerfeld–Runge and Snell's laws, the Lagrange integral invariant

On account of the vector identity curl grad $\equiv 0$, the wave normal $\mathbf{p} = \hat{\mathbf{p}}n$ defined in equation (9.32) satisfies

$$\nabla \times \mathbf{p} = \nabla \times (\hat{\mathbf{p}}n) = 0, \tag{9.62}$$

a fact first discovered by Sommerfeld and Runge [10] and later came to be known as the *Sommerfeld–Runge law*. One can construct a vector field $\hat{\mathbf{p}}(x, y, z)n(x, y, z)$ on knowing the refractive index and ray directions, which are in turn dictated by the initial conditions for launching rays (initial location and 'velocities of rays' as in example 9.1.3.1). The unit vector $\hat{\mathbf{p}}$ also has special properties. In a homogeneous medium n is a constant and equation (9.62) implies $\nabla \times \hat{\mathbf{p}} = 0$. Otherwise, since $\nabla \times n\hat{\mathbf{p}} = n\nabla \times \hat{\mathbf{p}} + \nabla n \times \hat{\mathbf{p}}$, taking a scalar product with $\hat{\mathbf{p}}$ yields

$$\hat{\mathbf{p}} \cdot \nabla \times \hat{\mathbf{p}} = 0. \tag{9.63}$$

Assuming that n is a continuous function of position, one may apply Stokes' theorem to an open surface S bounded by a closed curve C and deduce the *Lagrange's integral invariant* associated with this field $\hat{\mathbf{p}}n$

$$\oint_C n\hat{\mathbf{p}} \cdot \mathrm{d}\boldsymbol{\ell} = \iint_S \nabla \times (\hat{\mathbf{p}}n)\,\mathrm{d}s = 0. \tag{9.64}$$

Lagrange's integral invariant continues to hold good for piece-wise continuous media as the contour C can be deformed in that case to include material boundary as shown in figure 9.7, $C = (C_1 - K) \cup (C_2 + K)$. The contributions to the integral arising from the boundary K will be zero since the vector $(n_2\hat{\mathbf{p}}_2 - n_1\hat{\mathbf{p}}_1) \perp \mathrm{d}\boldsymbol{\ell}$ as is shown in example 9.1.6.1, where $\mathbf{p}_i$ is the wave normal at the interface in medium $i,\ i = 1, 2$.

The field $\mathbf{p} = \hat{\mathbf{p}}n$ thus acts like a conservative force field and implies that the integral

$$J(P_1, P_2) = \int_{P_1}^{P_2} n(x, y, z)\hat{\mathbf{p}}(x, y, z) \cdot \mathrm{d}\boldsymbol{\ell}, \tag{9.65}$$

taken between any two points P_1 and P_2 is independent of the path of integration (see figure 9.8).

Example 9.1.6.1. Snell's law.

In this example we start from the Sommerfeld–Runge law and derive the well known Snell's law in a stratified medium. Indeed we have from the vector identity $\nabla(\mathbf{a} \cdot \mathbf{b}) = \mathbf{a} \times \nabla \times \mathbf{b} + \mathbf{b} \times \nabla \times \mathbf{a} + (\mathbf{a} \cdot \nabla)\mathbf{b} + (\mathbf{b} \cdot \nabla)\mathbf{a}$ and equation (9.62) that

$$\begin{aligned}\hat{\mathbf{p}} \cdot \nabla \times \mathbf{p} = 0 &\Longrightarrow 2(\mathbf{p} \cdot \nabla)\mathbf{p} = \nabla(\mathbf{p} \cdot \mathbf{p})\\ &= 2n\nabla n \Longrightarrow (\hat{\mathbf{p}} \cdot \nabla)\mathbf{p} = \nabla n.\end{aligned} \tag{9.66}$$

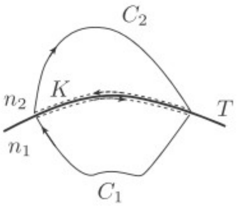

Figure 9.7. Lagrange's integral invariant in the presence of piece-wise continuous media.

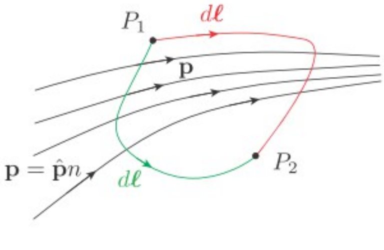

Figure 9.8. The integral $J(P_1, P_2)$ between two points is independent of the path taken.

Consider now a horizontally stratified medium with a refractive index changing only along one axis (say z). Then $\frac{\partial}{\partial x} = 0 = \frac{\partial}{\partial y}$ and $\nabla n = \hat{\mathbf{z}}\frac{\partial n}{\partial z}$. If the ray makes an angle $\theta(z)$ with the z-axis and has an azimuthal angle ϕ (independent of z), then in a local cylindrical coordinate system erected at any point $\hat{\mathbf{p}} = \hat{\boldsymbol{\rho}}\sin\theta + \hat{\mathbf{z}}\cos\theta$ and $(\hat{\mathbf{p}}\cdot\nabla)\mathbf{p} = \hat{\boldsymbol{\rho}}\cos\theta\frac{\partial}{\partial z}(n(z)\sin\theta(z)) + \hat{\mathbf{z}}\cos\theta\frac{\partial}{\partial z}(n(z)\cos\theta(z))$. Since ∇n has no radial component we conclude upon comparing both sides of equation (9.66) that

$$\frac{\partial}{\partial z}(n(z)\sin\theta(z)) = 0 \Longrightarrow n(z)\sin\theta(z) = \text{constant}, \tag{9.67}$$

which is a mathematical statement of Snell's law in a horizontally stratified medium. Note that the frequency of the wave does not explicitly enter into this equation. In the case of a boundary between two piece-wise continuous media with refractive indices n_1 and n_2 (see figure 9.7) and ray angles with respect to normal of θ_1 and θ_2, respectively, Snell's law reduces to the familiar result $n_1\sin\theta_1 = n_2\sin\theta_2$.

If on the two sides of the boundary K between two different homogeneous media (see figure 9.7) $\mathbf{p} = \hat{\mathbf{p}}_1 n_1$ and $\mathbf{p} = \hat{\mathbf{p}}_2 n_2$, then $\nabla\times\mathbf{p} = 0 \Longrightarrow (\hat{\mathbf{p}}_2 n_2 - \hat{\mathbf{p}}_1 n_1)\cdot \mathrm{d}\ell = 0$ from an application of Stokes' theorem to a closed rectangular contour consisting of the two dashed lines across K in figure 9.7 connected by vanishingly small vertical segments. Therefore the vector $(\hat{\mathbf{p}}_2 n_2 - \hat{\mathbf{p}}_1 n_1)$ has no tangential component at the interface, or, equivalently, it is perpendicular to the interface.

9.1.7 Transport of the geometrical optics field

The propagation of electric and magnetic field vectors and that of the Poynting vector in geometrical optics is most easily carried out in the frequency domain. We will first derive the transport equation for the time-harmonic electric field $\mathbf{E}$. The equation for the magnetic field follows from duality. From Maxwell's equations in a source-free and non-conducting region we have $\nabla\times\nabla\times\mathbf{E} - k^2\mathbf{E} = 0$, $\nabla\cdot(\varepsilon\mathbf{E}) = 0 = \varepsilon\nabla\cdot\mathbf{E} + \mathbf{E}\cdot\nabla\varepsilon$, where $k = k_0 n$, k_0 is the free-space wavenumber and n is the refractive index. Using the vector identity $\nabla\times\nabla\times\mathbf{E} = \nabla\nabla\cdot\mathbf{E} - \nabla^2\mathbf{E}$ and the above divergence equation we obtain the modified Helmholtz equation for the electric field

$$\nabla^2\mathbf{E} + k^2\mathbf{E} = -\nabla\left(\mathbf{E}\cdot\frac{\nabla\varepsilon}{\varepsilon}\right). \tag{9.68}$$

Let us consider the normalized space variables $\xi = k_0 x,\ \eta = k_0 y,\ \zeta = k_0 z$ and the corresponding gradient operator $\tilde{\nabla}$. In the normalized variables equation (9.68) reads

$$\tilde{\nabla}^2\mathbf{E} + n^2\mathbf{E} = -\tilde{\nabla}\left(\mathbf{E}\cdot\frac{\tilde{\nabla}\varepsilon}{\varepsilon}\right). \tag{9.69}$$

If the permittivity has a characteristic length scale L (that is, the permittivity varies non-trivially over a distance L)[5] then $|\widetilde{\nabla}\varepsilon|/\varepsilon \sim (k_0 L)^{-1}$. Consequently, for $k_0 L \gg 1$, the rhs of equation (9.69) and hence that of equation (9.68) may be ignored. Therefore for a slowly varying permittivity function the electric field satisfies the homogeneous vector Helmholtz equation

$$\nabla^2\mathbf{E} + n^2 k_0^2 \mathbf{E} \approx 0, \quad k_0 L \gg 1. \tag{9.70}$$

In a Cartesian coordinate system, each component of the electric field satisfies the scalar Helmholtz equation $\nabla^2 E + n^2 k_0^2 E = 0$. We now express each field component as

$$E(\mathbf{r}) = \mathrm{e}^{-jk_0 \mathscr{S}(\mathbf{r})} E_0(\mathbf{r}), \tag{9.71}$$

where the phase function $\mathscr{S}(\mathbf{r})$ (units of m) and the amplitude function $E_0(\mathbf{r})$ (units of V m^{-1}) are assumed to be slowly varying functions of position and independent of k_0. Now

$$\begin{aligned}\nabla^2 E = \nabla \cdot \nabla E = \big[&\nabla^2 E_0 - 2jk_0 \nabla\mathscr{S} \cdot \nabla E_0 - jk_0 E_0 \nabla^2 \mathscr{S} \\ &- k_0^2 (\nabla\mathscr{S})^2 E_0\big]\mathrm{e}^{-jk_0\mathscr{S}},\end{aligned}$$

where $(\nabla\mathscr{S})^2 = \nabla\mathscr{S} \cdot \nabla\mathscr{S}$. Substituting into the scalar Helmholtz equation we obtain

$$[(\nabla\mathscr{S})^2 - n^2]E_0 + \frac{j}{k_0}\big(2\nabla\mathscr{S} \cdot \nabla E_0 + E_0 \nabla^2\mathscr{S}\big) - \frac{1}{k_0^2}\nabla^2 E_0 = 0. \tag{9.72}$$

We choose the phase function $\mathscr{S}$ such that the term within the square bracket above vanishes. Then

$$(\nabla\mathscr{S})^2 = n^2, \tag{9.73}$$

which is seen to be the same equation as the eikonal equation satisfied by the function ψ in equation (9.31). Hence the family of surfaces $\mathscr{S} =$ constant constitute the wavefronts. Indeed we set $\mathscr{S} = \psi$ in the ensuing analysis. With this choice of the phase function, the amplitude function now satisfies

$$(2\nabla\psi \cdot \nabla E_0 + E_0 \nabla^2 \psi) = \frac{1}{jk_0}\nabla^2 E_0. \tag{9.74}$$

If the amplitude function has a length scale of ℓ, then $\nabla^2 E_0 \sim \mathcal{O}(\ell^{-2})$. At high enough frequencies such that $k_0 \ell \gg 1$, the term on the rhs of equation (9.74) may then be ignored. Therefore the amplitude function satisfies the simpler equation

$$\nabla\psi \cdot \nabla \ln(E_0) = -\frac{1}{2}\nabla^2\psi, \tag{9.75}$$

---

[5] Note that if ε varies as $\gamma_0\, \mathrm{e}^{-x/L_x}$ in the x-direction, then $\varepsilon^{-1}\partial\varepsilon/\partial\xi = (k_0 L_x)^{-1}$.

where we have utilized the fact that $\nabla \ln(E_0) = E_0^{-1}\nabla E_0$. Since $\nabla\psi = \mathbf{p} = \hat{\mathbf{p}}n$ (see equation (9.32)) the above equation for determining the amplitude function can also be written as

$$\hat{\mathbf{p}} \cdot \nabla \ln(E_0) = -\frac{1}{2n}\nabla \cdot \mathbf{p} = -\frac{1}{2n}\nabla \cdot (\hat{\mathbf{p}}n). \tag{9.76}$$

Similar equations are obtained for the components of a magnetic field vector. Once the gradient of the wavefront is calculated from the medium refractive index, the amplitude E_0 along the ray can be determined using equation (9.76). This procedure of obtaining the transport equations for field vectors is equivalent to extracting the leading term after expanding the time-harmonic fields ($\mathbf{E}(\mathbf{r})$, $\mathbf{H}(\mathbf{r})$) in inverse powers of the free-space wavenumber k_0 as done by Luneberg [11] and Kline [12].

The wave intensity I is defined as the absolute value of the time average of the Poynting vector and is $I = \frac{1}{2}\Re(\mathbf{E} \times \mathbf{H}^*) \cdot \hat{\mathbf{p}}$. In a source-free and non-conducting region we have from equation (5.17) that

$$\nabla \cdot (I\hat{\mathbf{p}}) = 0. \tag{9.77}$$

Consider a narrow tube formed by rays exiting an elemental area $\mathrm{d}S_1$ of a wavefront $\psi = c_1$ and arriving at an elemental area $\mathrm{d}S_2$ of the wavefront $\psi = c_2$, where c_1 and c_2 are constants. The rays are all parallel to the sidewalls of the tube as indicated in figure 9.9. Integrating the divergence equation (9.77) over the volume comprised by the tube and applying Gauss' divergence theorem we obtain

$$I_2\mathrm{d}S_2 = I_1\mathrm{d}S_1, \tag{9.78}$$

after noting that $\hat{\mathbf{n}} \cdot \hat{\mathbf{p}} = 0$ on the portion of surface along the tube, $\hat{\mathbf{n}} \cdot \hat{\mathbf{p}} = -1$ on $\mathrm{d}S_1$, $\hat{\mathbf{n}} \cdot \hat{\mathbf{p}} = +1$ on $\mathrm{d}S_2$ and I_1 and I_2 are the intensities on $\mathrm{d}S_1$ and $\mathrm{d}S_2$, respectively. Hence $I\mathrm{d}S$ remains constant along a tube of rays. The intensity decreases along a ray if the rays diverge between two wavefronts and intensity increases if the rays converge. It is possible to obtain an explicit expression for the intensity of the ray in terms of the wavefront $\psi =$ constant. We know from equation (9.32) that $\hat{\mathbf{p}} = (\nabla\psi)/n$. Therefore from $\nabla \cdot (\hat{\mathbf{p}}I) = 0$ we have

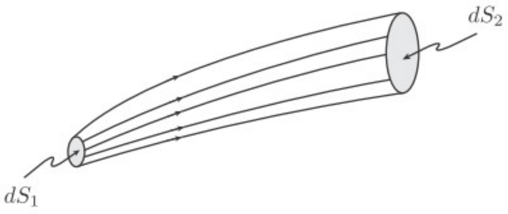

Figure 9.9. A tube of rays connecting two elemental areas $\mathrm{d}S_1$ and $\mathrm{d}S_2$ in an isotropic medium.

$$\left(\frac{I}{n}\right)\nabla^2\psi + \nabla\psi\cdot\nabla\left(\frac{I}{n}\right) = 0 \Longrightarrow \frac{1}{n(s)}\nabla\psi\cdot\nabla\ln\left(\frac{I}{n}\right) = -\frac{1}{n(s)}\nabla^2\psi, \tag{9.79}$$

where a factor $1/n(s)$, s = arclength parameter along the ray, was included on both sides in the last equation for convenience. We also know from (9.36)–(9.38) that when the arbitrary parameter τ along the ray is chosen to be the arclength parameter the quantity $\lambda(\tau)$ there becomes equal to $n^{-1}(s)$. Therefore along the ray with a parametric representation $x = x(s),\ \ y = y(s),\ \ z = z(s)$, the operator

$$\frac{1}{n(s)}\nabla\psi\cdot\nabla = \frac{\mathrm{d}x(s)}{\mathrm{d}s}\frac{\partial}{\partial x} + \frac{\mathrm{d}y(s)}{\mathrm{d}s}\frac{\partial}{\partial y} + \frac{\mathrm{d}z(s)}{\mathrm{d}s}\frac{\partial}{\partial z} = \frac{\mathrm{d}}{\mathrm{d}s},$$

in view of equations (9.36)–(9.38). Using this in equation (9.79) leads to

$$\frac{\mathrm{d}}{\mathrm{d}s}\ln\left(\frac{I(s)}{n(s)}\right) = -\frac{\nabla^2\psi}{n(s)}. \tag{9.80}$$

Integrating this between two points gives the intensity law for geometrical optics

$$\frac{I(s_2)}{I(s_1)} = \frac{n(s_2)}{n(s_1)}\mathrm{e}^{-\int_{s_1}^{s_2}\frac{\nabla^2\psi}{n(s)}\mathrm{d}s}. \tag{9.81}$$

The integral inside the exponent of equation (9.81) forms the basis for defining Radon transform (see chapter 14), which has utility in x-ray computed tomography.

Example 9.1.7.1. Intensity law in a homogeneous medium.
We would like to show in this example the intensity law for geometrical optics in a homogeneous medium. In a homogeneous medium the refractive index is constant and the rays propagate along straight lines. It is sufficient to consider the case of a vacuum ($n = 1$). Let us assume that the principal radii of curvature of the wavefront at $s = 0$ are given to be $\rho_1(s = 0) = \rho_{10}$ and $\rho_2(s = 0) = \rho_{20}$ and that the intensity at $s = 0$ is unity. For convenience we take $s = z$ and express the wavefront in terms of a local Cartesian system erected around the central ray (in the so-called Dupin coordinate system). We can approximately construct the wavefront as a quadratic function in terms of the radii of curvature as

$$\psi(x,\,y,\,z):\ z + \frac{x^2}{2\rho_1(z)} + \frac{y^2}{2\rho_2(z)} = 0,$$

see figure 9.10. If ρ_1 and ρ_2 are positive the wavefront will be convex in the direction of propagation as shown in the figure. If they are negative, the wavefront will be concave in the direction of propagation. For this wavefront

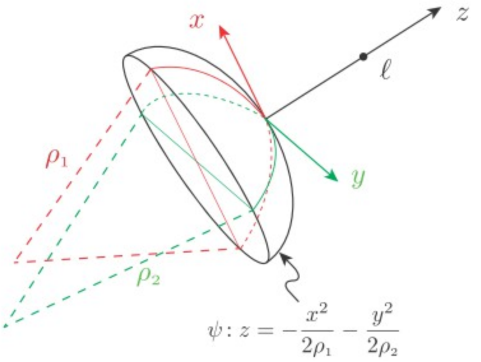

Figure 9.10. Wavefront having principal radii of curvature ρ_1 and ρ_2.

$$\nabla\psi = \hat{\mathbf{x}}\frac{x}{\rho_1(z)} + \hat{\mathbf{y}}\frac{y}{\rho_2(z)} + \hat{\mathbf{z}}\left(1 - \frac{x^2}{2\rho_1^2(z)}\rho_1'(z) - \frac{y^2}{2\rho_2^2(z)}\rho_2'(z)\right).$$

For the eikonal equation $|\nabla\psi|^2 = 1$ to be satisfied we require

$$\frac{x^2}{\rho_1^2}(1 - \rho_1') + \frac{y^2}{\rho_2^2}(1 - \rho_2') + \frac{1}{4}\left[\frac{x^2}{\rho_1^2}\rho_1' + \frac{y^2}{\rho_2^2}\rho_2'\right]^2 = 0.$$

Choosing $\rho_1' = 1 = \rho_2'$ yields $\rho_1(z) = \rho_{10} + z$; $\rho_2(z) = \rho_{20} + z$. However with this choice, the eikonal equation is satisfied exactly only for the central ray ($x = 0,\ y = 0$) and up to fourth order accuracy (that is the error will be proportional to $\mathcal{O}[(x/\rho_1)^4]$, $\mathcal{O}[(y/\rho_2)^4]$, $\mathcal{O}[(xy/\rho_1\rho_2)^2]$ for the other rays. Our main focus here is to derive the intensity law for the central ray and in that respect the above wavefront model is valid. The Laplacian of the wavefront in vacuum is

$$\begin{aligned}\nabla^2\psi &= \frac{1}{\rho_1(z)} + \frac{1}{\rho_2(z)} - \left(\frac{x^2}{\rho_1^3(z)} + \frac{y^2}{\rho_2^3(z)}\right)\\ &= \frac{1}{\rho_1(z)} + \frac{1}{\rho_2(z)} + \mathcal{O}\left(\frac{x^2}{\rho_1^3(z)}, \frac{y^2}{\rho_2^3(z)}\right)\\ &\sim \frac{1}{\rho_1(z)} + \frac{1}{\rho_2(z)},\end{aligned} \tag{9.82}$$

which is simply the mean curvature of the wavefront along the central ray[6]. Using this in equation (9.81) and integrating between $z = 0$ and $z = \ell$ gives

---

[6] It is shown in [13] that the above relation, i.e. $n^{-1}(s)\nabla^2\psi = \rho_1^{-1}(s) + \rho_2^{-1}(s)$ is valid also for an inhomogeneous isotropic medium. However, the ray trajectory will be non-rectilinear and the radii of curvature in an inhomogeneous medium will no longer be linear functions of arclength.

$$\int_0^{\ell}\left(\frac{1}{\rho_{10}+z}+\frac{1}{\rho_{20}+z}\right)\mathrm{d}z=\ln\left(\left[\frac{\rho_{10}+\ell}{\rho_{10}}\right]\left[\frac{\rho_{20}+\ell}{\rho_{20}}\right]\right)$$

and consequently

$$I(\ell)=\frac{\rho_{10}\rho_{20}}{(\rho_{10}+\ell)(\rho_{20}+\ell)}. \tag{9.83}$$

The square root of this quantity can be taken to be the factor affecting the amplitude of the field components along the central ray. On recognizing that $\psi = z = \ell$ along the ray, the electric field in a vacuum for the central ray under geometrical optics can then be written as

$$\mathbf{E}(\mathbf{r})\sim\mathbf{E}(\mathbf{r}_o)\sqrt{\frac{\rho_{10}\rho_{20}}{(\rho_{10}+\ell)(\rho_{20}+\ell)}}\,\mathrm{e}^{-jk_0\ell}, \tag{9.84}$$

where $\mathbf{r}_o$ denotes the point on the initial wavefront and $\mathbf{E}(\mathbf{r}_o)$ is the initial electric field at that point. If the initial radii of curvature are positive (diverging rays), the electric field amplitude falls along the propagating ray. On the other hand, if the initial radii of curvature are negative (converging rays), the electric field amplitude increases along the propagating ray. If the radii of curvature are infinite (parallel rays; plane wavefront) the amplitude stays constant. ■■

9.1.8 Other theorems of geometrical optics

Definition 9.1.1 *Congruence*. A system of curves which fill a portion of space in such a way that in general a single curve passes through each point of the region is called a congruence.

Definition 9.1.2 *Normal congruence*. If there exists a family of surfaces which cut each of the curves of a congruence orthogonally, the congruence is said to be normal.

Definition 9.1.3 *Rectilinear congruence*. If each curve of a congruence is a straight line, the congruence is said to be rectilinear.

Theorem 9.1.1 Theorem of Malus and Dupin [1, p 131].
A normal rectilinear congruence remains normal after any number of refractions or reflections.

Proof. It is sufficient to establish the theorem for a single interface. Consider a normal rectilinear congruence in a homogeneous medium of refractive index n_1 and assume that the rays undergo a refraction at an interface T which separates this medium from another homogeneous medium of refractive index n_2. Let S_1 be a

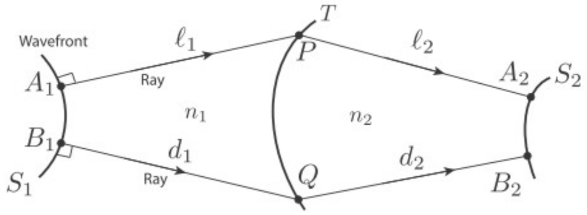

Figure 9.11. Geometry relating to the proof of the theorem of Malus and Dupin.

wavefront in medium 1, let A_1 and P be points of intersection on surfaces S_1 and T, and let A_2 be any point on the refracted ray. The optical path length between A_1 and A_2 is designated as $[A_1PA_2]$ and equals $\ell_1 n_1 + \ell_2 n_2$. Consider a second point B_1Q hitting the interface at Q and let B_2 be a point such that $[B_1QB_2] = \mathrm{d}_1 n_1 + \mathrm{d}_2 n_2 = [A_1PA_2] = \ell_1 n_1 + \ell_2 n_2$. As the point B_1 is varied on S_1, the corresponding point B_2 traverses a surface S_2. It is required to show that the ray $QB_2 \perp S_2$. Applying Lagrange's integral invariant to the closed path $A_1PA_2B_2QB_1A_1$ (see figure 9.11) we obtain

$$[A_1PA_2] + \int_{A_2B_2\in S_2} n_2\hat{\mathbf{p}}_2 \cdot \mathrm{d}\mathbf{r} - [B_2QB_1] + \int_{B_1A_1\in S_1} n_1\hat{\mathbf{p}}_1 \cdot \mathrm{d}\mathbf{r} = 0.$$

Using $[A_1PA_2] = [B_1QB_2] = [B_2QB_1]$ and $\hat{\mathbf{p}}_1 \perp \mathrm{d}\mathbf{r}$ on $B_1A_1 \in S_1$ (since A_1 and B_1 are rays originating from the wavefront S_1) gives

$$\int_{A_2B_2\in S_2} n_2\hat{\mathbf{p}}_2 \cdot \mathrm{d}\mathbf{r} = 0,$$

which implies that $\hat{\mathbf{p}}_2 \perp \mathrm{d}\mathbf{r}$ on S_2 since A_2, and consequently, S_2 is arbitrary. Therefore the refracted rays are orthogonal to S_2; in other words refracted rays form a *normal* congruence, and S_2 also constitutes a wavefront. It also follows from the proof presented that the optical path length between any two wavefronts (whether they are in the same medium or not) is the same for all *rays* connecting the two. Concave and convex lenses designed to project objects to image locations are examples of equality of optical path lengths between wavefronts located across various medium inhomogeneities. ■

9.2 Gradient metasurfaces and the generalized Snell's law

When a ray is reflected from an ordinary isotropic material half-space, the plane of incidence, the plane of reflection, and the plane of transmission remain the same and the angles of reflection and transmission are related to the angle of incidence via Snell's laws. Lately, researchers have exploited the additional degree of freedom provided by artificially modifying the properties of the surface of material discontinuity and shown that it is possible to have the plane of reflection and/or transmission different from the plane of incidence [14]. Below we discuss the mechanism that is

%9 + & > / ' & 0 ' ' - F 0

responsible for the twist in the planes of reflection and refraction and derive the equations of generalized Snell's law.

Consider a smooth surface S separating two piece-wise continuous media with refractive indices n_i, $i = 1, 2$. Let the surface be structured (by the inclusion of a two-dimensional array of sub-wavelength scatterers) to introduce a *constant* surface phase gradient $\mathbf{k}_s = \nabla\Psi$ rad m^{-1} oriented in an arbitrary direction along the surface. If $\hat{\mathbf{n}}$ is the unit normal on the surface then $\hat{\mathbf{n}} \cdot \mathbf{k}_s = 0$. Consider the optical path length $[P_1AP_2]$ between a point P_1 located in medium 1 and a point P_2 located in medium 2 via a point A on the surface. The line P_1A has a direction given by the unit vector $\hat{\mathbf{k}}_1(\mathbf{r}_s) = -(\hat{\mathbf{x}}\sin\theta_1\cos\phi_1 + \hat{\mathbf{y}}\sin\theta_1\sin\phi_1 + \hat{\mathbf{z}}\cos\theta_1)$, while the line AP_2 has a direction given by the unit vector $\hat{\mathbf{k}}_2(\mathbf{r}_s) = (\hat{\mathbf{x}}\sin\theta_2\cos\phi_2 + \hat{\mathbf{y}}\sin\theta_2\sin\phi_2 + \hat{\mathbf{z}}\cos\theta_2)$. The point A has a position vector $\mathbf{r}_s = \mathbf{s}_A + \hat{\mathbf{n}}r_n$ and the various angles are defined with respect to a *local origin* at A. The surface introduces an extra phase shift of $\mathbf{r}_s \cdot \mathbf{k}_s = \mathbf{s}_A \cdot \mathbf{k}_s$ on the propagating ray. Let the wavenumber in free space at the operating frequency be k_0. Then

$$k_0[P_1AP_2] = \int_{P_1}^{A} \mathbf{k}_1 \cdot d\mathbf{r} + \mathbf{k}_s \cdot \mathbf{s}_A + \int_{A}^{P_2} \mathbf{k}_2 \cdot d\mathbf{r},$$

where $\mathbf{k}_i = k_0 n_i \hat{\mathbf{k}}_i$, $i = 1, 2$. Our goal here is to determine the relation between $\mathbf{k}_1$, $\mathbf{k}_2$, $\hat{\mathbf{n}}$, and $\mathbf{k}_s$. Applying Fermat's principle, we take the first variation δ_A of the optical path length with respect to the coordinates of A and set it to zero. In the local coordinate system at A it is straightforward to see that $\delta_A\mathbf{r}_s = \delta_A\mathbf{s}_A + \mathcal{O}(\delta_A^2)$. With reference to figure 9.12 we also note

$$\delta_A \int_{P_1}^{A} \mathbf{k}_1 \cdot d\mathbf{r} = k_0 n_1 \delta_A \ell_1 = k_0 n_1 \hat{\mathbf{k}}_1 \cdot \delta_A\mathbf{s}_A = \mathbf{k}_1 \cdot \delta_A\mathbf{s}_A$$
$$\delta_A \int_{A}^{P_2} \mathbf{k}_2 \cdot d\mathbf{r} = k_0 n_2 \delta_A \ell_2 = k_0 n_2 \hat{\mathbf{k}}_2 \cdot \delta_A\mathbf{s}_A = \mathbf{k}_2 \cdot \delta_A\mathbf{s}_A.$$

Therefore we have from Fermat's principle that

$$(\mathbf{k}_1 + \mathbf{k}_s - \mathbf{k}_2) \cdot \delta_A\mathbf{s}_A = 0.$$

Since $\delta_A\mathbf{s}_A$ is arbitrary and lies on the surface, we have the condition that the quantity within the parenthesis above must be perpendicular to $\mathbf{s}_A$ or, equivalently, must be along the normal $\hat{\mathbf{n}}$ so that

$$\hat{\mathbf{n}} \times (\mathbf{k}_2 - \mathbf{k}_1) = \hat{\mathbf{n}} \times \mathbf{k}_s. \tag{9.85}$$

In a similar fashion it can be established by applying Fermat's principle to the optical path P_1AQ pertaining to the reflection problem that

$$\hat{\mathbf{n}} \times (\mathbf{k}_r - \mathbf{k}_1) = \hat{\mathbf{n}} \times \mathbf{k}_s, \tag{9.86}$$

where $\mathbf{k}_r = k_0 n_1 \hat{\mathbf{k}}_r$ is the wave vector in the direction of the reflected ray and $\hat{\mathbf{k}}_r$ is a unit vector in the direction of the reflected ray.

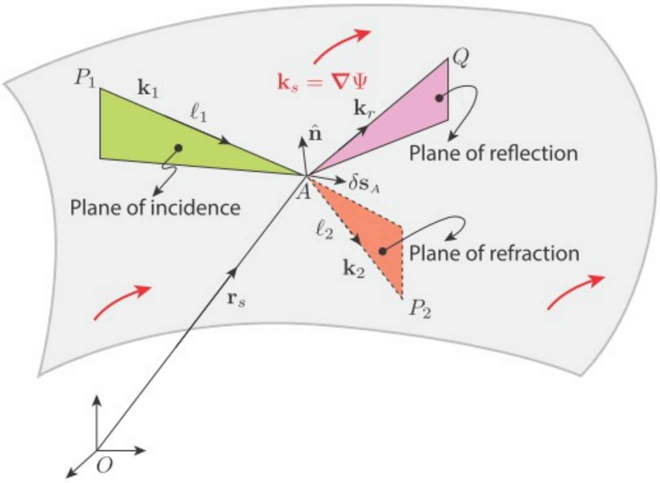

Figure 9.12. Reflection and refraction of light from a metasurface with phase discontinuity.

Example 9.2.0.1. Reflection and refraction from flat phase-gradient interface. When the interface is flat, we choose it to be the ($z = 0$)-plane on which $\hat{\mathbf{n}} = \hat{\mathbf{z}}$. Let the incident ray be in the xz-plane such that $\phi = \phi_1 = 0$, and $\theta = \theta_1$. In that case $\mathbf{k}_1 = -k_0 n_1(\hat{\mathbf{x}} \sin\theta_1 + \hat{\mathbf{z}}\cos\theta_1)$. Let the metasurface have a phase gradient given by $\mathbf{k}_\text{s} = k_\text{s}(\hat{\mathbf{x}}\cos\phi_\text{s} + \hat{\mathbf{y}}\sin\phi_\text{s})$ so that the gradient makes an angle ϕ_s with the xz-plane and k_s is its magnitude. Let the refracted ray have the wave vector $\mathbf{k}_2 = k_0 n_2(\hat{\mathbf{x}}\sin\theta_2 \cos\phi_2 + \hat{\mathbf{y}}\sin\theta_2\sin\phi_2 + \hat{\mathbf{z}}\cos\theta_2)$. Then equation (9.85) suggests that

$$k_0 n_2(\hat{\mathbf{y}}\sin\theta_2\cos\phi_2 - \hat{\mathbf{x}}\sin\theta_2\sin\phi_2) = (k_0 n_1 \sin\theta_1 + k_\text{s}\cos\phi_\text{s})\hat{\mathbf{y}} - k_\text{s}\hat{\mathbf{x}}\sin\phi_\text{s}$$

$$\Longrightarrow \sin\theta_2\sin\phi_2 = \frac{k_\text{s}}{k_0 n_2}\sin\phi_\text{s}$$

$$\text{and } \sin\theta_2\cos\phi_2 = \frac{n_1}{n_2}\sin\theta_1 + \frac{k_\text{s}}{k_0 n_2}\cos\phi_\text{s}.$$

Squaring and adding the last two equations gives

$$\sin\theta_2 = \sqrt{\left(\frac{n_1}{n_2}\right)^2 \sin^2\theta_1 + \left(\frac{k_\text{s}}{k_0 n_2}\right)^2 + \frac{2n_1 k_\text{s}}{k_0 n_2^2}\sin\theta_1\cos\phi_\text{s}}, \tag{9.87}$$

and dividing the second of the last two by the first gives

$$\cot\phi_2 = \frac{k_0 n_1}{k_\text{s}}\frac{\sin\theta_1}{\sin\phi_\text{s}} + \cot\phi_\text{s}, \tag{9.88}$$

For a normally incident wave $\theta_1 = 0$, but equation (9.87) clearly shows that $\theta_2 \neq 0$ unless the phase gradient $k_\text{s} = 0$. In general the angle θ_2 also depends on the frequency of operation. Furthermore, equation (9.88) gives $\phi_2 = \phi_\text{s} \neq 0$. In other words, refraction takes place out of the xz-plane if ϕ_s is different from zero, that is, if a non-zero phase gradient in the y-direction exists. In a sense, the phase gradient surface acts like a surface supporting running fluid that twists the plane of incidence upon refraction by the interface.

In a similar manner, denoting $\mathbf{k}_\mathrm{r} = k_0 n_1(\hat{\mathbf{x}} \sin\theta_\mathrm{r} \cos\phi_\mathrm{r} + \hat{\mathbf{y}} \sin\theta_\mathrm{r} \sin\phi_\mathrm{r} + \hat{\mathbf{z}} \cos\theta_\mathrm{r})$ gives

$$\sin\theta_\mathrm{r} = \sqrt{\sin^2\theta_1 + \left(\frac{k_\mathrm{s}}{k_0 n_1}\right)^2 + \frac{2k_\mathrm{s}}{k_0 n_1}\sin\theta_1 \cos\phi_\mathrm{s}}\,, \tag{9.89}$$

$$\cot\phi_\mathrm{r} = \frac{k_0 n_1}{k_\mathrm{s}}\frac{\sin\theta_1}{\sin\phi_\mathrm{s}} + \cot\phi_\mathrm{s}. \tag{9.90}$$

Equation (9.89) shows that the angle of reflection is not equal to the angle of incidence unless the phase gradient $k_\mathrm{s} = 0$. Furthermore, reflection takes place out of the plane of incidence since $\phi_\mathrm{r} \neq 0$ unless $k_\mathrm{s} = 0$. It is also seen once again that in general the twist in the plane of reflection depends on the frequency of operation. ■■

brackets only of the form $Q_1'Q_2 - Q_1Q_2'$, which requires derivatives of delta functions. However, no such derivatives appear if the only momentum variable that appears in the constraint, p_L, is conjugate to a field, L, that does not appear with spatial derivatives in the constraint.

The brackets (6.43) and (6.44) rely on general features that do not require a specific dependence on the momentum p_L, which moreover does not have a density weight. The quadratic dependence p_L^2 in $\mathrm{C}[Q]$ can therefore be replaced by any function $f_1(p_L)$. The brackets remain not only closed but also unchanged compared with the classical result (6.44). This result is in apparent conflict with our previous derivation, (6.37), which showed that the spacetime structure is necessarily affected by holonomy modifications.

However, after reformulating the constrained system by introducing $\mathrm{C}[Q]$, spacetime structure has been obscured because we no longer see the relationship with classical hypersurface-deformation brackets (2.154). In order to make the spacetime structure manifest after we modified the constraint $\mathrm{C}[Q]$ to

$$\mathrm{C}[Q] = \int_{-\infty}^{\infty} Q\left(-\frac{f_1(p_L)}{S} + \frac{S(S')^2}{L^2} + \frac{1}{2}\int SV(S)\mathrm{d}S + C_0\right)\mathrm{d}x, \tag{6.45}$$

we should retrace our steps that led us from $\mathrm{H}[N]$ and $\mathrm{D}[\epsilon]$ to $\mathrm{D}[\epsilon]$ and $\mathrm{C}[Q]$. In particular, as in Equation (6.41), a linear combination of some modified $\tilde{\mathrm{H}}[N]$ and $\mathrm{D}[\epsilon]$ should be equal to a multiplier function P times the x-derivative of the integrand of $\mathrm{C}[Q]$:

$$\begin{aligned}
&\tilde{\mathrm{H}}[2PS'/L] + \mathrm{D}[2Pf_3(p_L)/(SL)]\\
&= \int_{-\infty}^{\infty} P\frac{\mathrm{d}}{\mathrm{d}x}\left(-\frac{f_1(p_L)}{S} + \frac{S(S')^2}{L^2} + \frac{1}{2}\int SV(S)\mathrm{d}S\right)\mathrm{d}x\\
&= \int_{-\infty}^{\infty} 2P\left(-\frac{p_L'}{2S}\frac{\mathrm{d}f_1}{\mathrm{d}p_L} + \frac{S'}{L}\left(\frac{Lf_1(p_L)}{2S^2} + \frac{(S')^2}{2L} + \frac{SS''}{L} - \frac{SS'L'}{L^2} + \frac{LSV(S)}{4}\right)\right)\mathrm{d}x.
\end{aligned} \tag{6.46}$$

The multiplier in $\mathrm{D}[M]$ used in this equation may have to be adjusted compared with classical case, as indicated by the function $f_3(p_L)$.

Solving this equation for $\tilde{\mathrm{H}}[N]$ (which, incidentally, requires $f_3(p_L) = \frac{1}{2}\mathrm{d}f_1/\mathrm{f}p_L = f_2(p_L)$), we find that it is exactly of the form (6.36) in which the consistency condition (6.38) has already been implemented. Computing the Poisson bracket $\{\tilde{\mathrm{H}}[N_1], \tilde{\mathrm{H}}[N_2]\}$ therefore must lead to the previous results, Equation (6.37), with the same modification function (6.40). In particular, modifying or quantizing the simplified constraint $\mathrm{C}[Q]$ implies the same kind of signature change as seen for the original Hamiltonian $\mathrm{H}[N]$ (Bojowald et al. 2015).

6.2.2 Effective Line Element

Implications of the modified bracket on spacetime structure can be seen directly if one reconstructs the form of line elements compatible with the modified transformations, using the methods of canonical gravity. Classically, any transformation generated by the constraints of hypersurface deformations,

$$\delta F = \{F, \mathrm{H}[\epsilon^0] + \mathrm{D}[\vec{\epsilon}]\}, \tag{6.47}$$

is equivalent to a derivative in the direction of a spacetime vector field with components ξ^α, where

$$\xi^0 = \frac{\epsilon^0}{N}, \quad \vec{\xi} = \epsilon^i - \frac{\vec{M}}{N}\epsilon^0 \tag{6.48}$$

using the background lapse and shift functions, N and $\vec{M}$, of the spacetime on which the derivative is performed. These relations merely rewrite the reference directions normal and tangential to spatial slices, used in ϵ^0 and $\vec{\epsilon}$, as coordinate directions:

$$\epsilon^0 n^\alpha + \epsilon^i s_i^\alpha = \frac{\epsilon^0}{N}t^\alpha + \left(\epsilon^i - \frac{N^i}{N}\epsilon^0\right)s_i^\alpha = \xi^0 t^\alpha + \xi^i s_i^\alpha. \tag{6.49}$$

A general coordinate transformation may also change the background functions N and $\vec{M}$, defined such that

$$\mathrm{d}s^2 = -N^2\mathrm{d}t^2 + \sum_{i=1}^{3}\sum_{j=1}^{3} q_{ij}(\mathrm{d}x^i + M^i\mathrm{d}t)(\mathrm{d}x^j + M^j\mathrm{d}t) \tag{6.50}$$

with the spatial metric q_{ij}. This behavior is important in the present context because it depends on the brackets of constraints and therefore changes if the brackets are modified. In general, if the brackets of constraints C_A are of the form

$$\{\mathrm{C}_A, \mathrm{C}_B\} = \sum_D F_{AB}^D \mathrm{C}_D \tag{6.51}$$

with suitable functions F_{AB}^D, a transformation of the metric should be combined with the transformation

$$\delta_\epsilon N^A = \frac{\partial \epsilon^A}{\partial t} + \sum_{BC} N^B \epsilon^C F_{BC}^A \tag{6.52}$$

of the background functions. (The notation here is somewhat formal, as the summations may include integrations over spatial coordinates.) This condition ensures that time evolution in the form of constrained Hamilton's equations,

$$\frac{\mathrm{d}F}{\mathrm{d}t} = \{F, \mathrm{H}[N] + \mathrm{D}[\vec{M}]\}, \tag{6.53}$$

is compatible with gauge transformations (Bojowald 2010).

For the brackets of classical canonical gravity, the general relation (6.51) implies

$$\delta_\epsilon N = \frac{\partial \epsilon^0}{\partial t} + \vec{\epsilon}\cdot\nabla N - \vec{M}\cdot\nabla\epsilon^0 \tag{6.54}$$

and

$$\delta_\epsilon \vec{M} = \frac{\partial \vec{\epsilon}}{\partial t} + (\vec{\epsilon} \cdot \nabla)\vec{M} - (\vec{M} \cdot \nabla)\vec{\epsilon} - \mathbf{q}^{-1}(N\nabla\epsilon^0 - \epsilon^0\nabla N), \tag{6.55}$$

where $\mathbf{q}^{-1}$ represents the inverse metric as a matrix with components q^{ij}. However, if the bracket (2.279) is modified, the latter relation should be changed to

$$\delta_\epsilon \vec{M} = \frac{\partial \vec{\epsilon}}{\partial t} + (\vec{\epsilon} \cdot \nabla)\vec{M} - (\vec{M} \cdot \nabla)\vec{\epsilon} - \beta\mathbf{q}^{-1}(N\nabla\epsilon^0 - \epsilon^0\nabla N). \tag{6.56}$$

The coefficients of the line element (6.50) therefore transform differently, in a way that no longer matches the coordinate transformations of $\mathrm{d}t$ and $\mathrm{d}x^i$. In order to obtain an invariant expression, the form (6.50) must be modified.

Still working with spherically symmetric models, we have two components, q_{xx} and $q_{\varphi\varphi}$, of the spatial metric in

$$\mathrm{d}s^2 = -N(x, t)^2\mathrm{d}t^2 + q_{xx}(x, t)(\mathrm{d}x + M(x, t)\mathrm{d}t)^2 + q_{\varphi\varphi}(x, t)(\mathrm{d}\vartheta^2 + \sin^2\vartheta\mathrm{d}\varphi^2). \tag{6.57}$$

If we apply a small coordinate transformation $t' = t + \xi^0$ and $x' = x + \xi^x$, where

$$\xi^0 = \frac{\epsilon^0}{N}, \quad \vec{\xi} = \vec{\epsilon} - \frac{\vec{M}}{N}\epsilon^0 \tag{6.58}$$

in terms of gauge parameters, the infinitesimal coordinate differences transform as

$$\begin{aligned}\mathrm{d}x' = \mathrm{d}(x + \epsilon^x - (N^x/N)\epsilon^0) = \mathrm{d}x + \frac{\partial(\epsilon^x - (M/N)\epsilon^0)}{\partial t}\mathrm{d}t \\ + \frac{\partial(\epsilon^x - (M/N)\epsilon^0)}{\partial x}\mathrm{d}x\end{aligned} \tag{6.59}$$

and

$$\mathrm{d}t' = \mathrm{d}(t + \epsilon^0/N) = \mathrm{d}t + \frac{\partial(\epsilon^0/N)}{\partial t}\mathrm{d}t + \frac{\partial(\epsilon^0/N)}{\partial x}\mathrm{d}x. \tag{6.60}$$

The derivation of these transformations is analogous to methods used in the construction of Bardeen variables in Section 1.4.2. Inserting these transformations in the line element, we obtain the corresponding change

$$\begin{aligned}\delta q_{xx} = \frac{\epsilon^0}{N}\frac{\partial q_{xx}}{\partial t} + \left(\epsilon^x - \frac{M}{N}\epsilon^0\right)\frac{\partial q_{xx}}{\partial x} + 2q_{xx}\frac{\partial}{\partial x}\left(\epsilon^x - \frac{M}{N}\epsilon^0\right) \\ + 2q_{xx}M\frac{\partial}{\partial x}\left(\frac{\epsilon^0}{N}\right)\end{aligned} \tag{6.61}$$

of the spatial metric, along with

$$\delta M = \frac{\partial \epsilon^x}{\partial t} + \epsilon^x\frac{\partial M}{\partial x} - M\frac{\partial \epsilon^x}{\partial x} - \frac{1}{q_{xx}}\left(N\frac{\partial \epsilon^0}{\partial x} - \epsilon^0\frac{\partial N}{\partial x}\right) \tag{6.62}$$

and

$$\delta N = \frac{\partial \epsilon^0}{\partial t} + \frac{\partial N}{\partial x}\epsilon^x - M\frac{\partial \epsilon^0}{\partial x}. \tag{6.63}$$

In particular, Equation (6.62) is not compatible with the transformation (6.56) that results from modified brackets.

Applying the same methods (Bojowald et al. 2018) shows that the modified bracket is compatible with standard coordinate changes of t and x in an effective line element

$$\begin{aligned} \mathrm{d}s^2 = &-\beta(t)N(x,\,t)^2\mathrm{d}t^2 + q_{xx}(x,\,t)(\mathrm{d}x + M(x,\,t)\mathrm{d}t)^2 + q_{\varphi\varphi}(x,\,t) \\ &(\mathrm{d}\vartheta^2 + \sin^2\vartheta\mathrm{d}\varphi^2), \end{aligned} \tag{6.64}$$

using the same function β as in Equation (2.279), and assuming that β depends only on time. (This assumption applies in situations of perturbative inhomogeneity, in which modifications β result only from the background dynamics. If the assumption is violated, it remains unknown whether a more general version of an effective line element still exists, or whether the spacetime structure is entirely non-Riemannian.) When the sign of β changes, it is now clear that we obtain a positive definite line element, as expected for four-dimensional space of Euclidean signature.

6.2.3 Implications of Signature Change

Signature change is an unexpected and counter-intuitive phenomenon. It is an implication not only of certain discrete spatial structures in a consistent spacetime (Bojowald & Paily 2012; Mielczarek 2014; Bojowald & Mielczarek 2015), but has also been found, in a variety of technical realizations, in minisuperspace models (Martin 1994), string theory (Perry & Teo 1993), matrix models (Chaney et al. 2015; Chaney & Stern 2017; Steinacker 2018; Stern & Xu 2018), and causal dynamical triangulations (Ambjørn et al. 2015). While signature change is possible also in classical solutions, in which case it has to be arranged by hand, patching together solutions of Lorentzian and Euclidean gravity along a hypersurface of zero extrinsic curvature, it is always singular in this case (Ellis et al. 1992; Hayward 1993; Dray et al. 1995; Alty & Fewster 1996; Dray et al. 1997). Modified spacetime structures, by contrast, allow for non-singular signature change, for instance when the function β in Equation (2.279) smoothly goes through zero.

In the present context, setting aside details of signature change, the general outcome that a non-classical geometrical structure is realized when the quadratic classical curvature dependence of the Hamiltonian is replaced by a non-quadratic function, evades the slicing problem observed in Section 6.1.2: It is possible to have non-quadratic modifications in a covariant theory, but the covariance relations implied by closed Poisson brackets of the constraints are modified and do not correspond to classical general covariance. The corresponding non-classical spacetime structure is not compatible with the usual form of slicing independence, which is why we obtained a contradiction in Section 6.1.2. Slicing independence is obtained only after transforming to a new effective line element such as Equation (6.64), if one exists. However, the precise transformation remains unknown in the general situation in which the spacetime dependence of β is not only through time.

Conceptually, signature change also helps to explain why models of loop quantum cosmology can be non-singular with standard matter sources, even though they do not violate the usual energy conditions applied in singularity theorems of general relativity. Holonomy modifications in loop quantum cosmology do modify the equations of motion, but the most general singularity theorems are insensitive to the specific dynamics of general relativity and only use broadly applicable geometrical properties such as the geodesic deviation equation. It is therefore not obvious how precisely loop quantum cosmology may be able to evade these theorems.

Signature change presents one possible answer to this question, the only one known so far. In this view, the mathematical outcome of singularity theorems remains unchanged, as it should. These theorems show that, given certain assumptions on initial conditions such as the existence of universal expansion or the presence of trapped surfaces, timelike geodesics cannot last for an infinite amount of time. In the usual spacetime interpretation, this mathematical result is taken to show that spacetime has a boundary at some finite time in the past or future beyond which general relativity does not provide an extension. This finite boundary presents a singularity, not necessarily in terms of diverging densities or curvatures, but as a limitation of the spacetime description derived from the theory.

Signature change solves the singularity problem almost by cutting the Gordian knot; it removes the conceptual problem posed by the required inextendability of timelike geodesics by removing time itself: The assumptions and the outcome of singularity theorems remain mathematically valid, but timelike geodesics end just because time exists only in a limited region within a large universe subject to signature change. As a manifold, the universe does have an extension beyond the point where timelike geodesics end, but only in a four-dimensional spacelike manner. This extended universe is still geometrical, but the geometry is not Riemannian throughout. Only in certain subregions, might an effective line element exist which can map the geometry restricted to such regions to Riemannian form. With this generalized interpretation, singularity theorems do not imply boundaries to the whole manifold of the universe. However, there are still boundaries to causal behavior because there is no deterministic evolution through a region with Euclidean signature.

In particular, a well-posed system of partial differential equations in a geometry with signature change requires some final conditions and cannot be obtained purely as an initial-value problem. This general conclusion follows from the fact that a Euclidean-signature metric implies elliptic partial differential equations for test fields, rather than hyperbolic wave equations. The same general outcome can be seen also in the context of geodesics. If we assume that an effective line element of the form (6.64) can be used (as is the case for instance in the Schwarzschild interior), its time-time component approaches zero in a region where $\beta \to 0$, close to signature change. All light cones in such a region, determined as usual by the condition

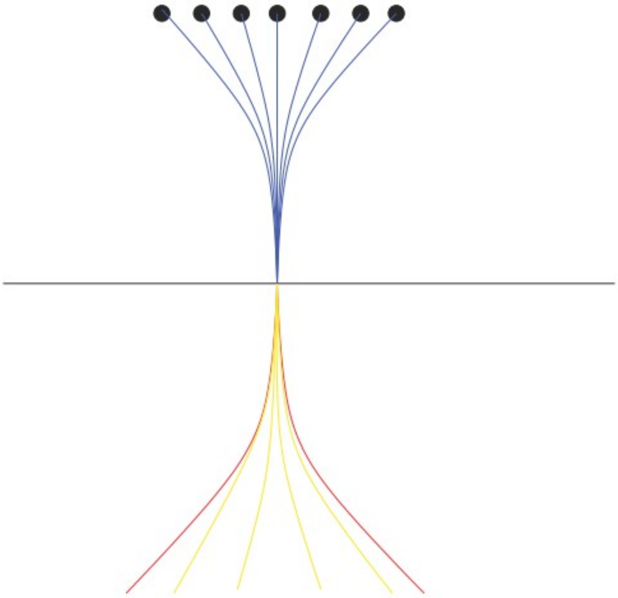

Figure 6.3. Illustration of a family of geodesics in a geometry with signature change, such that Lorentzian signature is realized in the bottom half and Euclidean signature in the top half. In the Lorentzian region, light cones (red) exist but collapse to a unique direction at the transition hypersurface. All timelike geodesics (yellow) therefore approach the same direction. Similarly, all spacelike geodesics in the Euclidean region that approach the tip of the red light cone on the transition hypersurface approach this point in the same asymptotic direction. Any blue spacelike geodesic could therefore be used to extend a given yellow timelike geodesic in a differentiable manner. Unique extensions of timelike geodesics into the Euclidean region as spacelike geodesics (blue) are possible only if a second endpoint is specified (black circles), selecting a specific blue geodesic. The required final position amounts to future data required for a well-posed problem.

$\mathrm{d}s^2 = 0$, have tiny spatial extensions which collapse to zero at $\beta = 0$. Therefore, all timelike geodesics (as well as lightlike ones) approach a unique direction at the hypersurface of signature change, as shown in Figure 6.3.

There are no light cones in the Euclidean region, but an analysis of the geodesic equation shows that also there, geodesics that approach the hypersurface of signature change do so along the normal direction asymptotically close to the hypersurface. Intuitively, this happens because geodesics in a space of Euclidean signature have the shortest distance among all curves connecting two different points. If t is a coordinate normal to the hypersurface of signature change (using the usual letter for the time coordinate even when there is no time in the Euclidean region), the metric component g_{tt} goes through zero where signature change takes place. Therefore, the line element in the Euclidean region is the smallest in the direction of t, which is the direction that geodesics have to follow.

We demonstrate this property formally in two dimensions, using a general line element

$$\mathrm{d}s^2 = th_1(t,\, x)\mathrm{d}t^2 + 2\sqrt{|t|}\, h_2(t,\, x)\mathrm{d}t\mathrm{d}x + g_{xx}(t,\, x)\mathrm{d}x^2 \tag{6.65}$$

with positive coefficients $h_1 > 0$ and $g_{xx} > 0$, such that $d := h_1 g_{xx} - h_2^2 > 0$. Therefore,

$$\det g = th_1 g_{xx} - |t|h_2^2 = -|t|(h_1 g_{xx} + h_2^2) = -|t|(d + 2h_2^2) < 0 \tag{6.66}$$

for $t < 0$ (the Lorentzian region) while

$$\det g = th_1 g_{xx} - th_2^2 = t(h_1 g_{xx} - h_2^2) > 0 \tag{6.67}$$

for $t > 0$ (the Euclidean region).

Along spacelike or timelike worldlines, we have

$$\frac{\mathrm{d}s^2}{\mathrm{d}\lambda^2} = th_1\left(\frac{\mathrm{d}t}{\mathrm{d}\lambda}\right)^2 + 2\sqrt{|t|}\, h_2 \frac{\mathrm{d}t}{\mathrm{d}\lambda}\frac{\mathrm{d}x}{\mathrm{d}\lambda} + g_{xx}\left(\frac{\mathrm{d}x}{\mathrm{d}\lambda}\right)^2 = \pm 1 \tag{6.68}$$

with the upper sign for $t > 0$ (spacelike worldlines in the Euclidean region, where the curve parameter λ is then proper distance) and the lower sign for $t < 0$ (timelike worldlines in the Lorentzian region, where λ is then proper time). Thus, near $t = 0$ the component $\mathrm{d}t/\mathrm{d}\lambda$ of the tangent vector dominates because the equation can be solved for

$$\begin{aligned}\frac{\mathrm{d}t}{\mathrm{d}\lambda} &= -\frac{1}{\sqrt{|t|}\, h_1}\left(\mathrm{sgn}(t) h_2 \frac{\mathrm{d}x}{\mathrm{d}\lambda} \pm \sqrt{(h_2^2 - \mathrm{sgn}(t) h_1 g_{xx})\left(\frac{\mathrm{d}x}{\mathrm{d}\lambda}\right)^2 \pm \mathrm{sgn}(t) h_1}\right)\\ &= O(|t|^{-1/2})\end{aligned} \tag{6.69}$$

in terms of $\mathrm{d}x/\mathrm{d}\lambda = O(1)$. The dominant contributions to the geodesic equation are then

$$\frac{\mathrm{d}^2 t}{\mathrm{d}\lambda^2} \sim -\frac{1}{2t}\left(\frac{\mathrm{d}t}{\mathrm{d}\lambda}\right)^2 (1 + O(t)), \quad \frac{\mathrm{d}^2 x}{\mathrm{d}\lambda^2} \sim \left(\frac{\mathrm{d}t}{\mathrm{d}\lambda}\right)^2 O(\sqrt{|t|}). \tag{6.70}$$

Therefore, $x(\lambda)$ is approximately constant, while the first equation, written as

$$0 \sim 2t\frac{\mathrm{d}^2 t}{\mathrm{d}\lambda^2} + \left(\frac{\mathrm{d}t}{\mathrm{d}\lambda}\right)^2 = 2\sqrt{|t|}\,\mathrm{sgn}(t)\frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\sqrt{|t|}\,\frac{\mathrm{d}t}{\mathrm{d}\lambda}\right) \tag{6.71}$$

implies that $\sqrt{|t|}\,\mathrm{d}t/\mathrm{d}\lambda$ is approximately constant. Along geodesics, the slope

$$\frac{\mathrm{d}t}{\mathrm{d}x} = \frac{\mathrm{d}t/\mathrm{d}\lambda}{\mathrm{d}x/\mathrm{d}\lambda} \sim \frac{\mathrm{const}}{\sqrt{|t|}} \tag{6.72}$$

therefore approaches infinity near $t = 0$ in both the Lorentzian and the Euclidean region, as shown in Figure 6.3.

No timelike geodesics exist in the Euclidean region, but we can try to extend a given timelike geodesic arriving at the hypersurface of signature change from the Lorentzian side as a spacelike geodesic extending into the Euclidean region.

However, because all timelike geodesics arriving at a given point on the hypersurface of signature change do so in the same direction, the extension cannot be unique. In addition to specifying initial values to determine which timelike geodesic we are interested in, we have to specify future conditions in the Euclidean region in order to determine an extension by a spacelike geodesic. Because future conditions are required, evolution cannot be deterministic.

The relevant geometry therefore implies a mixture of different, previously irreconcilable scenarios for the interior of black holes. Since quantum modifications are used in the dynamics, it may be possible that the interior does not reach infinite curvature or density of collapsing matter but rather bounces or extends otherwise through the classical singularity. However, interpreted in the corresponding spacetime structure, this transition is not deterministic and requires future data. This latter feature is reminiscent of proposals that tried to address the singularity problem in black hole models by imposing a future condition for wave functions at the singularity (Horowitz & Maldacena 2004; Bouhmadi-López et al. 2019), as some kind of generalization of DeWitt's condition in cosmological models.

Although there is a consistent realization of spacetime in such models, their analysis remains difficult (Bojowald 2015; Ben Achour et al. 2018a, 2018b; Aruga et al. 2019). In particular, the question of how a non-singular interior might be connected to an exterior spacetime, opening up into the original universe or splitting off into a baby universe, remains open. In order to address this question one would like to have access to an effective line element, but β cannot be just time dependent in the exterior as required for Equation (6.64). The non-Riemannian geometry in the exterior therefore remains hard to address.

6.2.4 Perturbative Inhomogeneity

Deformed hypersurface-deformation brackets have been found also for perturbative inhomogeneity in cosmological models (Bojowald et al. 2008; Cailleteau et al. 2012, 2014; Cuttell & Sakellariadou 2014; Cuttell 2019), in a form very similar to those in spherically symmetric models (Barrau et al. 2015). In particular, there is a multiplier β as in Equation (6.30) which becomes negative at Planckian curvature, indicating signature change.

Equations of motion for matter fields, such as a scalar in models of inflation, are relevant in cosmology. These are partial differential equations of a type that depends on the signature of spacetime—hyperbolic in Lorentzian signature and elliptic in Euclidean signature. The conclusion that this behavior is directly related to the sign of β can be obtained from a reconstruction of consistent equations of motion from the (deformed) brackets, following the methods of Kuchař (1976a, 1976b, 1976c).

It is now convenient to Legendre transform the brackets for Hamiltonians, such as $\mathrm{H}(\phi, p_\phi)$ for a scalar field ϕ with momentum p_ϕ, to Lagrangian form, introducing the "velocity" $v(x) = \partial \mathrm{H}/\partial p_\phi(x) = \{\phi, \mathrm{H}[N]\}/N$. The Lagrangian (density) is then defined as $\mathrm{L} = p_\phi v - \mathrm{H}$, such that

$$\left.\frac{\partial \mathrm{H}}{\partial \phi}\right|_{p_\phi \text{ constant}} = -\left.\frac{\partial \mathrm{L}}{\partial \phi}\right|_{v \text{ constant}} \tag{6.73}$$

and

$$p_\phi(x) = \frac{\partial \mathrm{L}}{\partial v(x)}. \tag{6.74}$$

The bracket of two smeared Hamiltonian constraints then equals

$$\{\mathrm{H}[N], \mathrm{H}[M]\} = \int \mathrm{d}^3x \int \mathrm{d}^3y N(y) \frac{\delta \mathrm{H}(y)}{\delta \phi(x)} v(x) M(x) - (N \leftrightarrow M) \tag{6.75}$$

$$= -\int \mathrm{d}^3x \int \mathrm{d}^3y \frac{\delta \mathrm{L}(y)}{\delta \phi(x)} v(x) N(y) M(x) - (N \leftrightarrow M) \tag{6.76}$$

$$= \mathrm{D}[\beta(N\nabla M - M\nabla N)], \tag{6.77}$$

introducing the diffeomorphism constraint $\mathrm{D}[\vec{\epsilon}] = \int \vec{\epsilon} \cdot p_\phi \nabla \phi \mathrm{d}^3x$ in the last step, where we assume brackets of the form (2.279). Comparing the last two lines,

$$\frac{\delta \mathrm{L}(x)}{\delta \phi(x')} v(x') + \beta(x) \vec{\mathrm{D}}(x) \cdot \nabla_x \delta(x, x') - (x \leftrightarrow x') = 0 \tag{6.78}$$

where $\vec{\mathrm{D}}(x) = p_\phi(x) \nabla \phi(x)$.

Using the standard geometrical structure of space, the Lagrangian density must be of the form $\mathcal{L} = \sqrt{\det q}\ \mathrm{L}(\phi, v, \psi)$ with a Lagrange function L that can depend pointwise on ϕ, its velocity v normal to spatial slices, and the rotationally invariant combination

$$\psi = \sum_{i=1}^{3} \sum_{j=1}^{3} q^{ij} \frac{\partial \phi}{\partial x^i} \frac{\partial \phi}{\partial x^j} \tag{6.79}$$

of spatial derivatives. Comparing coefficients of $\nabla \phi$ in Equation (6.78), after an application of the chain rule

$$\frac{\delta \mathrm{L}(x)}{\delta \phi(x')} = \frac{\partial \mathrm{L}(x)}{\partial \phi(x)} \frac{\delta \phi(x)}{\delta \phi(x')} + 2 \frac{\partial \mathrm{L}(x)}{\partial \psi(x)} \nabla \phi(x) \cdot \nabla \delta(x, x'), \tag{6.80}$$

implies

$$\beta p_\phi + 2v \frac{\partial \mathrm{L}}{\partial \psi} = \beta \frac{\partial \mathrm{L}}{\partial v} + 2v \frac{\partial \mathrm{L}}{\partial \psi} = 0. \tag{6.81}$$

Therefore, L must be of the form $\mathrm{L}(\phi, \psi - v^2/\beta)$.

%9 7' ' '

For $\beta > 0$, the combination $\psi - v^2/\beta$ has coefficients of opposite signs in its spatial and temporal derivatives, respectively, implying hyperbolic equations of motion from any Lagrangian consistent with a bracket (2.279). For $\beta < 0$, by contrast, spatial and temporal derivatives enter the Lagrangian with equal signs (as in Euclidean field theory) and imply elliptic partial differential equations for the field.

If β changes its sign dynamically, for instance if it depends on a varying curvature scale as in Equation (6.40), we have a mixed-type problem of partial differential equations that requires a combination of initial values and final values. For instance, a free scalar field on a cosmological background with Hubble parameter H might be subject to the mixed-type wave equation

$$-\frac{\partial^2\phi}{\partial t^2} + \beta(H)\Delta\phi = 0 \tag{6.82}$$

(using the spatial Laplacian Δ) if spacetime is modified, with hypersurface deformations according to Equation (2.279).

A well-posed formulation, introduced by Tricomi (1968) and shown in two dimensions in Figure 6.4; imposes initial values on a single light ray C, or half the usual characteristic problem. Where the light ray approaches the hypersurface of signature change, it is smoothly connected to an arc A in the Euclidean region. If the arc reaches all the way to the end of a second light ray C' starting at the same event as C but moving in the opposite direction, the problem is well-posed: For smooth data of ϕ (but none of its derivatives) on the union $C \cup A$, there is a unique and smooth solution in the region bounded by C, A and C' which depends stably on the data. (Had one tried to evolve usual initial data into the Euclidean region, there might still be a unique solution but it would not depend stably on the data.)

Notice, however, that solutions generically have a root-like pole at the far end of A where it touches C'. This “cosmic boom” is an analog of the sonic boom in hydrodynamics which can be described by similar mixed-type equations. It implies that even small perturbations may lead to solutions with large derivatives. Even if one can extend a metric into the Euclidean region, there may therefore be curvature divergences. In contrast to the standard Big Bang singularity, such divergences would be located at isolated points rather than on an entire spatial slice. As in hydrodynamics, they would be singularities of the effective spacetime description while the underlying fundamental theory, given by a consistent set of canonical constraints $\mathrm{H}[N]$ and $\mathrm{D}[M]$, would be non-singular. Nevertheless, such singularities in an effective cosmological description complicate any physical analysis based on perturbative inhomogeneity.

These examples show that spacetime properties in models of quantum cosmology can be rather counter-intuitive. An analysis of possible evolution at large curvature therefore requires great care and good control on mathematical conditions such as the treatment of well-posed initial-boundary problems that are not required classically. None of these features could have been found had one stayed at a restricted level of minisuperspace models, or perturbations on minisuperspaces.

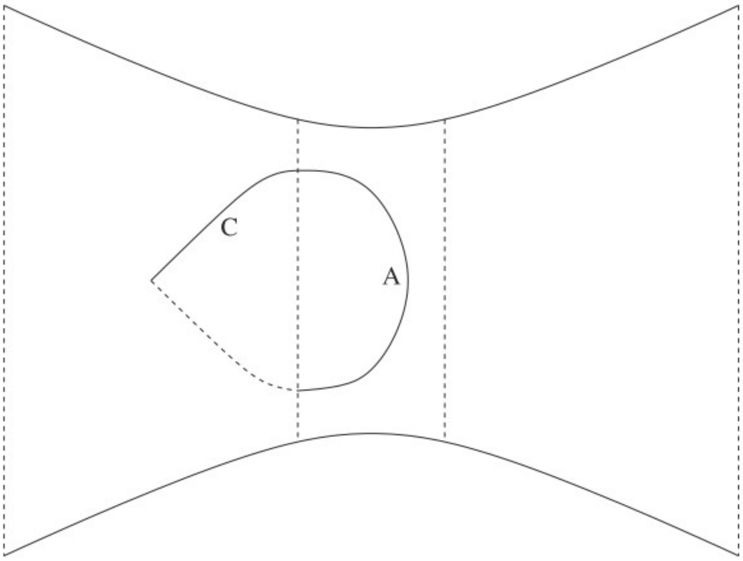

Figure 6.4. The two-dimensional Tricomi problem on a bouncing cosmological background. Initial data are posed on one light ray C in the Lorentzian region, smoothly connected to an arc A in the Euclidean region that ends at the endpoint of the second light ray starting at the same event as C.

6.3 Cosmology at Large Curvature

There are (at least) two general reasons why perturbative inhomogeneity cannot be sufficient to describe quantum spacetime very close to the Big Bang.

First, if we consider a contracting universe in order to understand the approach to a spacelike singularity, either in a potential pre-bounce universe or in backward evolution of our expanding universe, enhanced gravitational collapse in a dense universe implies large inhomogeneity. For instance, black hole formation is expected to happen frequently when the matter distribution gets confined to smaller and smaller space. And when we approach the Planck density, which after all equals more than one trillion solar masses in a proton-sized region, it is hard to imagine how further collapse could keep macroscopic regions at a sufficiently homogeneous distribution for perturbation theory to remain available. If we use perturbative inhomogeneity around a minisuperspace model in order to study the approach to a spacelike singularity, we therefore have to keep adjusting the size V_0 of homogeneous regions used to set up the minisuperspace model by a process of infrared renormalization (Bojowald 2019). This process must end when we reach Planckian size, at which time the infrared scale V_0 would merge with the ultraviolet.

Second, if inflation took place in the early universe, it can be consistent with observations only if it lasted for a sufficiently long time, stretching space by 60 e-folds, or a factor of at least $e^{60} = 1.14 \times 10^{26}$. Moreover, inflation must happen sufficiently early on in the history of the universe because high-energy processes of matter formation, such as baryogenesis, are still to take place after inflation ends.

%9 : 3 ' &

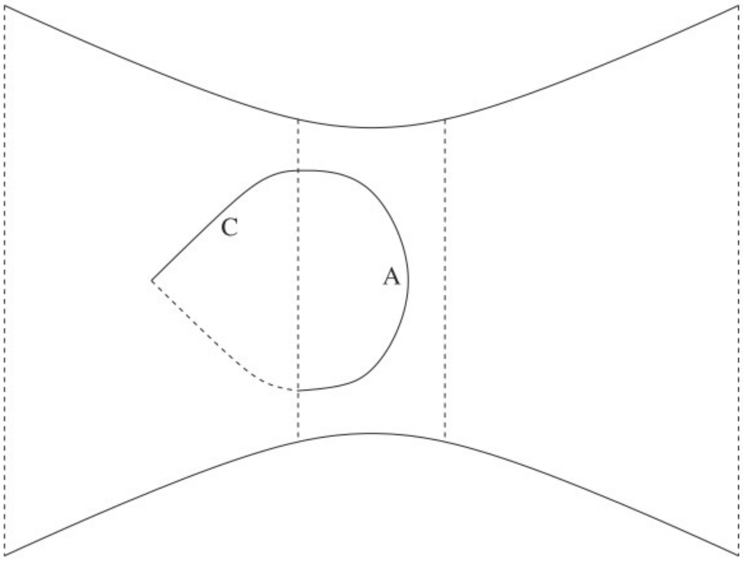

Figure 6.4. The two-dimensional Tricomi problem on a bouncing cosmological background. Initial data are posed on one light ray *C* in the Lorentzian region, smoothly connected to an arc *A* in the Euclidean region that ends at the endpoint of the second light ray starting at the same event as *C*.

6.3 Cosmology at Large Curvature

There are (at least) two general reasons why perturbative inhomogeneity cannot be sufficient to describe quantum spacetime very close to the Big Bang.

First, if we consider a contracting universe in order to understand the approach to a spacelike singularity, either in a potential pre-bounce universe or in backward evolution of our expanding universe, enhanced gravitational collapse in a dense universe implies large inhomogeneity. For instance, black hole formation is expected to happen frequently when the matter distribution gets confined to smaller and smaller space. And when we approach the Planck density, which after all equals more than one trillion solar masses in a proton-sized region, it is hard to imagine how further collapse could keep macroscopic regions at a sufficiently homogeneous distribution for perturbation theory to remain available. If we use perturbative inhomogeneity around a minisuperspace model in order to study the approach to a spacelike singularity, we therefore have to keep adjusting the size V_0 of homogeneous regions used to set up the minisuperspace model by a process of infrared renormalization (Bojowald 2019). This process must end when we reach Planckian size, at which time the infrared scale V_0 would merge with the ultraviolet.

Second, if inflation took place in the early universe, it can be consistent with observations only if it lasted for a sufficiently long time, stretching space by 60 *e*-folds, or a factor of at least $e^{60} = 1.14 \times 10^{26}$. Moreover, inflation must happen sufficiently early on in the history of the universe because high-energy processes of matter formation, such as baryogenesis, are still to take place after inflation ends.

While it is possible to construct inflation models in which these two conditions are met and the Planck scale is avoided even at the beginning of inflation, inflation is an inherently unstable process which is not always easy to stop once it gets started. Without fine-tuned initial conditions, inflation generically lasts longer than 60 *e*-folds, and if it overshoots this target by only about ten *e*-folds, some modes of inhomogeneity that are relevant for current observations of the cosmic microwave background would have had a wave length less than the Planck length at the beginning of inflation. It might still be possible to describe these modes as perturbative ones, but their equations of motion would be subject to quantum spacetime effects that, in general, require a derivation beyond perturbation theory. This *trans-Planckian problem* shows that the inflation scenario can be used to constrain models of quantum cosmology and the underlying approaches to quantum gravity (Martin & Brandenberger 2001; Brandenberger & Martin 2001; Niemeyer 2001; Bedroya & Vafa 2019; Bedroya et al. 2020).

6.3.1 Infrared Renormalization

Considering a collapsing universe, the BKL scenario, described in Section 1.6, suggests a new role for homogeneous dynamics asymptotically close to a spacelike singularity. Even if collapse has led to structure formation on all length scales, the dynamics at each spatial point in this scenario resembles the dynamics of a spatially homogeneous cosmological model.

However, this reference to homogeneity is local and does not imply that the entire space of a minisuperspace model is obtained. If we approach high curvature in forward or backward evolution, we may use homogeneous models, perhaps combined with perturbative inhomogeneity, but the size of regions described by such an approximation must progressively be reduced in order to keep track of gravitational collapse. If we fix a spatial coordinate system at some initial time, a useful parameter to describe this process is the coordinate volume of the region in which perturbative inhomogeneity is admissible as an approximation. Any modes that stretch over distances greater than $\sqrt[3]{V_0}$ must be described by non-perturbative inhomogeneity, or by a full theory of quantum gravity; see Figure 6.5.

As the comoving scale of inhomogeneity decreases, the value of V_0 should be reduced progressively, in a process of infrared renormalization described in Section 4.1.3. This process cannot be performed in a traditional minisuperspace model which works with a fixed set of operators and wave functions in which V_0 (appearing in the basic commutators) cannot be varied. Infrared renormalization therefore requires a new kind of effective theory in quantum cosmology, for instance based on algebraic equations with running V_0. Additional parameters that are usually believed to be constants in minisuperspace models, such as the magnitude of holonomy modifications in loop quantum cosmology given by p_0 in Equation (4.57), run along with V_0 and can therefore show different behaviors in low and high curvature regimes.

Also quantum corrections generically depend on V_0. This behavior initially seems puzzling in minisuperspace models because V_0 refers to the coordinate size of an

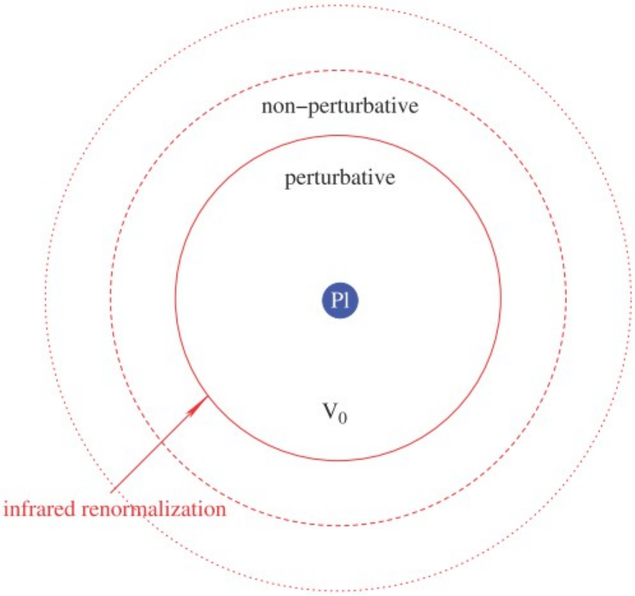

Figure 6.5. Infrared renormalization reduces the size V_0 of any region in which perturbative inhomogeneity can be used, tracking the scale of gravitational collapse in an approach to high curvature (red circles). A lower limit for the size is set by the Planck scale (blue circle).

arbitrary averaging region used to define homogeneous variables. And even if spatial coordinates have been fixed, the averaging region may be changed without affecting the classical dynamics. In classical cosmology, there is no obvious physical process that corresponds to changing V_0, suggesting that observables or their quantum corrections should be independent of V_0. However, quantum corrections generically depend on V_0 because it appears in the basic variables, in particular $V = V_0 a^3$, that define a quantum minisuperspace model. Uncertainty relations, such as

$$\Delta_\omega V \Delta_\omega H \geqslant \frac{2\pi G\hbar}{c^2} = 2\pi c \ell_{\mathrm{Pl}}^2 \tag{6.83}$$

in a state ω, based on the momentum $p_V = -Hc^2/(4\pi G)$ of V according to Equation (1.16), by contrast, impose a lower bound given by fundamental parameters. Numerator and denominator in unitless relative fluctuations, $V^{-1}\Delta_\omega V$, must therefore depend differently on V_0 because the classical scaling, $V \propto V_0$ and H independent of V_0 realized for expectation values $\omega(\hat{V})\ \omega_\omega(\hat{H})$, cannot be applied to volume fluctuations, $\Delta_\omega V$ together with $\Delta_\omega H$, without violating the uncertainty bound.

If V_0 is macroscopic, which is a valid assumption at late times given large-scale homogeneity, relative volume fluctuations can be miniscule, implying largely classical behavior. For microscopic V_0, by contrast, large relative fluctuations and significant quantum effects are expected. Importantly, even the tiny Planckian value on the right-hand side of Equation (6.83) does not imply that fluctuation terms can always be ignored because the BKL scenario is asymptotic and does not provide any lower bound on the size of regions in which homogeneity may be assumed, close to a spacelike singularity.

From a more general perspective that includes the build-up of inhomogeneity, the value of V_0 does have physical meaning once spatial coordinates have been fixed. The time dependence of V_0 describes the varying scale of inhomogeneity, limiting the size of regions in which minisuperspace models can be used. If a quantum version of the BKL scenario is available, local quantum effects should depend only on the volume of the typical regions that may be considered homogeneous at any given time, but not on back-reaction effects from inhomogeneous modes on scales greater than $\sqrt[3]{V_0}$. The initially puzzling dependence of quantum corrections on V_0, seen in Section 4.1, therefore models the quantum interactions (or their absence) between different modes. As V_0 shrinks in a BKL-type scenario, more modes are pushed into the full inhomogeneous region and therefore, by the BKL assumption, no longer interact significantly with the homogeneous center.

A valid version of numerical quantum cosmology should include infrared renormalization by combining homogeneous or perturbative quantum cosmological models in the interior region of Figure 6.5 with numerical relativity in the exterior in order to track the scale of inhomogeneity. One would have to extract the typical value of V_0 from the exterior simulation and feed it into the running scale of the interior. At high curvature, a full exterior simulation of quantum gravity would have to be used. The complexity of such simulations has so far prevented detailed implementations. The approach to a spacelike singularity in minisuperspace-based quantum cosmology therefore remains unclear. This caveat applies in particular to bounce claims made in loop quantum cosmology.

The process of infrared renormalization, adjusting V_0 to the infrared scale of inhomogeneity, is valid as long as curvature does not grow too much. At Planckian curvature, the infrared scale V_0 of a minisuperspace or perturbed model is pushed into the ultraviolet, indicating the breakdown of the minisuperspace perspective even if a quantum version of the BKL scenario may be realized. At this scale, quantum cosmology in all its versions necessarily becomes highly speculative.

6.3.2 The Trans-Planckian Problem

The necessity of infrared renormalization implies that minisuperspace models, on their own, cannot provide a full picture of spacetime at large curvature. Such models eventually break down in an approach to a spacelike singularity because the infrared scale on which they are based will have to be pushed into the ultraviolet in order to maintain an approximation of spacetime by an evolving homogeneous region.

The inflation scenario, described in Section 1.4.4, implies the opposite transition, from ultraviolet to infrared, because modes with short, Planckian wavelength are physically expanded by a large factor in expanding spacetime, and may become relevant for late-time observations of the cosmic microwave background long after inflation has ended. The trans-Planckian problem (Martin & Brandenberger 2001; Brandenberger & Martin 2001; Niemeyer 2001) or, in a stronger version, the trans-Planckian censorship conjecture (Bedroya & Vafa 2019; Bedroya et al. 2020) states that such modes should in consistent inflation models be prevented from becoming relevant at late times, given the (at least at present) uncontrolled nature of strong quantum-gravity effects.

A prominent example of modifications that may be required if quantum gravity becomes necessary in early stages of inflationary structure formation is given by non-classical dispersion relations, which would change relationships such as Equation (1.90) that involve the frequency of inhomogeneous modes for a given wave number. The classical continuum relationship could, for instance, be affected by discrete spacetime (much like dispersion effects implied by solid-state structures), fractal dimensions as derived from causal dynamical triangulations (Mielczarek 2017), higher-curvature terms in covariant actions or in Hořava–Lifshitz gravity (2.143), or by modified spacetime structures in canonical descriptions based on Equation (2.279). In addition to the dynamics, quantum spacetime effects could also change the form of the inflaton ground state, and therefore alter the amplitude (1.91) which in the standard treatment appears directly in the power spectrum (1.98).

The trans-Planckian problem is based on the fact that approximation methods used to study quantum field theory in inflation models cannot be applied with a fixed scale. (This feature is conceptually similar to infrared renormalization.) The rapidly expanding background drags along modes of perturbative inhomogeneity. When the wave length of these modes gets very large, the mode simply follows the expansion of space and stops evolving on its own, as described by the Mukhanov–Sasaki Equation (1.88), until much later when the expansion is no longer inflationary. While such an evolution can well be described semiclassically, a full quantum treatment with varying numbers of evolving degrees of freedom is challenging (Weiss 1985). It would, however, be required if full quantum gravity becomes relevant for some of the modes. As seen in the context of infrared renormalization, minisuperspace-based models are therefore insufficient once Planck-scale physics enters the equations.

6.3.3 Speculative Proposals

Potential properties of various approaches to quantum gravity have been used in myriad ways to suggest new ingredients for the standard Big Bang model. The main targets of such attempts are a non-singular description of the Big Bang singularity of general relativity, and alternatives or modifications of the inflation scenario of structure formation.

Another dichotomy exists between the origin of proposals from a background-independent or background-dependent theory, respectively. From a technical viewpoint, background-dependent approaches are more suitable for cosmological phenomenology because one can directly apply quantum effects to background spacetimes relevant for cosmology. The derivation of such effects for non-static backgrounds may not always be as direct as for static backgrounds, but in phenomenological investigations it is often possible to test possible non-static generalizations of known effects in static backgrounds. Some examples, mainly from string theory, will be given below. For a comprehensive exposition, see Calcagni (2017).

Background-independent Approaches

In background-independent approaches, by contrast, one must first show that it is even possible to have any states that in some approximation may be considered continuum background spacetimes. This problem is often challenging, making it all the more difficult to extend quantum effects to cosmologically relevant spacetimes. As described in Section 5.2.3, the only non-perturbative approach in which suitable cosmological backgrounds have been shown to exist is given by causal dynamical triangulations. But the task of working out cosmological scenarios remains challenging even in this approach.

Loop quantum gravity is probably unique among non-perturbative approaches in that a large number of cosmological applications has been published in this field, mainly in the context of loop quantum cosmology. Initially, loop quantum cosmology drew interest after it was shown in minisuperspace models that the Big Bang singularity may be resolved because wave functions can be extended uniquely across zero scale factor (Bojowald 2001). Since then, however, it has been difficult to extend derivations of cosmological implications beyond the minisuperspace level. Many studies have worked with combinations of minisuperspace models and perturbative inhomogeneity that were only later found to violate covariance; see Section 6.2.4. The application of minisuperspace models helps one to avoid the main difficulties of background-independent approaches because the assumption of spatial homogeneity implies a rather strong background structure, even if it does not completely determine the metric. The over-reliance on minisuperspace models in cosmological applications of loop quantum gravity therefore means that the background-independent nature that characterizes this approach has not yet been tested.

An application of strict minisuperspace models or perturbations also makes it impossible to implement infrared renormalization and to address the trans-Planckian problem, as already discussed in this section. In fact, most claims made in loop quantum cosmology are based on models that fail to implement basic properties of effective field theory (Bojowald 2019, 2020), such as the necessity of scale-dependent coupling parameters (or quantum corrections) because different energy scales usually activate different numbers of relevant degrees of freedom. Most derivations in loop quantum cosmology assume that a single effective theory without running parameters can (or even has to) be used at late times and at very early times (or well outside and deep inside black holes). Because of challenges in deriving such parameters from a full background-independent theory, such an assumption is completely unsupported, but it easily affects potential outcomes. While many very specific claims have been made in loop quantum cosmology, they are hardly reliable. Only qualitative features can at best be taken as a possible indication as to how high curvature might be approached in this framework (Bojowald 2015, 2020). The sensitivity to quantization ambiguities in this approach has already been discussed in Section 4.3.4.

There has been some interest in minisuperspace models in loop quantum cosmology because proposed modifications, such as the application of holonomy terms in Equation (4.57), can be rather drastic compared with the equations of general relativity. Such strong effects are necessary if one attempts to evade the conclusion, based on considerations of units, that quantum-gravity effects in observational cosmology should be suppressed by tiny factors given by the ratios of relevant scales: the Planck length divided by the typical length scale that appears in the physics of the cosmic microwave background. (Such dimensional expectations are also borne out in detail in canonical quantum gravity without loop modifications; Pinho & Pinto-Neto 2007; Falciano & Pinto-Neto 2009; Kiefer & Kraemer 2012.) However, the same effects that could imply significant implications in power spectra also have unexpected consequences in spacetime structures consistent with the underlying modifications, as shown in Section 6.2. In this context, we see a crucial implication of a background-independent approach: Since such an approach does not assume what spacetime structure it might realize, derivations of spacetime structures can potentially lead to counter-intuitive effects. These effects still remain to be understood in loop quantum gravity.

Background-dependent Approaches

Compared with general relativity coupled to standard matter ingredients, string theory provides many additional structures related to extra dimensions with non-trivial topology and supersymmetry that can be used to construct various new ingredients for cosmological phenomenology. In most cases, the same fields and interactions could be postulated as exotic matter terms in general relativity, but additional motivation from string theory can often provide additional support.

As usual with string theory, one of the main difficulties is to find suitable ingredients in the hay stack of degrees of freedom provided by compactified extra dimensions and supersymmetry. Once suitable ingredients have been identified, one must then show that they are stable with respect to cosmological dynamics. For instance, winding modes around compact extra dimensions are usually massive and, just based on the available energy, could therefore decay into lighter excitations such as momentum modes. Demonstrating stability or at least metastability requires an understanding of string interactions in a non-static background, which is often hard to achieve with some degree of rigor.

In this phenomenological spirit, string theory has made contributions to the two main branches of early-universe cosmology: identifying ingredients that can support inflation, and suggesting alternative scenarios that do not rely on inflation but can nevertheless explain observed properties of the nearly scale-free density power spectrum.

Inflation in String Theory: For reasons related to the presence of supersymmetry, string theory does not provide an obvious way to include a positive cosmological constant, or a field with a slightly varying positive potential that could play the role of an inflaton. Nevertheless, as shown in Kachru et al. (2003), it may be possible to do so with flux compactifications, given by higher-dimensional objects made out of interacting strings and winding around compact extra dimensions. In this context, one can address some of the stability questions to make it conceivable that this kind of inflation can last sufficiently long.

Another example, so-called Dirac–Born–Infeld theories, can be suggested for certain scalar fields in string theory (Silverstein & Tong 2004; Alishahiha et al. 2004). Any theory of this form is characterized by an action with a non-linear dependence on the usual kinetic energy of a scalar field, $X = -\frac{1}{2}\sum_{\alpha=0}^{3}\sum_{\beta=0}^{3} g^{\alpha\beta}(\partial\phi/\partial x^{\alpha})(\partial\phi/\partial x^{\beta})$, the same term (2.124) used in the definition of Horndeski theories (2.123) in Section 2.2.5. The Dirac–Born–Infeld version suggested by string theory is indeed of the general form (2.123), but with a more specific

$$H_1(\phi, X) = T(\phi)\left(1 - \sqrt{1 - 2\frac{X}{T(\phi)}}\right) - V(\phi) \tag{6.84}$$

as the only non-zero contribution, with free functions $T(\phi)$ and $V(\phi)$ depending only on the scalar field but not on its derivatives. For small $X/T(\phi)$, $H_1(\phi, X) \sim X - V(\phi)$ equals the standard Lagrangian of a scalar field, but the non-linear dependence on X for larger $X/T(\phi)$ can support inflation with weaker conditions on the potential than would be required for slow-roll inflation with an H_1 linear in X.

Alternatives to Inflation: Various ingredients from string theory have been used to suggest alternatives to inflation that could explain observational features such as a nearly scale-free power spectrum of the cosmic microwave background. Ekpyrotic and cyclic models (Khoury et al. 2001; Steinhardt & Turok 2002; Khoury et al. 2004) are based on the observation that the requirement of having an inflaton fluid with negative P such that $P \approx -\rho$, used in inflation, could be replaced by a stiff effective matter ingredient characterized by positive and large pressure, $P \gg \rho$. Certain perturbation modes with nearly scale-free power spectra can then be obtained. However, they are usually produced in a pre-expansion phase of cosmic collapse, and therefore require some well-defined replacement of the Big Bang singularity. This phase, in a fully dynamical context, remains hard to control in string theory.

The proposal of string-gas cosmology (Brandenberger & Vafa 1989; Kripfganz & Perlt 1988) replaces the dynamical era that is often used to generate a scale-free power spectrum, be it exponential expansion or an ekpyrotic transition, with a stationary equilibrium phase. In the presence of compact extra dimensions in a background spacetime of an ensemble of strings, one can expect a phase transition to take place at high temperature when winding modes become energetically accessible. If the temperature is sufficiently high to excite winding modes, an increased supply of energy no longer leads to enhanced thermal motion of strings described by momentum modes. The reduced thermal motion indicates that the temperature remains constant for some time even as more energy is supplied, just as it happens at well-known phase transitions such as evaporating water.

String-gas cosmology postulates that inflationary expansion can be replaced with a string-gas phase transition, starting with a high-temperature state at which many winding modes are excited. As these modes decay slowly, density perturbations are generated which, unlike in inflation where they originate from quantum fluctuations, are of thermal origin. Equilibrium thermodynamics can then be used to compute the expected power spectrum, which can indeed by nearly scale-free (Nayeri et al. 2006; Brandenberger et al. 2007). A largely open question in this context is how to combine string-gas cosmology, or any other scenario based on winding modes or T-duality such as pre-Big Bang cosmology (Veneziano 1991, 1999; Gasperini & Veneziano 1993, 2003), with manifestly T-dual spacetime structures described by double field theory where the metric $g_{\alpha\beta}$ is replaced by a larger matrix (5.131), in particular if non-associative spacetime features are realized as suggested by Equation (5.142); see Section 5.2.5.

Early-universe Cosmology without Planck-scale Physics

Given the difficulties encountered when trying to achieve rigorous control on Planck or string-scale physics in any approach to quantum gravity, it is of some interest to see whether non-singular scenarios of the early universe can be devised by completely avoiding the Planck scale. An example based on classical physics is the emergent universe (Ellis & Maartens 2004; Ellis et al. 2004), which starts with an initial configuration given by Einstein's static universe (Einstein 1917). A static isotropic solution with vanishing Hubble parameter and acceleration can be obtained in general relativity by balancing the cosmological constant, spatial curvature, and the matter density. Depending on the value of the cosmological constant at early times, the matter density can be well below the Planck density. Moreover, since Einstein's universe turns out to be unstable with respect to anisotropic perturbations, any sub-Planckian quantum fluctuation implies that it will eventually leave the static phase and could turn into an expanding universe.

The Hartle–Hawking proposal (Hartle & Hawking 1983) for an initial state of the universe closed off in Euclidean space is another example of an early-universe scenario that could avoid detailed Planck-scale physics; see Section 4.4.2. Here again, it is the cosmological constant that determines the curvature or density scale of the initial state and may be chosen to be sufficiently sub-Planckian. However, as discussed in more detail in Section 4.4.3, this proposal is unstable with respect to inhomogeneous perturbations (Feldbrugge et al. 2017, 2018; Di Tucci & Lehners 2018). Current proposals to solve the instability problem include quantum-gravity effects closer to the Planck scale, such as dynamical signature change (Bojowald & Brahma 2018), or special initial conditions with non-zero momenta (Vilenkin & Yamada 2018, 2019; Di Tucci & Lehners 2019) that may require new physics.

Finally, matter properties or higher-curvature terms in an effective action of gravity could avoid the Big Bang singularity by a bouncing solution that stays away from Planckian curvature (Wands 1999, 2009; Finelli & Brandenberger 2002; Battefeld & Peter 2015). It may also be possible to achieve such a bounce using quantum fluctuations without requiring detailed Planck-scale physics (Peter & Pinto-Neto 2008). In such scenarios, it is possible to obtain nearly scale-free power spectra from fluctuations seeded in the collapse phase. Open problems are related to the genericness of achieving bouncing behavior, and whether growing anisotropic shear in the collapse phase, (1.46), can be sufficiently controlled so as to ensure scale-free power spectra for a large set of initial values.

7 Vektoranalysis und Kurvenintegrale

Wir bewegen uns im Schwerefeld der Erde. Im täglichen Leben haben wir durch die Nutzung elektrischer Geräte mit elektrischen Feldern und Magnetfeldern zu tun. Die Bewegung von Flüssigkeiten und Gasen wird durch Geschwindigkeitsfelder beschrieben. In den genannten Fällen kann man die Felder durch Abbildungen aus dem $\mathbb{R}^3$ (dem dreidimensionalen physikalischen Raum, wo z.B. die Flüssigkeit strömt) in den $\mathbb{R}^3$ (den Raum der Geschwindigkeitsvektoren) auffassen. Solche Abbildungen, die wir in Kapitel 5 als "vektorwertige Abbildungen" bezeichnet hatten, nennt man im Rahmen der Vektoranalysis auch **Vektorfelder**. Man beschränkt den Begriff Vektorfeld dabei nicht auf Abbildungen aus dem $\mathbb{R}^3$ in den $\mathbb{R}^3$, sondern bezieht an verschiedenen Stellen der Theorie Abbildungen $\mathbb{R}^n \to \mathbb{R}^m$ mit $m > 1$ ein, wenn dann auch mitunter die physikalische Entsprechung abhanden kommt. Abbildungen aus dem $\mathbb{R}^n$ in $\mathbb{R}$, die wir bisher reellwertige Abbildungen genannt haben, bezeichnet man im Kontext der Analysis auch als **Skalarfelder**. Ein Beispiel für ein Skalarfeld ist die Temperatur als Funktion der drei Ortskoordinaten und der Zeit (d.h. $n = 4$) in einem Hörsaal. Mit dem Begriff "Feld" wird zum Ausdruck gebracht, dass die betreffende Größe (Vektor oder Skalar) auf einer gewissen Menge $D \subset \mathbb{R}^n$, $n > 1$ definiert ist. Im Folgenden sollen die grundlegenden Operatoren und Elemente der Vektoranalysis dargestellt werden. Ein Ziel ist der sichere Umgang mit Vektorfeldern. Außerdem werden mit den Potentialfeldern und ihren Eigenschaften wichtige Spezialfälle von Vektorfeldern behandelt. Schließlich wird erklärt, wie man die Arbeit berechnen kann, die eine Kraft leistet, wenn man einen Massenpunkt auf einer vorgegebenen Bahnkurve bewegt.

7.1 Die grundlegenden Operatoren der Vektoranalysis

In vielen Bereichen der Ingenieurwissenschaften und der Physik treten Differentialgleichungen der Art

$$\operatorname{rot}\mathbf{E} + \frac{\partial}{\partial t}\mathbf{B} = \mathbf{0} \tag{7.1}$$

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v}\cdot\nabla)\mathbf{v} = -\operatorname{grad} p + \operatorname{div}(\nu \operatorname{grad}\mathbf{v}) \tag{7.2}$$

$$\operatorname{div}\mathbf{v} = 0 \tag{7.3}$$

$$-\Delta\, p = f \tag{7.4}$$

auf. Der disziplinäre Hintergrund der Gleichungen ist hier von untergeordneter Bedeutung. Es sei nur bemerkt, dass es sich um mathematische Formulierungen von physikalischen Erfahrungssätzen (z.B. das Induktionsgesetz der Theorie elektromagnetischer Felder (7.1)) oder von Erhaltungsätzen (Impuls- und Massenerhaltung bei Strömungen reibungsbehafteter inkompressibler Medien), letztendlich natürlich auch Erfahrungssätze, handelt. Die Formulierungen benutzen typische **Operatoren** der Vektoranalysis **rot , grad , div ,** Δ und ∇, die auf die Vektorfelder **E** (elektrische Feldstärke), **B** (magnetische Induktion), **v** (Strömungsgeschwindigkeit) und das Skalarfeld p (statischer Druck, dividiert durch die konstante Dichte ρ) anzuwenden sind. Mit diesen Operatoren bezeichnet man bestimmte Kombinationen von partiellen Ableitungen nach den Ortskoordinaten, die im Folgenden erklärt werden. Wir bemerken am Rande, dass bei der Herleitung von Gleichungen wie (7.1) bis (7.3) aus den zugrundeliegenden physikalischen Vorgängen i. Allg. zunächst eine Formulierung mittels partieller Ableitungen entsteht. Vorteile der nachträglichen Einführung der angegebenen Operatoren bestehen zum einen in der Kompaktheit der Schreibweise, die man würdigen wird, wenn wir für die Gleichung (7.2) die NAVIER-STOKES-Gleichung, die Formulierung mittels partieller Ableitungen hergestellt haben werden. Zum anderen hat man mittels solcher Operatoren eine koordinatenunabhängige Schreibweise erreicht, die u.a. beim Übergang zu neuen Ortskoordinaten (z.B. von kartesischen zu Zylinder- oder Kugelkoordinaten) gewisse Vorteile bietet. Diese Operatoren erlauben auch eine kompakte, koordinatenunabhängige Formulierung der Integralsätze von GREEN, GAUSS und STOKES (s. Kapitel 8).
Wir wenden uns nun der Definition der grundlegenden Operatoren der Vektoranalysis mittels partieller Ableitungen von Skalar- oder Vektorfeldern nach den kartesischen Koordinaten zu. Dabei setzen wir der Einfachheit halber generell voraus, dass die dabei zu bildenden partiellen Ableitungen existieren und stetig sind. Wir betrachten im Folgenden Vektor- und Skalarfelder auf **Gebieten** $D \subset \mathbb{R}^n$, also auf offenen, zusammenhängenden Mengen. Nun sollen die Operatoren im Einzelnen definiert werden.

Definition 7.1. (Gradient eines Skalarfeldes)
Sei $\phi : D \to \mathbb{R},\ D \subset \mathbb{R}^n$, ein stetig partiell differenzierbares Skalarfeld. Der Operator grad ordnet durch die Vorschrift

$$\operatorname{grad} \phi = \begin{pmatrix} \frac{\partial \phi}{\partial x_1} \\ \frac{\partial \phi}{\partial x_2} \\ \vdots \\ \frac{\partial \phi}{\partial x_n} \end{pmatrix}$$

dem Skalarfeld ϕ das Vektorfeld grad $\phi : D \to \mathbb{R}^n$ zu. Der Vektor grad ϕ heißt **Gradient** von ϕ.

Definition 7.2. (LAPLACE-Operator Δ)
Sei $\phi : D \to \mathbb{R},\ D \subset \mathbb{R}^n$, ein 2-mal stetig partiell differenzierbares Skalarfeld. Der **LAPLACE-Operator** Δ ordnet durch die Vorschrift

$$\Delta\ \phi := \frac{\partial^2 \phi}{\partial x_1^2} + \frac{\partial^2 \phi}{\partial x_2^2} + ... + \frac{\partial^2 \phi}{\partial x_n^2}$$

dem Skalarfeld ϕ das Skalarfeld $\Delta\ \phi : D \to \mathbb{R}$ zu.

Definition 7.3. (Divergenz eines Vektorfeldes)
Sei $\mathbf{v} : D \to \mathbb{R}^n,\ D \subset \mathbb{R}^n$, ein stetig partiell differenzierbares Vektorfeld. Der Operator div ordnet durch die Vorschrift

$$\operatorname{div} \mathbf{v} = \frac{\partial v_1}{\partial x_1} + \frac{\partial v_2}{\partial x_2} + ... + \frac{\partial v_n}{\partial x_n}$$

dem Vektorfeld $\mathbf{v}$ das Skalarfeld div $\mathbf{v} : D \to \mathbb{R}$ zu. div $\mathbf{v}$ heißt **Divergenz** des Vektorfeldes $\mathbf{v}$.

Definition 7.4. (Rotation eines Vektorfeldes)
Sei $\mathbf{v} : D \to \mathbb{R}^3,\ D \subset \mathbb{R}^3$, ein stetig partiell differenzierbares Vektorfeld. Der Operator rot ordnet durch die Vorschrift

$$\operatorname{rot} \mathbf{v} = \begin{pmatrix} \frac{\partial v_3}{\partial x_2} - \frac{\partial v_2}{\partial x_3} \\ \frac{\partial v_1}{\partial x_3} - \frac{\partial v_3}{\partial x_1} \\ \frac{\partial v_2}{\partial x_1} - \frac{\partial v_1}{\partial x_2} \end{pmatrix}$$

dem Vektorfeld $\mathbf{v}$ das Vektorfeld rot $\mathbf{v} : D \to \mathbb{R}^3$ zu. Der Vektor rot $\mathbf{v}$ heißt **Rotation** des Vektors $\mathbf{v}$ bzw. zu $\mathbf{v}$ gehörendes Wirbelfeld in D.

Im Zusammenhang mit dem Satz von TAYLOR (vgl. Abschnitt 5.11.1) wurde der **Nabla-Operator** schon behandelt. Der Nabla-Operator ∇ kann als symbolischer Vektor aufgefasst werden. Im $\mathbb{R}^n$ hat man

$$\nabla := (\frac{\partial}{\partial x_1}, \frac{\partial}{\partial x_2}, \ldots, \frac{\partial}{\partial x_n})^T = \mathbf{e}_1 \frac{\partial}{\partial x_1} + \mathbf{e}_2 \frac{\partial}{\partial x_2} + \cdots + \mathbf{e}_n \frac{\partial}{\partial x_n}$$

($\mathbf{e}_1, \ldots, \mathbf{e}_n$ kanonische Basis des $\mathbb{R}^n$). Die Anwendung auf ein stetig partiell differenzierbares Skalarfeld ϕ bedeutet die symbolische Multiplikation von ∇ und ϕ:

$$\nabla \phi = (\mathbf{e}_1 \frac{\partial}{\partial x_1} + \mathbf{e}_2 \frac{\partial}{\partial x_2} + \cdots + \mathbf{e}_n \frac{\partial}{\partial x_n}) \phi = \operatorname{grad} \phi\ .$$

Die Anwendung des Operators $\nabla\cdot$ auf ein stetig differenzierbares Vektorfeld $\mathbf{v}$ bedeutet die Bildung des (formalen) skalaren Produkts zwischen dem symbolischen Vektor ∇ und dem Vektor $\mathbf{v}$. Wegen $\mathbf{e}_i \cdot \mathbf{e}_j = \delta_{ij}$ erhält man

$$\begin{aligned}\nabla \cdot \mathbf{v} &= (\mathbf{e}_1 \frac{\partial}{\partial x_1} + \mathbf{e}_2 \frac{\partial}{\partial x_2} + \cdots + \mathbf{e}_n \frac{\partial}{\partial x_n}) \cdot (v_1 \mathbf{e}_1 + v_2 \mathbf{e}_2 + \cdots + v_n \mathbf{e}_n) \\ &= \frac{\partial v_1}{\partial x_1} + \frac{\partial v_2}{\partial x_2} + \cdots + \frac{\partial v_n}{\partial x_n} = \operatorname{div} \mathbf{v} \ .\end{aligned}$$

Die Anwendung des Operators $\nabla\times$ auf ein stetig differenzierbares Vektorfeld $\mathbf{v} : \mathbb{R}^3 \to \mathbb{R}^3$ bedeutet die Bildung des (formalen) Vektorprodukts zwischen dem symbolischen Vektor ∇ und dem Vektor $\mathbf{v}$. Man erhält

$$\nabla \times \mathbf{v} = \begin{pmatrix} \frac{\partial}{\partial x_2} v_3 - \frac{\partial}{\partial x_3} v_2 \\ \frac{\partial}{\partial x_3} v_1 - \frac{\partial}{\partial x_1} v_3 \\ \frac{\partial}{\partial x_1} v_2 - \frac{\partial}{\partial x_2} v_1 \end{pmatrix} = \operatorname{rot} \mathbf{v} \ .$$

Eine weitere Möglichkeit zur Berechnung von $\operatorname{rot}\mathbf{v}$ erhält man mit der formalen Berechnung einer Determinante. Es ergibt sich durch Entwicklung nach der ersten Zeile

$$\begin{aligned}&\begin{vmatrix} \mathbf{e}_1 & \mathbf{e}_2 & \mathbf{e}_3 \\ \frac{\partial}{\partial x_1} & \frac{\partial}{\partial x_2} & \frac{\partial}{\partial x_3} \\ v_1 & v_2 & v_3 \end{vmatrix} \\ &\quad = \mathbf{e}_1 \left(\frac{\partial}{\partial x_2} \mathbf{v}_3 - \frac{\partial}{\partial x_3} \mathbf{v}_2 \right) + \mathbf{e}_2 \left(\frac{\partial}{\partial x_3} \mathbf{v}_1 - \frac{\partial}{\partial x_1} \mathbf{v}_3 \right) + \mathbf{e}_3 \left(\frac{\partial}{\partial x_1} \mathbf{v}_2 - \frac{\partial}{\partial x_2} \mathbf{v}_1 \right) \\ &\quad = \operatorname{rot} \mathbf{v} \ .\end{aligned}$$

Die Operatoren grad und Δ haben wir in den Definitionen auf Skalarfelder ϕ angewandt. Wir verabreden die Anwendung von Δ auf Vektorfelder wie folgt. Sei $\mathbf{v}$ ein stetig partiell differenzierbares Vektorfeld und $\mathbf{w}$ ein zweimal stetig partiell differenzierbares Vektorfeld. Dann definieren wir

$$\Delta \, \mathbf{w} = \begin{pmatrix} \Delta \, w_1 \\ \Delta \, w_2 \\ \\ \vdots \\ \Delta \, w_n \end{pmatrix} ,$$

also $\Delta\mathbf{w}$ als die komponentenweise Anwendung von Δ.
Die Verabredung gilt z.B. auch für den Operator $\mathbf{w} \cdot \nabla$, den wir im Zusammenhang mit dem Satz von TAYLOR verwendet haben: Wir setzen

$$(\mathbf{w} \cdot \nabla)\mathbf{v} = \begin{pmatrix} (\mathbf{w} \cdot \nabla) v_1 \\ (\mathbf{w} \cdot \nabla) v_2 \\ \vdots \\ (\mathbf{w} \cdot \nabla) v_n \end{pmatrix} .$$

Beispiele:
1) Betrachten wir das Zentralkraftfeld

$$\mathbf{K}(\mathbf{x}) = \frac{k}{|\mathbf{x}|^3}\mathbf{x}\,, \quad k \neq 0,\, k \in \mathbb{R}\,,$$

also mit $\mathbf{x} \in D = \mathbb{R}^3 \setminus \mathbf{0}$ ein Vektorfeld $\mathbf{K} : D \to \mathbb{R}^3$. Für $k < 0$ sind die Kraftvektoren $\mathbf{K}(\mathbf{x})$ überall nach dem Ursprung $\mathbf{x} = \mathbf{0}$ hin gerichtet, ihr Betrag ist auf Kugeln $|\mathbf{x}| = r$ konstant und nimmt mit r wie $\frac{1}{r^2}$ ab: $|\mathbf{K}(\mathbf{x})|_{|\mathbf{x}|=r} = \frac{|k|}{r^2}$. Offensichtlich geht es hier insbesondere um das Gravitationsgesetz, wobei in der Konstanten k die beiden sich anziehenden Massen, von denen eine um Punkt $\mathbf{x} = \mathbf{0}$ ruht, und die Gravitationskonstante zusammengefasst sind (vgl. (6.198)). Für die Divergenz und die Rotation errechnet man unter Beachtung der Beziehung $|\mathbf{x}| = \sqrt{x_1^2 + x_2^2 + x_3^2}$

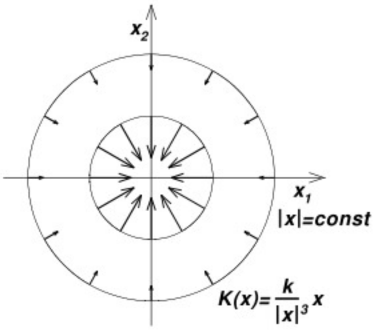

Abb. 7.1. Zentralkraftfeld $\mathbf{K}(\mathbf{x})$ für $k < 0$ in der Ebene $x_3 = 0$

$$\begin{aligned}
\operatorname{div}\mathbf{K}(\mathbf{x}) &= \operatorname{div}\frac{k}{|\mathbf{x}|^3}\mathbf{x} = \operatorname{div}\Big[\frac{k}{|\mathbf{x}|^3}\begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix}\Big] \\
&= \frac{\partial}{\partial x_1}\frac{k\,x_1}{|\mathbf{x}|^3} + \frac{\partial}{\partial x_2}\frac{k\,x_2}{|\mathbf{x}|^3} + \frac{\partial}{\partial x_3}\frac{k\,x_3}{|\mathbf{x}|^3} \\
&= k\Big[\frac{3}{|\mathbf{x}|^3} + x_1\frac{\partial}{\partial x_1}\frac{1}{|\mathbf{x}|^3} + x_2\frac{\partial}{\partial x_2}\frac{1}{|\mathbf{x}|^3} + x_3\frac{\partial}{\partial x_3}\frac{1}{|\mathbf{x}|^3}\Big] \\
&= k\Big[\frac{3}{|\mathbf{x}|^3} - (3x_1^2 + 3x_2^2 + 3x_3^2)\frac{1}{|\mathbf{x}|^5}\Big] = 0
\end{aligned}$$

und

$$\operatorname{rot}\mathbf{K}(\mathbf{x}) = \operatorname{rot}\frac{k}{|\mathbf{x}|^3}\mathbf{x} = \begin{pmatrix} \frac{\partial}{\partial x_2}\frac{k\,x_3}{|\mathbf{x}|^3} - \frac{\partial}{\partial x_3}\frac{k\,x_2}{|\mathbf{x}|^3} \\ \frac{\partial}{\partial x_3}\frac{k\,x_1}{|\mathbf{x}|^3} - \frac{\partial}{\partial x_1}\frac{k\,x_3}{|\mathbf{x}|^3} \\ \frac{\partial}{\partial x_1}\frac{k\,x_2}{|\mathbf{x}|^3} - \frac{\partial}{\partial x_2}\frac{k\,x_1}{|\mathbf{x}|^3} \end{pmatrix} = -\frac{1}{|\mathbf{x}|^5}\begin{pmatrix} 3x_2x_3 - 3x_3x_2 \\ 3x_1x_3 - 3x_3x_1 \\ 3x_2x_1 - 3x_1x_2 \end{pmatrix} = \mathbf{0}\,.$$

2) Wenn wir nun das Skalarfeld $\phi(\mathbf{x}) = -\frac{k}{|\mathbf{x}|}$ betrachten und den Gradienten berechnen, ergibt sich

$$\operatorname{grad}\phi(\mathbf{x}) = \operatorname{grad}\left(-k(x_1^2 + x_2^2 + x_3^2)^{-1/2}\right) = k\frac{1}{|\mathbf{x}|^3}\mathbf{x} = \mathbf{K}(\mathbf{x})\,.$$

Es gibt also ein Skalarfeld $\phi(\mathbf{x})$, aus dem man das Vektorfeld $\mathbf{K}(\mathbf{x})$ durch Gradientenbildung ableiten kann. Die einzelnen Rechnungen sollten zur Übung noch einmal genau nachvollzogen werden.

7.2 Rechenregeln und Eigenschaften der Operatoren der Vektoranalysis

Wenn $\phi : D \to \mathbb{R}, D \subset \mathbb{R}^3$, ein zweimal stetig differenzierbares Skalarfeld ist, so kann man vom Vektorfeld $\mathbf{v} = \operatorname{grad} \phi$ die JACOBI-Matrix $J_\mathbf{v}$ bilden, man erhält

$$J_\mathbf{v}(\mathbf{x}) = J_{\operatorname{grad} \phi}(\mathbf{x}) = \begin{pmatrix} \frac{\partial^2 \phi}{\partial x_1^2} & \frac{\partial^2 \phi}{\partial x_1 \partial x_2} & \frac{\partial^2 \phi}{\partial x_1 \partial x_3} \\ \frac{\partial^2 \phi}{\partial x_2 \partial x_1} & \frac{\partial^2 \phi}{\partial x_2^2} & \frac{\partial^2 \phi}{\partial x_2 \partial x_3} \\ \frac{\partial^2 \phi}{\partial x_3 \partial x_1} & \frac{\partial^2 \phi}{\partial x_3 \partial x_2} & \frac{\partial^2 \phi}{\partial x_3^2} \end{pmatrix} .$$

Dabei stellt man fest, dass die JACOBI-Matrix von $\mathbf{v} = \operatorname{grad} \phi$ gleich der HESSE-Matrix von ϕ ist.

Wenn wir den Begriff der Spur einer Matrix $A = (a_{ij})$ mit $\operatorname{Spur}(A) := a_{11} + a_{22} + a_{33}$ verwenden, kann man den LAPLACE-Operator angewendet auf ein Skalarfeld ϕ auch in der Form

$$\Delta \phi = \operatorname{Spur}(J_{\operatorname{grad} \phi}(\mathbf{x}))$$

schreiben.

Rechenregeln für Operatoren der Vektoranalysis:
Sei $\phi : D \to \mathbb{R}$, $D \subset \mathbb{R}^n$, ein zweimal stetig differenzierbares Skalarfeld und $\mathbf{v} : D \to \mathbb{R}^n, D \subset \mathbb{R}^n$, ein stetig differenzierbares Vektorfeld, so gelten die Regeln

(i) $\operatorname{rot}(\operatorname{grad} \phi) = \mathbf{0}$ (Satz von SCHWARZ)

(ii) $\operatorname{div}(\operatorname{rot} \mathbf{v}) = 0$

(iii) $\operatorname{div}(\operatorname{grad} \phi) = \Delta \phi$

(iv) $\operatorname{div}(\phi \mathbf{v}) = \operatorname{grad} \phi \cdot \mathbf{v} + \phi \operatorname{div} \mathbf{v}$

(v) $\operatorname{rot}(\phi \mathbf{v}) = \operatorname{grad} \phi \times \mathbf{v} + \phi(\operatorname{rot} \mathbf{v})$

(vi) $\operatorname{rot}(\operatorname{rot}(\mathbf{v})) = \operatorname{grad}(\operatorname{div}(\mathbf{v})) - \Delta \mathbf{v}$.

Die Regeln, in denen der Rotationsoperator vorkommt, gelten nur für $n = 3$.

Zum Beweis sei außer dem Hinweis auf eine umfängliche Rechnerei nur gesagt, dass die Vertauschbarkeit der Reihenfolge der Ableitungen benötigt wird.

Erinnern wir uns nun nochmal an die beiden Beispiele aus dem vorigen Abschnitt. Mit dem Skalarfeld

$$\psi(\mathbf{x}) = \frac{k}{|\mathbf{x}|^3}$$

können wir das Zentralkraftfeld $\mathbf{K}$ in der Form $\mathbf{K}(\mathbf{x}) = \psi(\mathbf{x})\mathbf{x}$ darstellen. Nach der Regel (iv) erhält man damit

$$\operatorname{div}(\psi\mathbf{x}) = \operatorname{grad}\psi \cdot \mathbf{x} + \psi \operatorname{div}\mathbf{x} = \operatorname{grad}\psi \cdot \mathbf{x} + 3\psi\ ,$$

womit die Rechnung de facto auf die Berechnung der Gradienten von ψ reduziert wird. Dafür rechnet man aus

$$\operatorname{grad}\psi(\mathbf{x}) = -\frac{3k}{|\mathbf{x}|^5}\mathbf{x}\ . \tag{7.5}$$

Andererseits ist $\mathbf{K}(\mathbf{x}) = \psi(\mathbf{x})\mathbf{x} = \psi(\mathbf{x})\mathbf{E}\mathbf{x}$ mit der Einheitsmatrix $\mathbf{E}$. Nach der Kettenregel erhält man

$$\mathbf{K}'(\mathbf{x}) = \psi(\mathbf{x})\mathbf{E} + \mathbf{x}\psi'(\mathbf{x})\ .$$

Man kann die JACOBI-Matrix in der Form

$$J_{\mathbf{K}}(\mathbf{x}) = \psi(\mathbf{x})\mathbf{E} + \mathbf{x} \cdot (\operatorname{grad}\psi(\mathbf{x}))^T$$

schreiben und erhält unter Berücksichtigung von (7.5)

$$J_{\mathbf{K}}(\mathbf{x}) = \frac{k}{|\mathbf{x}|^5}(|\mathbf{x}|^2\mathbf{E} - 3\mathbf{x}\mathbf{x}^T)\ .$$

Wenn man die in der Klammer stehende Matrix genau aufschreibt, erhält man die Diagonalelemente

$$-2x_1^2 + x_2^2 + x_3^2\ , \qquad x_1^2 - 2x_2^2 + x_3^2\ , \qquad x_1^2 + x_2^2 - 2x_3^2\ ,$$

so dass sich für die Spur der JACOBI-Matrix der Wert Null ergibt! Damit kann man für die Funktion ϕ aus dem Beispiel 2 des vorigen Abschnittes schlussfolgern, dass

$$\operatorname{div}\mathbf{K}(\mathbf{x}) = \operatorname{Spur}(J_{\operatorname{grad}\phi}(\mathbf{x})) = \operatorname{Spur}(J_{\mathbf{K}}(\mathbf{x})) = 0$$

ist.

Beispiel: Wir hatten zu Beginn des Abschnittes einige partielle Dfferentialgleichungen in Operatorform aufgeschrieben. Im Folgenden sollen die NAVIER-STOKES-Gleichungen

$$\frac{\partial\mathbf{v}}{\partial t} + (\mathbf{v}\cdot\nabla)\mathbf{v} = -\operatorname{grad}p + \operatorname{div}(\nu\operatorname{grad}\mathbf{v})\ , \quad \operatorname{div}\mathbf{v} = 0 \tag{7.6}$$

mittels kartesischer Koordinaten einmal vollständig ausgeschrieben dargestellt werden. Wenn wir die obigen Definitionen der Operatoren für das zweimal stetig differenzierbare Vektorfeld $\mathbf{v}:\mathbb{R}^3\to\mathbb{R}^3$ und das stetig differenzierbare Skalarfeld $p:\mathbb{R}^3\to\mathbb{R}$ anwenden, erhalten wir für die erste Gleichung

$$\frac{\partial v_1}{\partial t}+v_1\frac{\partial v_1}{\partial x_1}+v_2\frac{\partial v_1}{\partial x_2}+v_3\frac{\partial v_1}{\partial x_3}= \tag{7.7}$$

$$-\frac{\partial p}{\partial x_1}+\frac{\partial}{\partial x_1}(\nu\frac{\partial v_1}{\partial x_1})+\frac{\partial}{\partial x_2}(\nu\frac{\partial v_1}{\partial x_2})+\frac{\partial}{\partial x_3}(\nu\frac{\partial v_1}{\partial x_3})$$

$$\frac{\partial v_2}{\partial t}+v_1\frac{\partial v_2}{\partial x_1}+v_2\frac{\partial v_2}{\partial x_2}+v_3\frac{\partial v_2}{\partial x_3}= \tag{7.8}$$

$$-\frac{\partial p}{\partial x_2}+\frac{\partial}{\partial x_1}(\nu\frac{\partial v_2}{\partial x_1})+\frac{\partial}{\partial x_2}(\nu\frac{\partial v_2}{\partial x_2})+\frac{\partial}{\partial x_3}(\nu\frac{\partial v_2}{\partial x_3})$$

$$\frac{\partial v_3}{\partial t}+v_1\frac{\partial v_3}{\partial x_1}+v_2\frac{\partial v_3}{\partial x_2}+v_3\frac{\partial v_3}{\partial x_3}= \tag{7.9}$$

$$-\frac{\partial p}{\partial x_3}+\frac{\partial}{\partial x_1}(\nu\frac{\partial v_3}{\partial x_1})+\frac{\partial}{\partial x_2}(\nu\frac{\partial v_3}{\partial x_2})+\frac{\partial}{\partial x_3}(\nu\frac{\partial v_3}{\partial x_3}).$$

Für die Gleichung $\operatorname{div}\mathbf{v}=0$ ergibt sich

$$\frac{\partial v_1}{\partial x_1}+\frac{\partial v_2}{\partial x_2}+\frac{\partial v_3}{\partial x_3}=0\,. \tag{7.10}$$

Insbesondere bei den Gleichungen (7.7), (7.8), (7.9) wird deutlich, welche Übersichtlichkeit mit der Verwendung der Operatoren der Vektoranalysis möglich wird.

7.3 Potential und Potentialfeld

Im obigen Beispiel 2 haben wir mit dem Skalarfeld ϕ ein Feld gefunden, dessen Gradientenfeld gleich einem vorgegebenen Vektorfeld $\mathbf{K}$ ist.
Aus einem gegebenen stetig differenzierbaren Skalarfeld kann man durch Gradientenbildung stets ein Vektorfeld (Gradientenfeld) $\mathbf{v}$ gewinnen. Ist umgekehrt ein Vektorfeld $\mathbf{v}$ gegeben, so ist die Existenz eines Skalarfeldes ϕ mit der Eigenschaft $\operatorname{grad}\phi=\mathbf{v}$ keineswegs immer gesichert. Wir formulieren die entsprechenden Begriffe in Definition 7.5.

Definition 7.5. (Potential, Potentialfeld, Gradientenfeld)

Sei $\mathbf{v}$ ein Vektorfeld. Ein differenzierbares Skalarfeld ϕ, das die Gleichung

$$\operatorname{grad}\phi=\mathbf{v}$$

erfüllt, nennt man ein **Potential** oder eine Stammfunktion von $\mathbf{v}$.
Wenn es zu einem Vektorfeld $\mathbf{v}$ ein Potential ϕ gibt, nennt man $\mathbf{v}$ **Potentialfeld** oder Gradientenfeld (auch der Begriff konservatives Feld wird verwendet).

In den nächsten Abschnitten werden wir feststellen, dass die Kenntnis von Potentialen viele Aufgabenstellungen, z.B. die Berechnung der Arbeit, stark vereinfacht. Deshalb werden wir Kriterien zur Überprüfung der Potentialfeldeigenschaft behandeln und Methoden zur Berechnung von Potentialen darlegen. Wir weisen darauf hin, dass im Folgenden mit t irgendein Kurvenparameter bezeichnet wird, der nicht notwendig die Bedeutung der Zeit hat, auch wenn wir Ableitungen $\frac{d}{dt}$ mit $(\dot{\ })$ abkürzen (z.B. $\frac{dx}{dt} = \dot{x}$).

7.4 Skalare Kurvenintegrale

Ein praktischer Hintergrund der Kurvenintegrale besteht in der Berechnung der Länge von Kurven und der Summation (Integration) einer Belegungsfunktion entlang der Kurve. Ein einfaches Beispiel hierfür ist die Berechnung der Gesamtschneemasse auf einer Freileitung, wobei die Freileitung als Kurve im $\mathbb{R}^3$ betrachtet wird und die heterogen verteilte Schneemasse pro Kurvenabschnitt als Belegungsfunktion f vorgegeben ist. Die skalare Integration der Funktion entlang der Kurve ergibt dann die Gesamtmasse. Die Eigenmasse der Freileitung muss man natürlich noch hinzunehmen, will man die Gesamtmasse der Leitung plus Schneemasse bestimmen. Den Begriff der Kurve haben wir im Kapitel 5 definiert. Zur Erinnerung soll noch einmal das skalare Bogenelement ds einer Kurve $\gamma(t) = (x_1(t), x_2(t))^T$ im $\mathbb{R}^2$

$$ds = \sqrt{\dot{x}_1^2 + \dot{x}_2^2}\, dt = |\dot{\gamma}(t)|\, dt,$$

die Bogenlänge $s(t)$ des Stückes einer Kurve, das dem Parameterintervall $[t_a, t]$ entspricht,

$$s(t) = \int_{t_a}^{t} \sqrt{\dot{x}_1^2 + \dot{x}_2^2}\, dt = \int_{t_a}^{t} |\dot{\gamma}(t)|\, dt$$

und die Bogenlänge L der gesamten Kurve

$$L = \int_{\gamma} ds = \int_{t_a}^{t_e} \sqrt{\dot{x}_1^2 + \dot{x}_2^2}\, dt = \int_{t_a}^{t_e} |\dot{\gamma}(t)|\, dt$$

angegeben werden; dabei verwenden wir die Definitionen 2.31 und 5.14. Die Verallgemeinerung auf Kurven γ im $\mathbb{R}^n$ (vgl. Definitionen 5.12, 5.13, 5.14) fassen wir zusammen in

Definition 7.6. (Bogenelement, Bogenlänge einer Kurve im $\mathbb{R}^n$)
Sei $\gamma(t) = (x_1(t), x_2(t), \ldots, x_n(t))^T$, $t \in [t_a, t_e]$, eine Kurve im $\mathbb{R}^n$. Dann bezeichnen wir mit

$$ds = \sqrt{\dot{x}_1^2(t) + \dot{x}_2^2(t) + \cdots + \dot{x}_n^2(t)}\, dt =: |\dot{\gamma}(t)|\, dt$$

das **Bogenelement** der Kurve (an der Stelle $\gamma(t)$). Für die **Bogenlänge** $s(t)$ des Kurvenstücks, das dem Parameterintervall $[t_a, t]$ $(t \le t_e)$ entspricht, gilt

$$s(t) = \int_{t_a}^{t} \sqrt{\dot{x}_1^2(\tau) + \dot{x}_2^2(\tau) + \cdots + \dot{x}_n^2(\tau)}\, d\tau = \int_{t_a}^{t} |\dot{\gamma}(\tau)|\, d\tau\ .$$

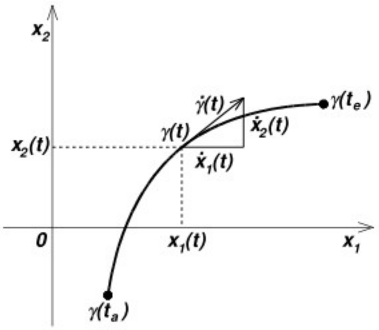

Abb. 7.2. Bezeichnungen bei Kurven γ im $\mathbb{R}^2$

Für die Gesamtlänge L der Kurve γ gilt

$$L = s(t_e) = \int_{t_a}^{t_e} \sqrt{\dot x_1^2(\tau) + \dot x_2^2(\tau) + \cdots + \dot x_n^2(\tau)}\, d\tau \ .$$

Wir werden im Zusammenhang mit Kurvenintegralen immer voraussetzen, dass es sich bei den betrachteten Kurven γ um **reguläre Kurven** im Sinne der Definition 5.13 handelt, d.h. für $\gamma(t) = (x_1(t), x_2(t), \ldots, x_n(t))^T$ wird

$$\dot x_1^2(t) + \dot x_2^2(t) + \cdots + \dot x_n^2(t) = |\dot\gamma(t)|^2 > 0$$

für $t \in \,]t_a, t_e[$ vorausgesetzt.

Definition 7.7. (skalares Kurvenintegral einer Funktion)

Eine Funktion $f : \mathbb{R}^n \supset \gamma([t_a, t_e]) \to \mathbb{R}$ sei auf allen Punkten einer Kurve $\gamma : [t_a, t_e] \to \mathbb{R}^n$ stetig. Dann heißt

$$\int_\gamma f\, ds := \int_{t_a}^{t_e} f(\gamma(t))|\dot\gamma(t)|\, dt$$

das **skalare Kurvenintegral** der Funktion f.

Man nennt die skalaren Kurvenintegrale auch **Kurvenintegrale 1. Art**. Auch die Bezeichnung Linienintegrale 1. Art findet man manchmal.

Wir verstehen die Kurvenintegrale $\int_\gamma f(s)\, ds$ (wie die Integrale $\int_a^b f(x)\, dx$ über Intervalle der x-Achse) als Integrale im RIEMANNschen Sinn, d.h. als Grenzwert der RIEMANNschen Zwischensummen oder als gemeinsamen Grenzwert von Ober- und Untersummen bei immer feiner werdenden Zerlegungen des Intervalls $[t_a, t_e]$; vgl. dazu Abschnitt 2.13.4. Einer Zerlegung des Parameterintervalls $[t_a, t_e]$,

$$t_a = t_0 < t_1 < \cdots < t_{\nu-1} < t_\nu < \cdots < t_{n-1} < t_n = t_e \ ,$$

entspricht eine Zerlegung der Kurve in n Kurvenstücke durch die Teilpunkte

$$\gamma(t_0),\ \gamma(t_1), \ldots, \gamma(t_{\nu-1}),\ \gamma(t_\nu), \ldots, \gamma(t_{n-1}),\ \gamma(t_n) \ .$$

Wir wählen n Zwischenwerte t_ν^* mit $t_{\nu-1} \leq t_\nu^* \leq t_\nu$ ($\nu = 1,2,\ldots,n$) und haben damit auch n Punkte $\gamma(t_\nu^*)$ auf der Kurve gewählt. Mit $\Delta t_\nu = t_\nu - t_{\nu-1}$ ist

$$\Delta s_\nu = |\gamma(t_\nu) - \gamma(t_{\nu-1})| \approx |\dot{\gamma}(t_\nu^*)|\Delta t_\nu \ .$$

Die RIEMANNschen Zwischensummen für das skalare Kurvenintegral sind dann

$$Z_n = \sum_{\nu=1}^{n} f(\gamma(t_\nu^*))\Delta s_\nu \approx \sum_{\nu=1}^{n} f(\gamma(t_\nu^*))|\dot{\gamma}(t_\nu^*)|\Delta t_\nu \ .$$

Jeder einzelne Summand stellt im Fall $\gamma \in \mathbb{R}^2$ näherungsweise den Inhalt eines Flächenstücks $\Delta_\nu F$ dar. Diese anschauliche Deutung ist für Kurven γ im $\mathbb{R}^2$ möglich, weil man sich die zu integrierende Funktion f über der in der (x_1, x_2)-Ebene verlaufenden Kurve γ aufgetragen denken kann (s. Abb. 7.3); Für $\gamma : [t_a, t_e] \to \mathbb{R}^n$ mit $n > 2$ wird diese Veranschaulichung schwierig oder unmöglich.

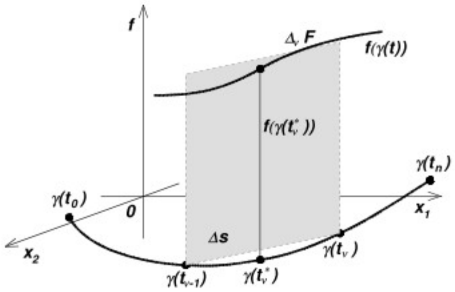

Abb. 7.3. Zur Definition des skalaren Kurvenintegrals für $\gamma : [t_a, t_e] \to \mathbb{R}^2$

Man kann zeigen, dass die RIEMANNschen Zwischensummen (gegen das skalare Kurvenintegral) konvergieren, wenn $f(\gamma(t))$ stetig ist. Handelt es sich bei der Kurve γ um eine aus k Kurvenstücken γ_j zusammengesetzte Kurve, so ergibt sich das Kurvenintegral in der Form

$$\int_\gamma f\,ds = \sum_{j=1}^{k} \int_{\gamma_j} f\,ds \ .$$

Das Kurvenintegral der Funktion $f \equiv 1$ ist gleich der Länge L der Kurve γ. Zur Veranschaulichung des Kurvenintegrals für $\gamma \in \mathbb{R}^3$ kann man sich etwa vorstellen, dass man entlang einer Kurve durch eine Funktion f eine Masseverteilung gegeben hat (Masse eines Drahts). Mit dem Kurvenintegral kann man dann die Gesamtmasse berechnen, wobei der in irgendeiner Weise befestigte Draht durch die Kurve γ beschrieben wird.

Beispiele:
1) Betrachten wir den Kreis mit beliebigem Radius r

$$\gamma(t) = r\begin{pmatrix}\cos t\\ \sin t\end{pmatrix} \ , \ t \in [0,2\pi] \ ,$$

und die Belegungsfunktion $f(x,y) = x^2 - y^2$. Für $f(\gamma(t))$ errechnet man

$$f(\gamma(t)) = (\cos^2 t - \sin^2 t)r^2 = r^2 \cos 2t \ ,$$

und für $\dot{\gamma}(t)$ erhält man

$$\dot{\gamma}(t) = r \begin{pmatrix} -\sin t \\ \cos t \end{pmatrix} \quad \text{und damit} \quad |\dot{\gamma}(t)| = r \ .$$

Für das Kurvenintegral der Funktion f errechnet man schließlich

$$\begin{aligned} \int_\gamma f \, ds &= \int_0^{2\pi} f(\gamma(t))|\dot{\gamma}(t)| \, dt = r^3 \int_0^{2\pi} \cos 2t \, dt \\ &= r^3 \frac{1}{2} \sin 2t|_0^{2\pi} = 0 \ . \end{aligned}$$

2) Eine Verkehrsmaschine fliegt auf einem nördlichen Breitenkreis (geographische Breite $\frac{\pi}{4}$) von Europa nach Nordamerika. Die Entfernung von Start- und Zielort ist gleich einem Viertel des Breitenkreisumfangs. Während des Fluges sondert das Flugzeug Schadstoffe nach der Formel

$$f(x,y,z) = c[1 + \cos(4 \arctan \frac{y}{x})]$$

ab. Die jeweilige Flughöhe ist im Vergleich zum Erdradius vernachlässigbar. Zu berechnen ist die während des Fluges abgegebene Schadstoffmenge.
Wenn wir die Erdoberfläche im $\mathbb{R}^3$ parametrisieren, erhält man unter Nutzung der Kugelkoordinaten

$$\gamma(\lambda) = \begin{pmatrix} x(\lambda) \\ y(\lambda) \\ z(\lambda) \end{pmatrix} = \begin{pmatrix} R\cos\phi \, \cos\lambda \\ R\cos\phi \, \sin\lambda \\ R\sin\phi \end{pmatrix} \ , \phi = \frac{\pi}{4} \ , \lambda \in [0, \frac{\pi}{2}] \ .$$

Hier ist $R \approx 6370\,\text{km}$ der Erdradius; die Flughöhe des Flugzeugs über der Erdoberfläche ist demgegenüber vernachlässigbar.
Für $f(\gamma(\lambda))$ errechnet man

$$f(\gamma(\lambda)) = c[1 + \cos(4 \arctan \frac{\sin\lambda}{\cos\lambda})] = c[1 + \cos(4\lambda)] \ .$$

Wegen $\dot{\gamma}(\lambda) = \frac{R}{\sqrt{2}}(-\sin\lambda, \cos\lambda, 0)^T$ ist

$$|\dot{\gamma}(\lambda)| = \frac{R}{\sqrt{2}} \sqrt{\sin^2\lambda + \cos^2\lambda} = \frac{R}{\sqrt{2}} \ .$$

Damit errechnet man die gesamte während des Fluges abgegebene Schadstoffmenge mit dem Kurvenintegral zu

$$M = \int_\gamma f \, ds = \int_0^{\frac{\pi}{2}} c[1 + \cos(4\lambda)] \frac{R}{\sqrt{2}} \, d\lambda = \frac{cR}{\sqrt{2}} \frac{\pi}{2} \ .$$

Schritte zur Berechnung des skalaren Kurvenintegrals einer Funktion:

1) Parametrisierung der Kurve $\gamma : [t_a, t_e] \to \mathbb{R}^n$

2) Berechnung der Funktionswerte $f(\gamma(t))$ der Belegungsfunktion

3) Berechnung von $|\dot{\gamma}(t)|$

4) Berechnung des Kurvenintegrals $\int_\gamma f\, ds = \int_{t_a}^{t_e} f(\gamma(t))|\dot{\gamma}(t)|\, dt$.

Satz 7.1. *(Rechenregeln für Kurvenintegrale und Mittelwertsatz)*
Sei γ eine Kurve und $f,\, g : \mathbb{R}^n \supset \gamma([t_a, t_e]) \to \mathbb{R}$ stetige Funktionen und $\alpha \in \mathbb{R}$, dann gelten die Regeln

(i) $\int_\gamma (f+g)ds = \int_\gamma f\, ds + \int_\gamma g\, ds$ (Additivität des Integrals),

(ii) $\int_\gamma \alpha f\, ds = \alpha \int_\gamma f\, ds$ (Homogenität des Integrals),

(iii) $\int_\gamma f\, ds = f(\gamma(\tau)) \cdot L$ (Mittelwertsatz);

dabei ist L die Länge der Kurve und $\gamma(\tau)$ ein geeigneter Kurvenpunkt.

7.5 Vektorielles Kurvenintegral – Arbeitsintegral

Sei $\mathbf{k}$ ein auf einer vorgegebenen Kurve γ definiertes Vektorfeld $\mathbf{k} : \mathbb{R}^n \supset \gamma([t_a, t_e]) \to \mathbb{R}^n$. Zur Veranschaulichung setze man $n = 3$ und stelle sich $\mathbf{k}$ als Kraftfeld vor. Möchte man eine punktförmige Masse, d.h. die Idealisierung eines endlich ausgedehnten Objektes mit einer Masse m, dessen räumliche Ausdehnung gegenüber der Länge der Kurve vernachlässigbar ist (ein Beispiel wäre eine Rakete auf dem Weg zum Mond), oder eine Punkt-Ladung entlang der Kurve γ durch das Kraftfeld bzw. durch ein elektrisches Feld bewegen, muss Arbeit geleistet werden. Aus dem Physikunterricht wissen wir, dass sich die Arbeit als Produkt der Kraft und des Weges ergibt. Die Arbeit ΔA, die auf einem sehr kurzen Wegstück Δs bei der Bewegung der Masse durch das Kraftfeld $\mathbf{k}$ verrichtet wird, kann man als Produkt der Tangentialkomponente von $\mathbf{k}$, also der in Kurvenrichtung wirksamen Komponente des Kraftfeldes, mit dem Wegstück Δs

$$\Delta A = k_t \Delta s$$

verstehen. Die Tangentialkomponente k_t der Kraft in Richtung der Kurve ergibt sich durch das Skalarprodukt

$$k_t = \mathbf{k} \cdot \mathbf{t} \quad \text{mit} \quad \mathbf{t} = \frac{\dot{\gamma}(t)}{|\dot{\gamma}(t)|}\ .$$

In der Abb. 7.4 ist diese Situation skizziert. Auf der Bahnkurve $\gamma(t)$ eines im Kraftfeld $\mathbf{k}$ bewegten Objekts ist durch wachsende Werte des Parameters t eine Richtung definiert. In dieser Richtung wächst auch die Bogenlänge s; der Tangentenvektor $\dot{\gamma}(t)$ zeigt ebenfalls in diese Richtung. $\mathbf{k}$ habe im Kurvenpunkt $\gamma(t)$ eine in Richtung des Tangenteneinheitsvektors $\mathbf{t}$ positive Komponente k_t (d.h. $\mathbf{k} \cdot \mathbf{t} > 0$). Bei Bewegungen um ein Wegstück Δs in Richtung wachsender t bzw.

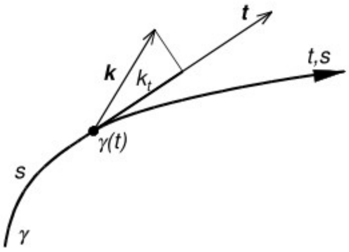

Abb. 7.4. Kraftvektor **k** und Tangentialkomponente k_t, Kurventangentenvektor **t**

s ist $\Delta s > 0$, also wird vom Kraftfeld die Arbeit $\Delta A = k_t \Delta s > 0$ geleistet. Ist dagegen $k_t < 0$ im Punkt $\gamma(t)$, so leistet das Kraftfeld Arbeit, wenn $\Delta s < 0$ ist, d.h. bei einer Bewegung in Richtung fallender t oder s: $\Delta A = k_t \Delta s > 0$. Will man auch in diesem Fall eine Bewegung in Richtung wachsender t oder s erreichen, so ist $\Delta A = k_t \Delta s < 0$, und für diese Bewegung muss gegen das Kraftfeld **k** Arbeit geleistet werden.

Man macht sich dies leicht klar am Beispiel des senkrechten Fallens oder Hebens eines Körpers (Masse m) im Erdschwerefeld. Unabhängig von der Orientierung der Kurve $\gamma(t)$ leistet das Erdschwerefeld Arbeit ($\Delta A > 0$), wenn der Körper fällt, wie es sein muss.

Für die Arbeit, die das Feld **k** an der Stelle $\gamma(t)$ bei Verschiebung eines Körpers um ein kleines Wegstück $\Delta s = |\dot{\gamma}(t)| \Delta t$ längs der Kurve γ leistet, gilt

$$\begin{aligned}\Delta A &= k_t(\gamma(t))\Delta s = \mathbf{k}(\gamma(t)) \cdot \mathbf{t}(\gamma(t))\, \Delta s \\ &= \mathbf{k}(\gamma(t)) \cdot \frac{\dot{\gamma}(t)}{|\dot{\gamma}(t)|}\, \Delta s = \mathbf{k}(\gamma(t)) \cdot \dot{\gamma}(t)\, \Delta t\ .\end{aligned}$$

Hieraus leitet man auf dem üblichen Weg (RIEMANNsche Summen, Folge immer feiner werdender Zerlegungen des Parameterintervalls $[t_a, t_e]$, Grenzübergang, vgl. die Betrachtungen beim skalaren Kurvenintegral) die Definition des vektoriellen Kurvenintegrals ab: Ist **k** ein Kraftfeld, so legen die obigen Überlegungen die Bezeichnung Arbeitsintegral nahe. Es sei aber darauf hingewiesen, dass diese Deutung keineswegs zwingend ist; bei **k** kann es sich z.B. auch um das Vektorfeld der Strömungsgeschwindigkeit eines Fluids handeln.

Definition 7.8. (Arbeitsintegral)
Sei $\gamma : [t_a, t_e] \to \mathbb{R}^n$ eine Kurve und **k** ein auf γ definiertes stetiges Vektorfeld $\mathbf{k} : \mathbb{R}^n \supset \gamma([t_a, t_e]) \to \mathbb{R}^n$. Dann wird das **Integral des Vektorfeldes** (vektorielles Kurvenintegral) entlang der Kurve γ, das auch **Arbeitsintegral** genannt wird, mit $\int_\gamma \mathbf{k} \cdot \mathbf{ds}$ bezeichnet und durch

$$\int_\gamma \mathbf{k} \cdot \mathbf{ds} := \int_{t_a}^{t_e} (\mathbf{k}(\gamma(t)) \cdot \dot{\gamma}(t))\, dt \tag{7.11}$$

definiert. $\mathbf{ds} = \dot{\gamma}(t)\, dt$ bezeichnet man als **vektorielles Bogenelement**. Besteht die Kurve γ aus den m Kurvenstücken $\gamma_1, ..., \gamma_m$, so definiert man

$$\int_\gamma \mathbf{k} \cdot \mathbf{ds} := \sum_{i=1}^{m} \int_{\gamma_i} \mathbf{k} \cdot \mathbf{ds} \, .$$

Wenn γ eine geschlossene Kurve ist, d.h. $\gamma(t_a) = \gamma(t_e)$ gilt, dann verwendet man statt der Bezeichnung $\int_\gamma \mathbf{k} \cdot \mathbf{ds}$ auch die Symbolik

$$\oint_\gamma \mathbf{k} \cdot \mathbf{ds} \, .$$

Man nennt das vektorielle Kurvenintegral auch **Kurven- oder Linienintegral 2. Art**. Für vektorielle Kurvenintegrale über Vektorfelder $\mathbf{k}$ und Kurven γ im $\mathbb{R}^2$ oder $\mathbb{R}^3$ ($\gamma([t_a, t_e]) \subset \mathbb{R}^2$ oder $\mathbb{R}^3$) findet man in der Literatur auch die Bezeichnung

$$\int_A^E (P \, dx + Q \, dy + R \, dz) \, . \tag{7.12}$$

Dabei ist

$$P(x, y, z)\mathbf{e}_1 + Q(x, y, z)\mathbf{e}_2 + R(x, y, z)\mathbf{e}_3 = \mathbf{k}(x, y, z) \, ,$$

und mit $\gamma(t) = (\gamma_1(t), \gamma_2(t), \gamma_3(t))^T$ gilt $dx = \dot{\gamma}_1(t) \, dt$, $dy = \dot{\gamma}_2(t) \, dt$, $dz = \dot{\gamma}_3(t) \, dt$. Es ist $\gamma(t_a) = A, \gamma(t_b) = E$. Damit ist (7.12) nur eine andere Bezeichnung für unser $\int_\gamma \mathbf{k} \cdot \mathbf{ds}$ aus Definition 7.8.

Satz 7.2. *(Rechenregeln für Kurvenintegrale 2. Art)*
Sei γ eine Kurve im $\mathbb{R}^n$ und seien $\mathbf{v}, \mathbf{v}_1, \mathbf{v}_2 : \mathbb{R}^n \supset \gamma([t_a, t_e]) \to \mathbb{R}^n$ stetige Vektorfelder und $\alpha \in \mathbb{R}$. Dann gelten die Regeln

(i) $\int_\gamma (\mathbf{v}_1 + \mathbf{v}_2) \cdot \mathbf{ds} = \int_\gamma \mathbf{v}_1 \cdot \mathbf{ds} + \int_\gamma \mathbf{v}_1 \cdot \mathbf{ds}$,

(ii) $\int_\gamma \alpha \mathbf{v} \cdot \mathbf{ds} = \alpha \int_\gamma \mathbf{v} \cdot \mathbf{ds}$.

(iii) Ist γ^* die Kurve, die aus γ durch Umkehrung des Durchlaufsinns entsteht, d.h., $\gamma^*(t) := \gamma(t_a + t_e - t)$, $t \in [t_a, t_e]$, so folgt

$$\int_{\gamma^*} \mathbf{v} \cdot \mathbf{ds} = - \int_\gamma \mathbf{v} \cdot \mathbf{ds} \, .$$

Algorithmus zur Berechnung des Arbeitsintegrals:

1) Parametrisierung der Kurve $\gamma : [t_a, t_e] \to \mathbb{R}^n$

2) Berechnung der Werte $\mathbf{k}(\gamma(t))$ in den Kurvenpunkten

3) Berechnung des Tangentenvektors $\dot{\gamma}(t)$

4) Berechnung des Kurvenintegrals

$$\int_\gamma \mathbf{k} \cdot \mathbf{ds} = \int_{t_a}^{t_e} (\mathbf{k}(\gamma(t)) \cdot \dot{\gamma}(t)) \, dt \, .$$

Der eben beschriebene Algorithmus macht noch einmal deutlich, dass das Arbeitsintegral des Vektorfeldes **k** entlang der Kurve γ gleich dem skalaren Kurvenintegral der Tangentialkomponente des Vektorfeldes an der Kurve, nämlich $k_t = \mathbf{k} \cdot \dot{\gamma}(t)$ ist. Damit wird auch deutlich, dass das skalare Bogenelement ds gleich dem Betrag des vektoriellen Bogenelements **ds** ist.

Beispiele:
1) Ein Hausmann ($80\,\mathrm{kg}$ Masse) muss seine Fenster putzen. Welche Arbeit leistet er, wenn er mit einem 10 kg schweren Wassereimer in 5 Sekunden auf die Leiter steigt, die 2 m hoch ist, und 1 m von der Hauswand entfernt steht (Leiter ist $\sqrt{5}\,\mathrm{m}$ lang und bildet mit der Hauswand ein rechtwinkliges Dreieck mit den 2 und 1 m langen Katheten)?
Diese Aufgabe bedeutet die Berechnung eines Integrals eines Vektorfeldes entlang einer Kurve. Für die Kurve γ ergibt sich $\gamma(\alpha) = \binom{(\alpha-1)\mathrm{m}}{(2\alpha)\mathrm{m}}$, $\alpha \in [0{,}1]$. Das Kraftfeld, durch das sich der Hausmann mit seinem Eimer beim Aufstieg bewegt, ergibt sich nach NEWTON als Produkt der Masse $m = 90\,\mathrm{kg}$ (Eigenmasse des Hausmanns plus Wassereimer) und der Erdbeschleunigung $\mathbf{g} = (0, -9{,}81\,\frac{\mathrm{m}}{\mathrm{s}^2})^T$,

$$\mathbf{k} = \mathrm{m}\mathbf{g} = \begin{pmatrix} 0 \\ -90 \cdot 9{,}81\,\frac{\mathrm{kg\,m}}{\mathrm{s}^2} \end{pmatrix} .$$

Für den Tangentenvektor $\dot{\gamma}(\alpha)$ ergibt sich $\dot{\gamma}(\alpha) = \binom{1\mathrm{m}}{2\mathrm{m}}$. Damit ergibt sich für die vom Kraftfeld **k** geleistete Arbeit

$$\begin{aligned} A &= \int_\gamma \mathbf{k} \cdot \mathbf{ds} = \int_0^1 \mathbf{k}(\gamma(\alpha)) \cdot \dot{\gamma}(\alpha)\, d\alpha \\ &= \int_0^1 (-882{,}9)\frac{\mathrm{kg\,m}}{\mathrm{s}^2} 2\mathrm{m}\, d\alpha = -1765{,}8\,\frac{\mathrm{kg\,m}}{\mathrm{s}^2}\mathrm{m} = -1765{,}8\,\mathrm{Nm} . \end{aligned}$$

Der Hausmann muss daher die Arbeit $1765{,}8\,\mathrm{Nm}$ leisten, wenn er sich und den Eimer gegen das Schwerefeld auf die Leiter hieven will. Dabei ist es uninteressant, wie lange er dafür braucht, denn wir haben ja nach der Arbeit und nicht nach der Leistung gefragt.
2) Es ist die Arbeit zu berechnen, die ein Satellit auf einer Umrundung eines Planeten (kreisförmig über dem Äquator $z = 0$) mit dem Zentralkraftfeld $\mathbf{K}(\mathbf{x}) = \frac{k}{|\mathbf{x}|^3}\mathbf{x}$ leistet. Der Planet hat dabei den Radius R, und der Satellit fliegt in einer Höhe H über der Planetenoberfläche (in der Konstante $k < 0$ sind die Massen des Planeten und des Satelliten berücksichtigt). Für die Flugkurve erhalten wir $\gamma(\phi) = ((R+H)\cos\phi, (R+H)\sin\phi, 0)^T, \phi \in [0{,}2\pi]$. Für die Arbeit des Feldes $\mathbf{K}(\mathbf{x})$ ergibt sich

$$\begin{aligned} A &= \int_0^{2\pi} \frac{k}{(R+H)^3} \begin{pmatrix} (R+H)\cos\phi \\ (R+H)\sin\phi \\ 0 \end{pmatrix} \cdot \begin{pmatrix} -(R+H)\sin\phi \\ (R+H)\cos\phi \\ 0 \end{pmatrix} d\phi \\ &= \frac{k}{R+H} \int_0^{2\pi} [-\cos\phi\sin\phi + \sin\phi\cos\phi]\, d\phi = 0 , \end{aligned}$$

d.h. es wird weder vom Kraftfeld **K** noch vom Satelliten Arbeit geleistet: Kraftvektor und Tangentenvektor der Flugkurve stehen senkrecht aufeinander.

7.6 Stammfunktion eines Gradientenfeldes

Wir hatten im Abschnitt 7.3 schon den Begriff der Stammfunktion oder des Potentials eines Gradientenfeldes eingeführt. f heißt Stammfunktion eines Vektorfeldes $\mathbf{v}$, wenn $\operatorname{grad} f = \mathbf{v}$ gilt. Im Folgenden wird sich zeigen, dass die Kenntnis einer Stammfunktion die Berechnung von Arbeitsintegralen wesentlich erleichtert.

Satz 7.3. *(erster Hauptsatz für Potentialfelder)*

Sei $D \subset \mathbb{R}^n$ ein Gebiet und $\mathbf{v} : D \to \mathbb{R}^n$ ein Potentialfeld mit der Stammfunktion f. Dann gilt für jede in D verlaufende Kurve $\gamma : [t_a, t_e] \to \mathbb{R}^n$

$$\int_\gamma \mathbf{v} \cdot \mathbf{ds} = f(\gamma(t_e)) - f(\gamma(t_a)) \tag{7.13}$$

Beweis: Es gilt unter Nutzung der Kettenregel

$$\begin{aligned}\int_\gamma \mathbf{v} \cdot \mathbf{ds} &= \int_{t_a}^{t_e} \mathbf{v}(\gamma(t)) \cdot \dot{\gamma}(t)\, dt = \int_{t_a}^{t_e} \operatorname{grad} f(\gamma(t)) \cdot \dot{\gamma}(t)\, dt \\ &= \int_{t_a}^{t_e} \frac{d\, f(\gamma(t))}{d\, t}\, dt = f(\gamma(t_e)) - f(\gamma(t_a)) \quad .\end{aligned}$$

☐

Der folgende Satz liefert äquivalente Aussagen zu Kurvenintegralen und Gradientenfeldern, die möglicherweise unnötige Arbeit ersparen.

Satz 7.4. *(Kurvenintegrale und Potentialfelder)*

Sei $D \subset \mathbb{R}^n$ ein Gebiet, $\gamma : [t_a, t_e] \to D$ eine Kurve in D und $\mathbf{v} : D \to \mathbb{R}^n$ ein stetiges Vektorfeld, dann sind die folgenden Aussagen äquivalent:

1) *Für alle Kurven γ hängt das Kurvenintegral $\int_\gamma \mathbf{v} \cdot \mathbf{ds}$ nur vom Anfangs- und Endpunkt der Kurve ab. Diese Eigenschaft heißt* **Wegunabhängigkeit** *des Kurvenintegrals.*
2) *Für alle geschlossenen Kurven γ, d.h. $\gamma(t_a) = \gamma(t_e)$, gilt $\oint_\gamma \mathbf{v} \cdot \mathbf{ds} = 0$.*
3) *$\mathbf{v}$ ist ein Potentialfeld.*

Beweis: Mit der Eigenschaft

$$\int_{\gamma^*} \mathbf{v} \cdot \mathbf{ds} = -\int_\gamma \mathbf{v} \cdot \mathbf{ds} \,.$$

für die Kurve γ^*, deren Endpunkt mit dem Anfangspunkt von γ und deren Anfangspunkt mit dem Endpunkt von γ übereinstimmt, erhält man sofort für die Kurve $\gamma^\# = \gamma \cup \gamma^*$

$$\oint_{\gamma^\#} \mathbf{v} \cdot \mathbf{ds} = \int_\gamma \mathbf{v} \cdot \mathbf{ds} + \int_{\gamma^*} \mathbf{v} \cdot \mathbf{ds} = \int_\gamma \mathbf{v} \cdot \mathbf{ds} - \int_\gamma \mathbf{v} \cdot \mathbf{ds} = 0 \,.$$

Damit ist 1) $\to$ 2) bewiesen. Betrachtet man nun γ^* als die Kurve, die aus γ durch Umkehrung des Durchlaufsinns entsteht, d.h. $\gamma^*(t) := \gamma(t_a + t_e - t)$, $t \in [t_a, t_e]$, so folgt aus 2) die Wegunabhängigkeit. Der Nachweis 3) $\to$ 2) ist offensichtlich. Der Nachweis 2) $\to$ 3) ist etwas komplizierter. Man betrachtet dazu ein $\mathbf{x}_0 \in D$ und kann in D ein $\mathbf{x}$ finden, so dass ein Polygonzug $\gamma_x = [[\mathbf{x}_0, \mathbf{x}_1], [\mathbf{x}_1, \mathbf{x}_2]...[\mathbf{x}_k, \mathbf{x}]]$ existiert, der vollständig im Gebiet D liegt. Da D offen ist, gibt es für jedes $\mathbf{x} \in D$ ein $r > 0$ mit $\mathbf{x} + \mathbf{z} \in D$ für alle $\mathbf{z} \in \mathbb{R}^n$ mit $|\mathbf{z}| < r$. Wenn wir mit $\mathbf{e}_j$ den $j-$ten Einheitsvektor bezeichnen, so ist für $h \in \mathbb{R}$ mit $h < r$ stets $\mathbf{x} + h\mathbf{e}_j \in D$. Aufgrund von 1) ist die Funktion

$$f(\mathbf{x}) := \int_{\gamma_x} \mathbf{v} \cdot \mathbf{ds} \quad \text{für} \quad \mathbf{x} \in D \tag{7.14}$$

unabhängig vom gewählten Polygonzug γ_x. Wenn wir die $j-$te Komponentenfunktion von $\mathbf{v}$ mit v_j bezeichnen, gilt $v_j = \mathbf{v} \cdot \mathbf{e}_j$. Wegen der Wegunabhängigkeit des Kurvenintegrals gilt

$$f(\mathbf{x} + h\mathbf{e}_j) = \int_{\gamma_x} \mathbf{v} \cdot \mathbf{ds} + \int_{[\mathbf{x}, \mathbf{x}+h\mathbf{e}_j]} \mathbf{v} \cdot \mathbf{ds}\ ,$$

und damit folgt

$$\begin{aligned} \frac{f(\mathbf{x} + h\mathbf{e}_j) - f(\mathbf{x})}{h} &= \frac{1}{h} \int_{[\mathbf{x}, \mathbf{x}+h\mathbf{e}_j]} \mathbf{v} \cdot \mathbf{ds} = \frac{1}{h} \int_0^1 \mathbf{v}(\mathbf{x} + th\mathbf{e}_j) \cdot \mathbf{e}_j \, dt \\ &= \frac{1}{h} \int_0^1 v_j(\mathbf{x} + th\mathbf{e}_j) \, dt = v_j(\mathbf{x} + \tau h\mathbf{e}_j) \end{aligned}$$

aufgrund des Mittelwertsatzes mit einer geeigneten Zahl $\tau \in [0{,}1]$. Wegen der Stetigkeit der Komponentenfunktionen v_j ergibt sich nun

$$\lim_{h \to 0} \frac{f(\mathbf{x} + h\mathbf{e}_j) - f(\mathbf{x})}{h} = v_j(\mathbf{x}) \quad \text{und damit} \quad \operatorname{grad} f(\mathbf{x}) = \mathbf{v}(\mathbf{x})\ .$$

□

Im Beweis des Satzes 7.4 wurde mit der Formel (7.14) eine Möglichkeit aufgezeigt, ausgehend von einem Potentialfeld $\mathbf{v}$ eine Stammfunktion f zu konstruieren. Bevor man allerdings mit dem Integrieren beginnen kann, muss man wissen, ob es sich überhaupt lohnt, d.h., man muss wissen, ob $\mathbf{v}$ ein Gradientenfeld ist. Im Folgenden sollen hinreichende Kriterien für Gradientenfelder besprochen werden. Dazu wird der Begriff der Doppelpunktfreiheit einer Kurve und die Eigenschaft eines Gebietes benötigt, einfach zusammenhängend zu sein.

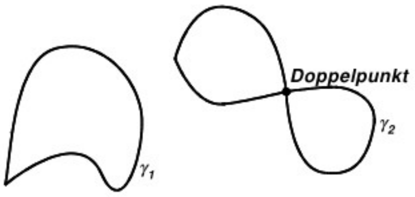

Abb. 7.5. Doppelpunkt freie Kurve γ_1 und Kurve mit Doppelpunkt γ_2

Definition 7.9. (Doppelpunktfreiheit)
Eine Kurve $\gamma : [t_a, t_e] \to \mathbb{R}^n$ heißt **doppelpunktfrei**, wenn

$$\gamma(t_1) \neq \gamma(t_2) \quad \text{für} \quad t_1 \neq t_2,\ t_1, t_2 \in (t_a, t_e)$$

und $\gamma(t_a) \neq \gamma(t)$ für $t \in (t_a, t_e)$ gilt.

Der Begriff des einfach zusammenhängenden Gebiets soll anschaulich erklärt werden, da hier auf komplizierte topologische Betrachtungen verzichtet werden soll. Der Begriff "Gebiet" enthielt bereits die Eigenschaft einer Menge, "zusammenhängend" zu sein. Wir spezialisieren nun auf "einfach zusammenhängend":

Definition 7.10. (einfach zusammenhängendes Gebiet)
Ein Gebiet $D \subset \mathbb{R}^n$ $(n \geq 2)$ heißt **einfach zusammenhängend** oder **kontrahierbar**, wenn jede geschlossene, doppelpunktfreie Kurve in D stetig auf einen Punkt $\mathbf{x} \in D$ zusammengezogen werden kann.

Im $\mathbb{R}^2$ bedeutet "einfach zusammenhängend", dass das Gebiet keine Löcher haben darf. Ein Kreisring ist also nicht einfach zusammenhängend. Im $\mathbb{R}^3$ kann ein Gebiet ein Loch haben, z.B. ist eine Kugelschale einfach zusammenhängend. Andererseits ist ein Torus nicht einfach zusammenhängend.

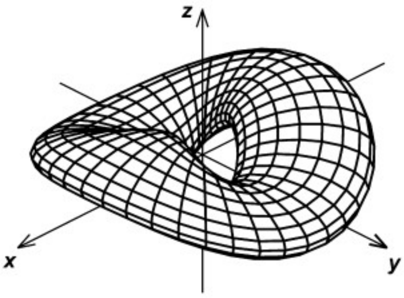

Abb. 7.6. Torus als nicht einfach zusammenhängendes Gebiet im $\mathbb{R}^3$

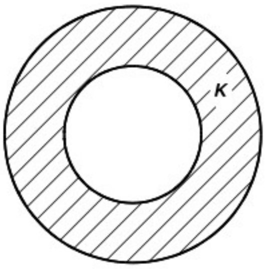

Abb. 7.7. Kreisring als nicht einfach zusammenhängendes Gebiet im $\mathbb{R}^2$

Es ist offensichtlich, dass jedes **konvexe** Gebiet **einfach zusammenhängend ist** (vgl. Definition 5.8).

Bevor wir ein weiteres Kriterium zur Entscheidung, ob ein Vektorfeld $\mathbf{v}$ ein Potentialfeld ist, formulieren, führen wir eine kurze Rechnung durch. Wenn Ψ ein differenzierbares Skalarfeld $\Psi : D \to \mathbb{R},\ D \subset \mathbb{R}^3$ ist, dann stellt man die Identität

$$\operatorname{rot}(\operatorname{grad}\Psi) = \mathbf{0} \tag{7.15}$$

fest. D.h. wenn ein Vektorfeld die gewünschte Darstellung $\mathbf{v} = \operatorname{grad}\Psi$ besitzt, dann gilt notwendigerweise die Beziehung (7.15). Mit dieser Erkenntnis wird nachfolgend ein Kriterium für Potentialfelder formuliert, das sogar notwendig und hinreichend ist.

Satz 7.5. *(Kriterium für die Existenz eines Potentials, zweiter Hauptsatz für Potentialfelder)*

Sei $D \subset \mathbb{R}^n$ ein einfach zusammenhängendes Gebiet ($n \geq 2$) und $\mathbf{v} : D \to \mathbb{R}^n$ ein stetig differenzierbares Vektorfeld. Dann ist $\mathbf{v}$ genau dann ein Potentialfeld, wenn die JACOBI-Matrix $J_{\mathbf{v}}(\mathbf{x})$ für alle $\mathbf{x} \in D$ symmetrisch ist, also

$$J_{\mathbf{v}}(\mathbf{x}) = J_{\mathbf{v}}(\mathbf{x})^T$$

gilt. Die Forderung nach der Symmetrie der JACOBI-Matrix nennt man auch **Integrabilitätsbedingung**. *Für den Fall $n = 3$ ist die Symmetrie der JACOBI-Matrix gleichbedeutend mit der Gleichung*

$$\textit{rot}\,\mathbf{v}(\mathbf{x}) = \mathbf{0} \quad .$$

Beweis: Es soll nur gezeigt werden, dass für ein Potentialfeld $\mathbf{v}$ die JACOBI-Matrix symmetrisch ist, denn der Beweis der anderen Richtung des Satzes wird analog zum Beweis des Satzes 7.4 geführt. Da $\mathbf{v}$ stetig differenzierbar ist, und ein f mit $\operatorname{grad} f = \mathbf{v}$ existiert, folgt die zweifache stetige Differenzierbarkeit von f. Damit gilt nach dem Satz von SCHWARZ

$$\frac{\partial v_i}{\partial x_j} = \frac{\partial^2 f}{\partial x_i \partial x_j} = \frac{\partial^2 f}{\partial x_j \partial x_i} = \frac{\partial v_j}{\partial x_i} \;,$$

also

$$J_{\mathbf{v}}(\mathbf{x}) = J_{\mathbf{v}}(\mathbf{x})^T \quad .$$

□

Mit dem Satz 7.5 liegt nun ein leicht zu überprüfendes Kriterium für Potentialfelder vor.

Beispiele:
1) Betrachten wir das Vektorfeld

$$\mathbf{v}(x, y, z) = \begin{pmatrix} yz^2 \cos(xy) + 2xy \\ xz^2 \cos(xy) + x^2 + z \\ 2z \sin(xy) + y + 2z \end{pmatrix} \;,$$

das auf ganz $\mathbb{R}^3$ und damit auf einem einfach zusammenhängenden Gebiet definiert ist. Nach dem Kriterium des Satzes 7.5 ist $\mathbf{v}$ ein Potentialfeld, wenn $\operatorname{rot} \mathbf{v}(\mathbf{x}) = \mathbf{0}$ gilt. Für die Rotation errechnet man

$$\begin{pmatrix} 2zx\cos(xy) + 1 - [x2z\cos(xy) + 1] \\ y2z\cos(xy) - 2zy\cos(xy) \\ z^2\cos(xy) - xyz^2\sin(xy) + 2x - [z^2\cos(xy) - yz^2x\sin(xy) + 2x] \end{pmatrix} = \mathbf{0} \;,$$

und damit ist $\mathbf{v}$ ein Potentialfeld.

2) Wenn wir das Wirbelfeld $\mathbf{v}(x,y) = \frac{1}{x^2+y^2}\begin{pmatrix} -y \\ x \end{pmatrix}$ auf $D = \mathbb{R}^2 \setminus (0{,}0)$ betrachten, haben wir mit D ein Gebiet, das **nicht einfach zusammenhängend** ist. Wenn wir als Kurve γ den Einheitskreis betrachten ($\gamma(\phi) = (\cos\phi, \sin\phi)^T,\ \phi \in [0{,}2\pi]$), dann ergibt sich

$$\oint_\gamma \mathbf{v} \cdot \mathbf{ds} = 2\pi \neq 0\ ,$$

womit $\mathbf{v}$ auf D nach Satz 7.4 kein Potentialfeld ist. Die Berechnung der JACOBI-Matrix ergibt mit

$$J_{\mathbf{v}}(x,y) = \begin{pmatrix} 2\frac{yx}{(x^2+y^2)^2} & -\frac{-y^2+x^2}{(x^2+y^2)^2} \\ -\frac{-y^2+x^2}{(x^2+y^2)^2} & -2\frac{yx}{(x^2+y^2)^2} \end{pmatrix}$$

eine **symmetrische Matrix**. Allerdings kann das Kriterium aus Satz 7.5 in $\mathbb{R}^2 \setminus \mathbf{0}$ nicht angewandt werden, da D nicht einfach zusammenhängend ist. Wenn $\mathbf{v}$ auf $\mathbb{R}^2 \setminus (0{,}0)$ eine Stammfunktion hätte, käme dafür nur $f(x,y) = \arctan\frac{y}{x} = \phi$ in Frage, wegen

$$f_x = \frac{-y}{x^2+y^2}\ , \qquad f_y = \frac{x}{x^2+y^2}\ .$$

Es liegt mit f aber kein Potential vor, weil $\arctan\frac{y}{x}$ in $\mathbb{R}^2 \setminus \mathbf{0}$ nicht eindeutig definiert werden kann.

Genauer: In einem Punkt P (o.B.d.A. im 1. Quadranten der (x,y)-Ebene) habe die Funktion $f(x,y)$ den Wert $f(P) = \phi$ mit $\tan\phi = \frac{y}{x}$. Lässt man P auf einer geschlossenen Kurve um $(0{,}0)$ herum laufen, so kommt P nach einer ϕ-Änderung um 2π mit sich selbst zur Deckung. Wird f dabei immer stetig fortgesetzt, so erhält man $f(P) = f(P) + 2\pi$ bzw. $\tan(\phi + 2\pi) = \tan\phi = \frac{y}{x}$. f ist also nicht eindeutig und kommt deshalb als Stammfunktion nicht in Frage. Aber in jedem einfach zusammenhängenden Gebiet D, das den Ursprung $\mathbf{0}$ nicht enthält, ist $\mathbf{v}$ Potentialfeld mit der Stammfunktion $f(x,y) = \arctan\frac{y}{x} (= \phi)$. In solchen Gebieten gibt es keine geschlossenen Kurven, auf denen sich ϕ um 2π ändern kann (Abb. 7.8).

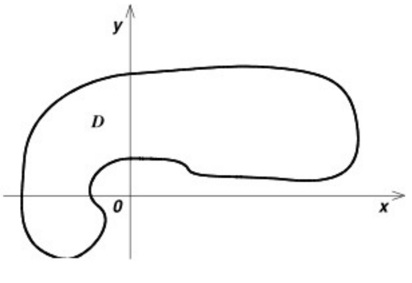

Abb. 7.8. Einfach zusammenhängendes Gebiet D mit $(0{,}0) \notin D$

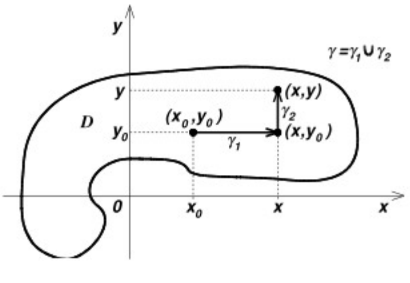

Abb. 7.9. Zur Methode mit dem Kurvenintegral

7.7 Berechnungsmethoden für Stammfunktionen

Wir haben weiter oben schon die Vorteile der Kenntnis einer Stammfunktion erkannt, wenn man z.B. an die Integration des Potentialfeldes entlang einer Kurve denkt. Mit dem folgenden Algorithmus soll nun für das Potentialfeld aus Beispiel 1 eine Stammfunktion bestimmt werden. Man nennt die Methode auch **Ansatzmethode**. Wir gehen davon aus, dass

$$\operatorname{grad} f(x,y,z) = \begin{pmatrix} f_x \\ f_y \\ f_z \end{pmatrix} = \begin{pmatrix} yz^2\cos(xy) + 2xy \\ xz^2\cos(xy) + x^2 + z \\ 2z\sin(xy) + y + 2z \end{pmatrix} = \mathbf{v}(x,y,z) \tag{7.16}$$

gelten muss.

1) Aus der Gleichung

$$f_x = yz^2\cos(xy) + 2xy$$

folgt mittels Integration nach x

$$f(x,y,z) = yz^2\frac{\sin(xy)}{y} + x^2y + C(y,z)\ , \tag{7.17}$$

wobei $C(y,z)$ eine von x unabhängige Funktion sein soll.

2) Das Ergebnis (7.17) wird nun nach y partiell differenziert, man erhält dann

$$f_y = z^2x\cos(xy) + x^2 + C_y(y,z)\ ,$$

so dass sich zur Bestimmung von $C(y,z)$ mit (7.16) die Gleichung

$$z^2x\cos(xy) + x^2 + C_y(y,z) = xz^2\cos(xy) + x^2 + z \quad \text{bzw.} \quad C_y(y,z) = z$$

ergibt. Die Integration nach y ergibt

$$C(y,z) = zy + D(z)\ ,$$

wobei $D(z)$ nicht mehr von x und y, sondern nur noch von z abhängt. Aus (7.17) erhält man damit

$$f(x,y,z) = z^2\sin(xy) + x^2y + zy + D(z) \tag{7.18}$$

3) Das Ergebnis (7.18) wird nun partiell nach z differenziert, und man erhält

$$f_z = 2z\sin(xy) + y + D_z(z)\ ,$$

so dass sich zur Bestimmung von $D(z)$ mit (7.16) die Gleichung

$$2z\sin(xy) + y + D_z(z) = 2z\sin(xy) + y + 2z \quad \text{bzw.} \quad D_z(z) = 2z$$

ergibt. Die Integration nach z ergibt schließlich $D(z) = z^2 +$ const., so dass wir mit

$$f(x,y,z) = z^2\sin(xy) + x^2y + zy + z^2 + \text{const.}$$

eine Stammfunktion gefunden haben.

Die Punkte 1) bis 3) lassen sich in der beschriebenen Weise zur Berechnung einer Stammfunktion eines beliebigen vorgegebenen Potentialfeldes anwenden.

Im Beweis des Satzes 7.4 wurde mit

$$f(\mathbf{x}) := \int_{\gamma_x} \mathbf{v} \cdot \mathbf{ds} \quad \text{für} \quad \mathbf{x} \in D$$

eine Stammfunktion für ein vorgegebenes stetig differenzierbares Vektorfeld $\mathbf{v}$ definiert. Dabei war γ_x ein beliebiger in D liegender Polygonzug, der irgendeinen Punkt $\mathbf{x}_0 \in D$ mit dem Punkt $\mathbf{x} \in D$ verbindet. Will man die Stammfunktion f explizit bestimmen, muss man sich einen günstigen Punkt $\mathbf{x}_0 \in D$ und einen günstigen Polygonzug von $\mathbf{x}_0$ nach $\mathbf{x}$ in D suchen, für den sich das Kurvenintegral leicht berechnen lässt. Falls die Strecke

$$\gamma_x(t) = \mathbf{x}_0 + t(\mathbf{x} - \mathbf{x}_0) \quad t \in [0,1]$$

in D verläuft, hat man das Integral

$$f(\mathbf{x}) = \int_0^1 \mathbf{v}(\mathbf{x}_0 + t(\mathbf{x} - \mathbf{x}_0)) \cdot (\mathbf{x} - \mathbf{x}_0)\, dt$$

zu berechnen. Die beschriebene Methode zur Berechnung einer Stammfunktion nennt man **Methode mit dem Kurvenintegral**. Wir wollen diese Methode am Beispiel des Vektorfeldes $\mathbf{v}(x,y) = (\frac{-y}{x^2+y^2}, \frac{x}{x^2+y^2})^T$ auf einem einfach zusammenhängenden Gebiet D, das den Ursprung nicht enthält, erproben (Abb. 7.9).

$$\begin{aligned}
f(x,y) &= \int_{\gamma} \mathbf{v} \cdot \mathbf{ds} = \int_{\gamma_1} \mathbf{v} \cdot \mathbf{ds} + \int_{\gamma_2} \mathbf{v} \cdot \mathbf{ds} \\
&= \int_{x_0}^{x} \frac{-y_0}{\xi^2 + y_0^2} d\xi + \int_{y_0}^{y} \frac{x}{x^2 + \eta^2} d\eta \\
&= \arctan \frac{y_0}{\xi} \Big|_{x_0}^{x} + \arctan \frac{\eta}{x} \Big|_{y_0}^{y} \\
&= \arctan \frac{y_0}{x} - \arctan \frac{y_0}{x_0} + \arctan \frac{y}{x} - \arctan \frac{y_0}{x} \\
&= \arctan \frac{y}{x} - \arctan \frac{y_0}{x_0} = \arctan \frac{y}{x} + c\,.
\end{aligned}$$

7.8 Vektorpotentiale

Bei der Behandlung und Definition von Potentialfeldern und Potentialen hatten wir durch die Identität

$$\operatorname{rot}(\operatorname{grad} \Psi) = \mathbf{0}$$

für alle zweimal stetig differenzierbaren skalaren Funktionen Ψ ein Kriterium zur Überprüfung der Potentialfeldeigenschaft eines Vektorfeldes $\mathbf{v}$, d.h. die Forderung

$$\operatorname{rot} \mathbf{v} = \mathbf{0}\,,$$

erhalten. Wenn man die Divergenz der Rotation eines Vektorfeldes $\mathbf{w}$, also $\operatorname{div}(\operatorname{rot}\mathbf{w})$, berechnet, stellt man

$$\operatorname{div}(\operatorname{rot}\mathbf{w}) = 0$$

fest. Gibt es für ein vorgegebenes Vektorfeld $\mathbf{v}$ ein Vektorfeld $\mathbf{w}$ mit

$$\mathbf{v} = \operatorname{rot}\mathbf{w}\ ,$$

so muss notwendigerweise die Bedingung $\operatorname{div}\mathbf{v} = 0$ gelten. Diese Überlegungen führen auf den Begriff des Vektorpotentials.

Definition 7.11. (Vektorpotential)
Sei $\mathbf{v} : D \to \mathbb{R}^3,\ D \subset \mathbb{R}^3$, gegeben. Existiert ein differenzierbares Vektorfeld $\mathbf{w} : \mathbb{R}^3 \to \mathbb{R}^3$ mit

$$\mathbf{v} = \operatorname{rot}\mathbf{w}\ ,$$

so heißt $\mathbf{w}$ **Vektorpotential** von $\mathbf{v}$.

Die Vorüberlegungen zur Definition 7.11 führen auf das folgende Kriterium zur Entscheidung, ob ein vorgegebenes Vektorfeld $\mathbf{v}$ ein Vektorpotential besitzt.

Satz 7.6. *(Kriterium für die Existenz eines Vektorpotentials)*

Sei $\mathbf{v} : D \to \mathbb{R}^3,\ D \subset \mathbb{R}^3$, ein differenzierbares Vektorfeld. Ist D eine offene konvexe Menge, dann ist die Bedingung

$$\operatorname{div}\mathbf{v} = 0$$

notwendig und hinreichend für die Existenz eines Vektorpotentials $\mathbf{w}$ mit $\mathbf{v} = \operatorname{rot}\mathbf{w}$. Statt der Forderung der Konvexität von D reicht hier auch die schwächere Forderung, dass D einfach zusammenhängend ist.

Bei der Berechnung von Vektorpotentialen gibt es eine Analogie zur Berechnung von skalaren Potentialen. Bei skalaren Potentialen war die Berechnung bis auf eine additive Konstante durch die Ansatzmethode und die Kurvenintegral-Methode immer möglich. Hat man ein Vektorpotential $\mathbf{w}_0$ von $\mathbf{v}$ mit $\mathbf{v} = \operatorname{rot}\mathbf{w}_0$ gefunden, und ist $\mathbf{w}_1$ ein Potentialfeld, dann ist $\mathbf{w} = \mathbf{w}_0 + \mathbf{w}_1$ ebenfalls ein Vektorpotential von $\mathbf{v}$, weil

$$\mathbf{v} = \operatorname{rot}\mathbf{w} = \operatorname{rot}\mathbf{w}_0 + \operatorname{rot}\mathbf{w}_1 = \operatorname{rot}\mathbf{w}_0$$

gilt, da $\operatorname{rot}\mathbf{w}_1 = \mathbf{0}$ für das Potentialfeld $\mathbf{w}_1$ ist. Vektorpotentiale sind also nur bis auf Potentialfelder eindeutig. Potentialfelder spielen bei Vektorpotentialen eine ähnliche Rolle wie die Konstanten bei skalaren Potentialen.

Will man für ein vorgegebenes Vektorfeld ein Vektorpotential berechnen, muss man mit einem geeigneten Ansatz beginnen. Im folgenden Beispiel soll dies demonstriert werden.

Beispiel: Für das auf ganz $\mathbb{R}^3$ definierte Vektorfeld $\mathbf{v}(x,y,z) = (xy, xz, -zy)^T$ stellen wir $\operatorname{div}\mathbf{v} = 0$ fest und damit die Existenz eines Vektorpotentials $\mathbf{w} = (w_1, w_2, w_3)^T$. Da $\mathbf{v} = \operatorname{rot}\mathbf{w}$ gelten muss, stehen die Gleichungen

$$xy = \frac{\partial w_3}{\partial y} - \frac{\partial w_2}{\partial z} \tag{7.19}$$

$$xz = \frac{\partial w_1}{\partial z} - \frac{\partial w_3}{\partial x} \tag{7.20}$$

$$-zy = \frac{\partial w_2}{\partial x} - \frac{\partial w_1}{\partial y} \tag{7.21}$$

zur Berechnung von w_1, w_2 und w_3 zur Verfügung. Das ist nicht eindeutig möglich. Wir fixieren $w_3 = c_3 = \text{const.}$ Damit erhält man nach Integration der Gleichung (7.19) nach z

$$w_2 = -xyz + C(x,y)\ .$$

Die Integration der Gleichung (7.20) ergibt

$$w_1 = x\frac{z^2}{2} + D(x,y)\ .$$

Man sieht nun, dass sich aus der dritten Gleichung (7.21) mit den bisherigen Ergebnissen für w_1 und w_2 die Beziehung

$$-zy = -zy + \frac{\partial C(x,y)}{\partial x} - \frac{\partial D(x,y)}{\partial y}$$

ergibt. Nun kann man $C(x,y)$ vorgeben und $D(x,y)$ durch

$$D(x,y) = \int \frac{\partial C(x,y)}{\partial x}\, dy$$

berechnen. Z.B. erhält man $D(x,y) = \sin y + c_1$ für $C(x,y) = x\cos y + c_2$. Für $C = \text{const.}$ folgt $D = \text{const.}$ Damit erhält man die Vektorpotentiale

$$\mathbf{u}(x,y,z) = \begin{pmatrix} x\frac{z^2}{2} + \sin y + c_1 \\ -xyz + x\cos y + c_2 \\ c_3 \end{pmatrix} \quad \text{bzw.} \quad \mathbf{w}(x,y,z) = \begin{pmatrix} x\frac{z^2}{2} + c_1 \\ -xyz + c_2 \\ c_3 \end{pmatrix}$$

mit reellen Konstanten c_1, c_2, c_3, und erkennt damit auch noch, dass $(\sin y, x\cos y, 0)^T$ ein Potentialfeld ist.

7.9 Aufgaben

1) Bilden Sie die Divergenz der NAVIER-STOKES-Gleichung (7.2) (bei $\nu = \text{const.}$) und vereinfachen Sie die Gleichung unter Nutzung der Gleichung (7.3), wobei eine entsprechende Glattheit des Vektorfeldes $\mathbf{v}$ und der skalaren Funktion p für die zu bildenden Ableitungen vorausgesetzt wird.

2) Berechnen Sie die Länge der Kurve

$$\gamma(t) = (t, e^t, 2)^T,\ t \in [0{,}4].$$

3) Berechnen Sie das skalare Kurvenintegral der Funktion $f(x,y,z) = \frac{x^2-y}{z}$ entlang dem Nordpolarkreis (arctic circle, geographische Breite $\phi_n = 67{,}5^o$, wobei der Äquator und der Nordpol die geographische Breite 0^o bzw. 90^o haben). Dabei nehmen wir die Erde als Kugel mit dem Radius $r = 6400\,km$ an.

4) Überprüfen Sie das Vektorfeld

$$\mathbf{w}(x,y,z) = \begin{pmatrix} yz\cos(xyz) + 2xz \\ xz\cos(xyz) + 2yz^2 \\ xy\cos(xyz) + x^2 + 2y^2z \end{pmatrix}$$

auf die Potentialfeldeigenschaft und berechnen Sie gegebenenfalls eine Stammfunktion.

5) Zeigen Sie, dass die folgenden Vektorfelder $\mathbf{v} : G \to \mathbb{R}^n$ eine symmetrische JACOBI-Matrix haben, aber keine Gradientenfelder in G sind. Woran liegt das?

$$(a)\ \mathbf{v}(x,y,z) = \tfrac{c}{x^2+y^2}\begin{pmatrix} -y \\ x \\ 0 \end{pmatrix}, \quad G = \{(x,y,z) \in \mathbb{R}^3 \mid (x,y) \neq (0{,}0)\}$$

$$(b) \quad \mathbf{w}(x,y) = \left(\begin{smallmatrix} \frac{y}{x^2+y^2}+y \\ x-\frac{x}{x^2+y^2} \end{smallmatrix}\right), \quad G = \{(x,y) \in \mathbb{R}^2 \mid (x,y) \neq (0{,}0)\}\ .$$

6) Berechnen Sie das Arbeitsintegral des Vektorfeldes $\mathbf{v} : \mathbb{R}^3 \to \mathbb{R}^3$, $\mathbf{v}(x,y,z) = (2xy + z^3, x^2, 3z^2x)^T$ längs des Kurvenstücks $\gamma(t) = (t{,}1-t{,}1)^T$, $0 \leq t \leq 1$.

7) Berechnen Sie die Arbeit, die Sie verrichten müssen, um in einem fahrenden Zug, der in 10 Sekunden gleichmäßig von 0 auf 120 $\frac{km}{h}$ beschleunigt, in einer Zeit von maximal 10 Sekunden 10 m in Fahrtrichtung zu gehen. Dabei gehen wir davon aus, dass Sie eine Masse von 75 kg haben.
Hinweis: Egal ob Sie die 10 m in einer, fünf oder zehn Sekunden zurücklegen. Die verrichtete Arbeit ist gleich.

8) Berechnen Sie das vektorielle Kurvenintegral des Vektorfeldes

$$\mathbf{v}(x,y,z) = \begin{pmatrix} ye^{xy} \\ xe^{xy} \\ z^2 \end{pmatrix} \text{ entlang der Kurve } \gamma(t) = \begin{pmatrix} \cos t \\ \sin^2 t \\ t^2 \sin t \cos t \end{pmatrix},\ t \in [0{,}2\pi]\ .$$

9) Überprüfen Sie, ob das Vektorfeld $\mathbf{v}(x,y,z) = (y,z,x)^T$ ein Vektorpotential besitzt und berechnen Sie gegebenenfalls ein Vektorpotential $\mathbf{w}$ von $\mathbf{v}$.

10) Berechnen Sie das Integral des Vektorfeldes $\mathbf{v}(x,y,z) = (-\frac{y}{x^2+y^2}, \frac{x}{x^2+y^2}, 2)^T$ entlang der Schraubenlinie

$$\gamma(t) = (\cos t, \sin t, t)^T,\ t \in [0{,}2\pi]\ .$$

8 Geometric theories

8.1 Systems of geometric rules

(a) The geometric rule scheme. We used first natural deduction as the logical calculus that is extended by rules. The axioms covered were formulas without essential disjunctions. With sequent calculus as the logical calculus to be extended, any universal axioms could be converted into rules. In this chapter, we shall show how the class of axioms convertible into rules is further extended into **geometric implications**, as in Chapter 5, but without the restrictions that natural deduction brings with itself. We recall the definition of a geometric implication:

Definition 8.1. *A formula in first-order logic is* **geometric** *if it does not contain* $\supset$ *or* $\forall$. *A* **geometric implication** *has the form, with* A *and* B *geometric formulas,*

$$\forall x \dots \forall z(A \supset B).$$

A **geometric theory** *is a theory axiomatized by geometric implications.*

The examples of geometric axioms mostly encountered in mathematics are **existential axioms**. An existential axiom can replace a construction and postulated properties of constructed objects. It has in this case the form $\forall x \dots \forall y \exists z A(x, \dots, y, z)$ and corresponds to the construction of some z from any given $x, \dots, y$, such that $A(x, \dots, y, z)$ holds. Constructions can have conditions, as in elementary geometry where an intersection point of two lines, say, can be constructed only if the lines are convergent. The existential axiom together with the condition can be given, when suitably formulated, as a geometric implication.

In lattice theory, the propositional part of existential axioms consists of atomic formulas $P(x, y, z)$. The rule that corresponds to such an existential axiom is, with parameters a, b in place of the universally quantified variables:

$$\frac{P(a, b, z), \Gamma \rightarrow \Delta}{\Gamma \rightarrow \Delta}\,{\scriptstyle E\text{-}Rule}$$

The rule has the variable restriction that the eigenvariable z must not be free in the conclusion. Assuming the premiss of the rule, application of the logical rule $L\exists$ followed by $L\forall$ twice gives as a conclusion

$$\forall x \forall y \exists z P(x, y, z), \Gamma \rightarrow \Delta$$

A cut with the axiomatic sequent $\rightarrow \forall x \forall y \exists z P(x, y, z)$ gives the conclusion of the rule. On the other hand, application of $R\exists$ to the initial sequent $P(x, y, z) \rightarrow P(x, y, z)$ followed by the rule and universal generalizations gives the axiom, so it follows that the rule has the same force as the existential axiom.

We shall give in the next Subsection (b) concrete examples of theories axiomatized by geometric implications.

Proposition 8.2. Canonical form for geometric implications. *Geometric implications can be reduced to conjunctions of formulas of the form*

$$\forall \overline{x}(P_1 \& \ldots \& P_m \supset \exists \overline{y}_1 M_1 \vee \ldots \vee \exists \overline{y}_n M_n)$$

Each P_i *is an atomic formula, each* M_j *is a conjunction of a list of atomic formulas* $\overline{Q}_j$*, and none of the variables in the vectors* $\overline{y}_j$ *are free in* P_i*.*

The **geometric rule scheme** that corresponds to geometric axioms has the form

Table 8.1 The geometric rule scheme

$$\frac{\overline{Q}_1(\overline{z}_1/\overline{y}_1), \overline{P}, \Gamma \rightarrow \Delta \quad \ldots \quad \overline{Q}_n(\overline{z}_n/\overline{y}_n), \overline{P}, \Gamma \rightarrow \Delta}{\overline{P}, \Gamma \rightarrow \Delta} GRS$$

The variables $\overline{y}_i$ are called the **replaced variables** of the scheme, and the variables $\overline{z}_i$ the **proper variables**, or **eigenvariables**. In what follows, we shall consider for ease of notation the case in which the vectors of variables $\overline{y}_i$ consist of a single variable. All the proofs can be adapted in a straightforward way to the general case.

The geometric rule scheme is subject to the following condition that expresses in a logic-free way the role of the existential quantifier in a geometric axiom:

Condition. *The eigenvariables must not be free in* $\overline{P}, \Gamma, \Delta$*.*

(b) Examples of geometric theories. We give some examples of elementary theories that can be given a geometric axiomatization. In some cases, as in plane projective geometry (example 3), a careful choice of the basic notions is needed, or else the theory fails to be geometric. It turns out that the standard axiomatizations of projective and affine geometry use what were called **co-geometric implications** in Chapter 5, and that a geometric axiomatization is found by the use of the basic notions of intuitionistic geometry. We shall analyse further this phenomenon when presenting the duality between classical and constructive notions and proofs in the next chapter.

1. Robinson arithmetic. The language has a constant 0, a unary successor function s, binary functions $+$ and $\cdot$. Atomic formulas have the form $r = t$, for arbitrary terms r and t. For free variables, parameters $a, b, c, \dots$ are used.

1. $\neg\, s(a) = 0$,
2. $s(a) = s(b) \supset a = b$,
3. $a = 0 \vee \exists y\, a = s(y)$,
4. $a + 0 = a$,
5. $a + s(b) = s(a + b)$,
6. $a \cdot 0 = 0$,
7. $a \cdot s(b) = a \cdot b + a$.

A classically equivalent axiomatization is obtained if 3 is replaced by:

$$3'.\ \ \neg\, a = 0 \supset \exists y\, a = s(y).$$

The axiom is not geometric because it has the implication $a = 0 \supset \perp$ in the antecedent of an implication.

2. Ordered fields and real-closed fields

I Axioms for non-degenerate linear order:
  1. $a \leqslant a$,
  2. $a \leqslant b \vee b \leqslant a$,
  3. $a \leqslant b \,\&\, b \leqslant c \supset a \leqslant c$,
  4. $\neg\, 1 \leqslant 0$.

II Axioms for ordered additive groups:
  5. $(a + b) + c = a + (b + c)$,
  6. $a + b = b + a$,
  7. $a + 0 = a$,
  8. $\exists y\, a + y = 0$,
  9. $a \leqslant b \supset a + c \leqslant b + c$.

III Axioms for multiplication:
10. $(a \cdot b) \cdot c = a \cdot (b \cdot c)$,
11. $a \cdot b = b \cdot a$,
12. $a \cdot 1 = a$,
13. $a = 0 \vee \exists y\, a \cdot y = 1$,
14. $a \cdot (b + c) = a \cdot b + a \cdot c$,
15. $a \leqslant b \,\&\, 0 \leqslant c \supset a \cdot c \leqslant b \cdot c$.

A classically equivalent axiomatization is obtained if in place of 13 the following axiom is chosen:

$$13'.\ \neg\, a = 0 \supset \exists y\, a \cdot y = 1.$$

This axiom, however, is not geometric, for the same reason as above.
Real-closed fields are obtained by adding the axioms that state the existence of square roots and zeros of polynomials of odd degree:

16. $0 \leqslant a \supset \exists y\, a = y \cdot y$,
17. $a_{2n+1} = 0 \vee \exists y\, a_{2n+1} \cdot y^{2n+1} + a_{2n} \cdot y^{2n} + \dots a_1 \cdot y + a_0 = 0$.

The classically equivalent axiomatization with 17 replaced by

$$17'.\ \neg\, a_{2n+1} = 0 \supset \exists y\, a_{2n+1} \cdot y^{2n+1} + a_{2n} \cdot y^{2n} + \dots a_1 \cdot y + a_0 = 0$$

is clearly not geometric.

3. Classical projective geometry with constructions. The basic concepts are: equality of two points, equality of two lines, and incidence of a point on a line. These are written $a = b$, $l = m$, and $a \in l$. There are two constructions: those of a connecting line $ln(a, b)$ of two points and of an intersection point $pt(l, m)$ of two lines.

I Axioms for the equality relations:

$$a = a, \quad a = c \,\&\, b = c \supset a = b,$$

$$l = l, \quad l = n \,\&\, m = n \supset l = m.$$

II Axioms of incidence:

$$a = b \vee a \in ln(a, b), \quad a = b \vee b \in ln(a, b),$$

$$l = m \vee pt(l, m) \in l, \quad l = m \vee pt(l, m) \in m.$$

III Uniqueness axiom:

$$a \in l \,\&\, b \in l \,\&\, a \in m \,\&\, b \in m \supset a = b \vee l = m.$$

IV Substitution axioms:

$$a \in l \,\&\, a = b \supset b \in l,$$

$$a \in l \,\&\, l = m \supset a \in m.$$

V Existence of three non-collinear points:

$$\exists x \exists y \exists z(\neg\, x = y \,\&\, \neg\, z \in ln(x, y)).$$

Because of axiom V, the above is not a geometric theory. We obtain a geometric axiomatization by the use of apartness between points and lines as a basic notion, instead of equality:

4. Constructive projective geometry with constructions. The basic concepts are: $a \neq b$, $l \neq m$, and $a \notin l$. The constructions are: $ln(a, b)$ and $pt(l, m)$.

I Axioms for apartness relations:

$$\neg\, a \neq a, \quad a \neq b \supset a \neq c \vee b \neq c,$$

$$\neg\, l \neq l, \quad l \neq m \supset l \neq n \vee m \neq n.$$

II Axioms of incidence:

$$\neg\,(a \neq b \,\&\, a \notin ln(a, b)),$$

$$\neg\,(a \neq b \,\&\, b \notin ln(a, b)),$$

$$\neg\,(l \neq m \,\&\, pt(l, m) \notin l),$$

$$\neg\,(l \neq m \,\&\, pt(l, m) \notin m).$$

III Uniqueness axiom:

$$a \neq b \,\&\, l \neq m \supset a \notin l \vee b \notin l \vee a \notin m \vee b \notin m.$$

IV Substitution axioms:

$$a \notin l \supset a \neq b \vee b \notin l,$$

$$a \notin l \supset l \neq m \vee a \notin m.$$

V Existence of three non-collinear points:

$$\exists x \exists y \exists z(x \neq y \,\&\, z \notin ln(x, y)).$$

As can be seen, we have now a geometric axiomatization of projective geometry. The classical basic concepts of equality and incidence are defined as negations of the basic concepts of constructive geometry, namely apartness of two points, apartness of two lines, and the 'outsideness' of a point from a line. On the other hand, these latter concepts can be defined as negations of the basic concepts of classical projective geometry, if the law of double negation is assumed: then, for example, $\neg\, a \notin l$ will be equivalent to $a \in l$.

Transitivity of equality in the classical axiomatization was given in the 'Euclidean' form, because, put in this way, it comes directly out as the contrapositive of the 'co-transitivity' of apartness.

Chapter 10 is devoted to an analysis of plane projective and affine geometry.

8.2 Proof theory of geometric theories

We shall turn after the above examples of geometric theories to the general proof theory of systems of geometric rules. In the extension of sequent calculi by such rules, all the structural properties are preserved.

Definition 8.3. *Let* **T** *be a geometric theory. Then* **G3cT** (**G3imT**) *is the system of sequent calculus obtained by adding to* **G3c** (**G3im**) *the geometric rules that correspond to the geometric axioms of* **T**, *together with the rules that arise from the closure condition.*

Theorem 8.4. Equivalence of axiomatic systems and rule systems. *A geometric axiom is derivable from the corresponding geometric rule. Conversely, a geometric rule is derivable from the corresponding geometric axiom in* **G3imT**+Ctr+Cut.

Proof. A geometric axiom $\to A$, represented as a sequent with an empty antecedent, is derivable from the corresponding geometric rule scheme. Below, an asterisk * denotes possibly iterated steps of a rule, the premisses are clearly derivable by $R\&$, and $M_i(z_i/y_i) \equiv \&\overline{Q}_i(z_i/y_i)$:

$$\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\overline{Q}_1(z_1/y_1), \overline{P} \to M_1(z_1/y_1), \dots, M_n(z_n/y_n)}{\overline{Q}_1(z_1/y_1), \overline{P} \to \exists y_1 M_1, \dots, \exists y_n M_n}{\scriptstyle R\exists^*} \quad \dots \quad \dfrac{\overline{Q}_n(z_n/y_n), \overline{P} \to M_1(z_1/y_1), \dots, M_n(z_n/y_n)}{\overline{Q}_n(z_n/y_n), \overline{P} \to \exists y_1 M_1, \dots, \exists y_n M_n}{\scriptstyle R\exists^*}}{\overline{P} \to \exists y_1 M_1, \dots, \exists y_n M_n}{\scriptstyle GRS}}{\overline{P} \to \exists y_1 M_1 \lor \dots \lor \exists y_n M_n}{\scriptstyle R\lor^*}}{P_1 \& \dots \& P_m \to \exists y_1 M_1 \lor \dots \lor \exists y_n M_n}{\scriptstyle L\&^*}}{\to P_1 \& \dots \& P_m \supset \exists y_1 M_1 \lor \dots \lor \exists y_n M_n}{\scriptstyle R\supset}}{\to \forall \overline{x}(P_1 \& \dots \& P_m \supset \exists y_1 M \lor \dots \lor \exists y_n M_n)}{\scriptstyle R\forall}$$

Conversely, a geometric rule is derivable from the corresponding geometric axiom $\to A$ in **G3im**+*Ctr*+*Cut* as shown below. In the derivation of the left premiss of cut, inverses of rules are used. These are admissible (and height-preserving) steps in **G3im**. Observe that the variable restriction in *GRS* now comes into use in the steps of $L\exists$:

$$\dfrac{\dfrac{\dfrac{\dfrac{\to \forall\overline{x}(P_1\&\ldots\&P_m \supset \exists y_1 M_1 \vee \ldots \vee \exists y_n M_n)}{\to P_1\&\ldots\&P_m \supset \exists y_1 M_1 \vee \ldots \vee \exists y_n M_n}{\scriptstyle R\forall Inv}}{P_1\&\ldots\&P_m \to \exists y_1 M_1 \vee \ldots \vee \exists y_n M_n}{\scriptstyle R\supset Inv}}{\overline{P} \to \exists y_1 M_1 \vee \ldots \vee \exists y_n M_n}{\scriptstyle L\&Inv} \quad \dfrac{\dfrac{\dfrac{\overline{Q}_1(z_1/y_1), \overline{P}, \Gamma \to \Delta}{M_1(z_1/y_1), \overline{P}, \Gamma \to \Delta}{\scriptstyle L\&^*}}{\exists y_1 M_1, \overline{P}, \Gamma \to \Delta}{\scriptstyle L\exists} \quad \ldots \quad \dfrac{\dfrac{\overline{Q}_n(z_n/y_n), \overline{P}, \Gamma \to \Delta}{M_n(z_n/y_n), \overline{P}, \Gamma \to \Delta}{\scriptstyle L\&^*}}{\exists y_n M_n, \overline{P}, \Gamma \to \Delta}{\scriptstyle L\exists}}{\exists y_1 M_1 \vee \ldots \vee \exists y_n M_n, \overline{P}, \Gamma \to \Delta}{\scriptstyle L\vee^*}}{\dfrac{\overline{P}, \overline{P}, \Gamma \to \Delta}{\overline{P}, \Gamma \to \Delta}{\scriptstyle Ctr^*}}{\scriptstyle Cut}$$

QED.

Remark. It is clear by the above derivation that the geometric rule scheme hides a cut on the formula $\exists y_1 M_1 \vee \ldots \vee \exists y_n M_n$. The substituted variables y_i are bound variables in the virtual cut formula, so it will be convenient to regard the substituted variables of the scheme as bound variables and to assume that in a derivation the sets of free and bound variables are disjoint.

The inversion lemmas for the propositional rules that hold for **G3c** and **G3im** hold for their geometric extensions as well, because the geometric rule scheme has only atomic formulas as principal and active formulas. So we have:

Lemma 8.5. Inversion. *All the inversions of the propositional rules that hold for* **G3c** *and* **G3im** *hold also for their geometric extensions.*

For the inversions of $L\exists$ and $R\forall$, we need to add a condition on the variable to avoid clashes with the proper variables of the geometric rules in the derivation.

Lemma 8.6. Substitution. *Given a derivation of* $\Gamma \to \Delta$ *in* **G3cT** (**G3imT**), *with x a free variable in* Γ, Δ, *t a term free for x in* Γ, Δ *and not containing any of the variables of the geometric rules in the derivation, we can find a derivation of* $\Gamma(t/x) \to \Delta(t/x)$ *in* **G3cT** (**G3im**) *with the same height.*

Proof. By induction on the height of the given derivation. For the logical rules, the proof is contained in lemma 4.1.2 of *Structural Proof Theory*, so we need to consider only the cases that arise from the addition of the geometric rule scheme. Suppose the last rule in the derivation of $\Gamma \to \Delta$ is GRS, with premisses

$$\overline{Q}_i(z_i/y_i), \overline{P}, \Gamma' \to \Delta$$

for $i = 1, \dots, n$. The $\overline{Q}_i$ are atomic and the term t is free for x in these premisses; thus by the induction hypothesis we get derivations of

$$\overline{Q}_i(z_i/y_i)(t/x), \overline{P}(t/x), \Gamma'(t/x) \to \Delta(t/x)$$

Since x is a free variable in Γ, Δ, by the remark at the end of the previous section we have $x \neq y_i$, and since the z_i are not free in $\overline{P}, \Gamma, \Delta$ we have $x \neq z_i$. Moreover, by hypothesis, t does not contain any of the y_i. Therefore the two substitutions in $\overline{Q}_i$ are independent and we have $Q_i(z_i/y_i)(t/x) \equiv Q_i(t/x)(z_i/y_i)$. Since t does not contain any of the z_i, the z_i are not free in $\overline{P}(t/x), \Gamma'(t/x) \to \Delta(t/x)$, so we can apply the geometric rule scheme to the premisses

$$\overline{Q}_i(t/x)(z_i/y_i), \overline{P}(t/x), \Gamma'(t/x) \to \Delta(t/x)$$

Now we get $\overline{P}(t/x), \Gamma'(t/x) \to \Delta(t/x)$, i.e., $\Gamma(t/x) \to \Delta(t/x)$. QED.

Lemma 8.7. Inversion for quantifier rules.

(i) *If* $\vdash_n \exists x A, \Gamma \to \Delta$ *and* y *is not among the variables of the geometric rules in the derivation, then* $\vdash_n A(y/x), \Gamma \to \Delta$.

(ii) *If* $\vdash_n \Gamma \to \Delta, \forall x A$ *and* y *is not among the variables of the geometric rules in the derivation, then* $\vdash_n \Gamma \to \Delta, A(y/x)$.

Proof. (i) By induction on height of derivation n, as in Lemma 6.2. If $n = 0$, then $\exists x A, \Gamma \to \Delta$ is either an initial sequent, or a conclusion of $L\bot$, or a conclusion of a zero-premiss geometric rule. In each case also $A(y/x), \Gamma \to \Delta$ is an initial sequent, or a conclusion of $L\bot$, or a conclusion of a zero-premiss geometric rule, thus $\vdash_0 A(y/x), \Gamma \to \Delta$.

If $n > 0$ and $\exists x A$ is principal in the last rule, the premiss gives a derivation of $A(z/x), \Gamma \to \Delta$, where z is not free in Γ, Δ. By Lemma 8.6, using the substitution y/z, we obtain a derivation of the same height of $A(y/x), \Gamma \to \Delta$. If $\exists x A$ is not principal in the last rule, we argue as in lemma 4.2.3 of *Structural Proof Theory* in the case the last rule is a logical rule. If the last rule is a geometric rule, with $\Gamma \equiv \overline{P}, \Gamma'$ and premisses

$$\overline{Q}_1(z_1/y_1), \overline{P}, \exists x A, \Gamma' \to \Delta, \dots, \overline{Q}_n(z_n/y_n), \overline{P}, \exists x A, \Gamma' \to \Delta$$

we get by the assumption that free and bound variables are disjoint and by the inductive hypothesis derivations of the sequents

$$\overline{Q}_1(z_1/y_1), \overline{P}, A(y/x), \Gamma' \to \Delta, \dots, \overline{Q}_n(z_n/y_n), \overline{P}, A(y/x), \Gamma' \to \Delta$$

Since y is none of the z_i, we can apply the geometric rule scheme to these premisses and obtain a derivation of $\overline{P}, A(y/x), \Gamma' \to \Delta$.

(ii) Similar to (i). QED.

Without loss of generality, we can assume by Lemma 8.6 that the following condition on variables is satisfied:

Disjointness condition. *In a derivation in* **G3cT** (**G3imT**), *the collections of proper variables of any two geometric rules are disjoint.*

Theorem 8.8. *The rules of weakening*

$$\frac{\Gamma \to \Delta}{A, \Gamma \to \Delta}{\scriptstyle LW} \qquad \frac{\Gamma \to \Delta}{\Gamma \to \Delta, A}{\scriptstyle RW}$$

are height-preserving admissible in **G3cT** *and in* **G3imT**.

Proof. Consider the last step in the derivation of the premiss of the weakening rules. Apply, inductively, weakening to the premisses $\Gamma_i \to \Delta_i$ of the last step to obtain $A, \Gamma_i \to \Delta_i$, then the rule that had been used as the last step, which gives $A, \Gamma \to \Delta$. Observe that if the last rule is geometric and the weakening formula A contains some of its variables, the variable condition is no longer satisfied after weakening with A. In this case the substitution lemma is applied to the premisses of the geometric rule to have new free variables that do not clash with those in A. The conclusion is then obtained by applying the inductive hypothesis and the geometric rule. QED.

Theorem 8.9. *The rules of contraction*

$$\frac{A, A, \Gamma \to \Delta}{A, \Gamma \to \Delta}{\scriptstyle LC} \qquad \frac{\Gamma \to \Delta, A, A}{\Gamma \to \Delta, A}{\scriptstyle RC}$$

are height-preserving admissible in **G3cT** *and in* **G3imT**.

Proof. By simultaneous induction for left and right contraction on the height of the derivation of the premiss. If it is an initial sequent, also the conclusion is. If the last rule is a propositional rule, then the conclusion follows as in theorem 3.2.2 of *Structural Proof Theory*. If it is $L\forall$, we apply the induction hypothesis to the premiss of the rule, and then the rule, and similarly if it is $L\exists$ with A not principal in it. If it is $L\exists$ with $A \equiv \exists x B$ and premiss $B(y/x), \exists x B, \Gamma \to \Delta$, by the variable condition on the geometric rule and the Remark after Theorem 8.4, y is not a variable in any geometric rule in the derivation, so we can apply the inversion lemma for $L\exists$ instantiated by y and obtain a derivation of $B(y/x), B(y/x), \Gamma \to \Delta$. By the induction hypothesis we get $B(y/x), \Gamma \to \Delta$ and by $L\exists$, $\exists x B, \Gamma \to \Delta$.

If the last rule is a geometric rule, we distinguish three cases: 1. No occurrence of A is principal in the rule. 2. One occurrence of A is principal, the other is not. 3. Both occurrences of A are principal.

The first case is handled by a straightforward induction and the second by the repetition of the principal formulas P_i in the premisses of the geometric rule. Finally, the third case is taken care of by the closure condition. QED.

We are now in the position to prove the admissibility of cut for our rule systems for geometric theories. We remark that the proof has the same structure as the proof of admissibility of cut for universal theories (Theorem 6.9 above), with an additional use of the substitution lemma in order to meet the variable restriction in the geometric rule scheme.

Theorem 8.10. *The rule of cut*

$$\frac{\Gamma \to \Delta, A \qquad A, \Gamma' \to \Delta'}{\Gamma, \Gamma' \to \Delta, \Delta'}{\scriptstyle Cut}$$

is admissible in **G3cT** *and in* **G3imT**.

Proof. By induction on the length of A with a subinduction on the sum of the heights of the derivations of $\Gamma \to \Delta, A$ and $A, \Gamma' \to \Delta'$. We need to consider only the cases that arise from the addition of the geometric rule scheme. The other cases are treated in the corresponding proof for **G3c** and **G3im**.

1. If the left premiss is a zero-premiss geometric rule, then also the conclusion is a zero-premiss geometric rule, because these have an arbitrary context as succedent.

2. If the right premiss is a zero-premiss geometric rule with A not principal in it, the conclusion is a zero-premiss geometric rule for the same reason as in case *1*.

3. If the right premiss is a zero-premiss geometric rule with A principal in it, A is atomic and we consider the left premiss. The case that it is a geometric zero-premiss rule is covered by *1*. If it is an initial sequent with A not principal, the conclusion is a logical axiom; otherwise, Γ contains the atom A and the conclusion follows from the right premiss by weakening. In the remaining cases we consider the last rule in the derivation of $\Gamma \to \Delta, A$. Since A is atomic, A is not principal in the rule. Let us consider the case of

a geometric rule (the others being dealt with similarly, except $R\supset$ and $R\forall$ that are covered in *4*). The derivation ends with

$$\dfrac{\dfrac{\overline{Q}_1(z_1/y_1),\,\overline{P},\,\Gamma''\to\Delta,A \quad \dots \quad \overline{Q}_n(z_n/y_n),\,\overline{P},\,\Gamma''\to\Delta,A}{\overline{P},\,\Gamma''\to\Delta,A}\,{\scriptstyle GRS} \qquad A,\Gamma'\to\Delta'}{\overline{P},\,\Gamma',\Gamma''\to\Delta,\Delta'}\,Cut$$

The cut cannot be simply permuted to the premisses of *GRS* because Γ', Δ' may bring in free variables that clash with the proper variables z_i and thus prevent the application of *GRS* after the cuts. Instead, we apply first the substitution lemma to the right premiss of cut and replace all the variables z_i, if any, by fresh variables w_i, and denote the substitution by w/z. Observe that by the variable condition in *GRS*, the substitution does not affect the cut formula A. We obtain the sequent

$$A,\Gamma'(w/z)\to\Delta'(w/z)$$

Now n cuts with the n premisses of *GRS* give, for $i = i, \dots n$, the n sequents

$$\overline{Q}_i(z_i/y_i),\,\overline{P},\,\Gamma'(w/z),\Gamma''\to\Delta,\Delta'(w/z)$$

By applying *GRS* to these n premisses we get

$$\overline{P},\,\Gamma'(w/z),\Gamma''\to\Delta,\Delta'(w/z)$$

The derivation is continued as before with the substitution (w/z) performed globally. Observe that by the disjointness condition, the substitution does not affect the active formulas of other geometric rules in the derivation. The cut has thus been replaced by n cuts with a left premiss that has a derivation of lower height and a right premiss of unaltered height.

Let us now consider the cases in which neither premiss is an axiom.

4. A is not principal in the left premiss. These cases are dealt with as above, with cut permuted upwards to the premisses of the last rule used in the derivation of the left premiss (with a suitable variable substitution to match the variable restrictions in the cases of quantifier rules and the geometric rule-scheme), except for $R\supset$ and $R\forall$ in **G3imT**. By the intuitionistic restrictions in these rules, A does not appear in the premisses, and the conclusion is obtained without cut by $R\supset$ ($R\forall$, resp.) and weakening.

5. A is principal only in the left premiss. Then A has to be a compound formula. Therefore, if the last rule of the right premiss is a geometric rule, A

cannot be principal in the rule, because only atomic formulas are principal in geometric rules. In this case cut is permuted to the premisses of the right premiss, with appropriate substitution of free variables as in *3*, if the right premiss is a *GRS*. If the right rule is a logical one with A not principal in it, the usual reductions are applied.

6. A is principal in both premisses. This case can involve only logical rules and is dealt with as in the usual proof for pure logic. QED.

Examples of proof analyses in geometric theories will be given in Chapter 10. In typical cases, it turns out that existential axioms are conservative relative to the derivability of atomic cases from atomic assumptions. If for the rest of the rules a subterm property can be shown, a positive solution for the said derivability problem follows. In this chapter, we shall present instead a general result about the proof theory of geometric theories.

8.3 Barr's theorem

We apply here the method of extension by rules to a general result for geometric theories.

Barr's theorem. *Let T be a geometric theory and let A be a geometric implication. If* **G3cT** $\vdash\ \rightarrow A$, then **G3imT** $\vdash\ \rightarrow A$.

Proof. Let A be $\forall\overline{x}(B \supset C)$ and consider a proof of A in **G3cT**. Because B and C do not contain $\supset$ or $\forall$, the derivation of A consists of geometric rules, rules for &, $\vee$, $\exists$, a step of $R\supset$ and steps of $R\forall$. The geometric rules can occur in any order among the logical rules, however, of the logical rules, $R\supset$ and $R\forall$ come last. The geometric rules have the same succedent in both the premisses and the conclusion, so therefore rules $R\supset$ and $R\forall$ are applied to single-succedent sequents. It follows that the given proof must already be a proof in **G3imT**. QED.

Therefore, through the method of proof analysis, the result reduces to a triviality: A classical proof of a geometric implication in a geometric theory formulated as a sequent system with rules is already an intuitionistic proof. If we add the requirement that the geometric implication must not contain $\perp$ in the antecedent, then the classical proof is even a proof in minimal logic.

Notes to Chapter 8

Interest in the study of geometric theories has arisen from different areas of logic and mathematics. In topos theory, geometric formulas are characterized as the fragment of first-order logic preserved by geometric morphisms. The statement of Barr's theorem in that context is as follows: *For any Grothendieck topos* **E***, there is a Boolean topos* **B** *and a surjective geometric morphism* $\gamma : \mathbf{B} \to \mathbf{E}$. Thus the conservativity result for geometric theories is proved using a completeness theorem for geometric theories in Grothendieck topoi and the construction of a suitable Boolean topos out of a Grothendieck topos (cf. Johnstone 1977, Mac Lane and Moerdijk 1992, p. 513). The preservation property extends beyond first-order logic to existential fixed-point formulas (cf. Blass 1988).

Palmgren (2002) indicates a proof-theoretical proof of Barr's theorem by showing that geometric implications are stable under the Dragalin-Friedman translation. A proof for the special case of the empty geometric theory is suggested in Troelstra and Van Dalen (1988) (exercise 2.6.14) by means of Kripke models.

The nature of geometric logic as the logic of finite observations has been emphasized in localic approaches to constructive topology (cf. Vickers 1989). Geometric theories can be treated, as any other theory, by the addition of Hilbert-style axioms to a logical proof system, but axiomatic systems are hard to analyse proof-theoretically. In Simpson (1994), geometric theories are presented through suitable rules that extend intuitionistic natural deduction. A proof of normalization for the extensions thus obtained is given and the systems applied in a systematic study of the proof theory of intuitionistic modal logic. Finally, in Coste, Lombardi, and Roy (2001), the so-called method of 'dynamical proof', which establishes the derivability of one atom from a finite set of atoms, is applied to certain specific geometric theories such as the theory of algebraically closed fields.

We observe that Barr's theorem is not a characterization of the intuitionistic fragment of geometric theories, because we can go beyond geometric implications and maintain the conservativity result. First, following Dragalin's suggestion (cf. Section 3.7.3 in Troelstra and Schwichtenberg 2000), we can modify the intuitionistic left rule for implication by admitting a multisuccedent conclusion in the left premiss

$$\frac{A \supset B, \Gamma \to \Delta, A \quad B, \Gamma \to \Delta}{A \supset B, \Gamma \to \Delta}\ {\scriptstyle L\supset}$$

Rule $L\supset$ of the classical calculus, without $A \supset B$ in the left premiss, is then admissible in the modified intuitionistic calculus; thus the difference between the intuitionistic and classical sequent systems is confined to rules $R\supset$ and $R\forall$. An operational definition of formulas for which the conservativity of classical derivations holds can be given: if a formula is derivable classically in a geometric theory and the derivation contains no steps of $R\supset$ and $R\forall$ with a non-empty context in the premiss, then the derivation is an intuitionistic derivation. However, this is an empty characterization that states nothing but that 'an intuitionistic derivation is an intuitionistic derivation'. A characterization in terms of only the form of the formulas, not of their derivations, would be desirable. There are classes of formulas, such as geometric implications, the form of which forces the derivation to be of the stated kind. The same is true, for example, if the formula does not contain in its positive part implications or universally quantified formulas as components of a disjunction. Even so, there are still formulas outside the mentioned classes for which the conservativity holds.

202202100150

Deus é uma realidade, Ele existe por si mesmo e não depende da análise objetiva ou o entendimento das pessoas.

Deus pode ser entendido de várias formas de acordo com as convicções do homem que tenta entender Deus, mas não devemos fazê-lo de forma a conceituá-lo simplisticamente hermenêutico.

O nada existe.

O conceito do nada se reflete na criação da noção do número zero, criado na Índia, ou melhor, descoberto e esboçado na forma como conhecemos, primeiramente descoberto pois esta realidade já existia, faltando somente a sua materialização no mundo fático ou "real", quando houve a retirada de uma pedra da sua posição matemática quando da resolução de uma operação matemática básica em que o espaço em que faltava a pedra, ou seja, o nada ou o zero existe independentemente da existência de uma pedra posicional para demarcar a existência daquele referido número.

O nada existe porque existe a Matemática.

A Matemática existe por si mesma.

A Matemática é descoberta, o homem inventa a forma como nós descrevemos os conceitos matemáticos.

A Matemática tem várias facetas e nós podemos adequá-la a cada realidade existente e que por sinal é infinita, para poder entendê-la, mas a Matemática não pode ser distorcida ou corrompida pelo homem.

Na Realidade, nós devemos tentar adequar a realidade à Matemática, pois para cada realidade nós teremos que conceituá-la de acordo com a Matemática imutável, cabendo a nós, meros mortais, inventar meios, métodos, formas para "tentar" descrever a nossa realidade dentro da Matemática.

Três premissas nós devemos ter em mente:

1) O nada sempre existiu, existe e existirá.
O nada é o reflexo oposto de Deus, uma face da mesma essência de Deus.
O Universo somente pode existir pois havia o nada.
A expansão do Universo também depende do nada.
O nada permitiu o Universo

se expandir, o nada suplica que o Universo o preencha. O espaço decorre do nada, o espaço não é criado pelo Universo, mas alterado por este.

↳ O Tempo sempre existiu, existe e existirá.
O tempo não é criado pelo Universo, mas alterado por este.

O nada existe e portanto, ele tem o seu próprio tempo e espaço.

2) A Matemática sempre existiu, existe e existirá.
A Matemática está em tudo para ser descoberta.
A realidade depende da Matemática, inclusive o seu próprio entendimento depende dela. Cabe a nós, descrever a realidade utilizando a Matemática.
A Matemática tem infinitos facetas e formas para descrever as infinitas realidade que ainda serão descobertas.

A Matemática e o nada decorrem de Deus.

O nada obriga, ocasiona a criação de alguma coisa. /

O nada foi dado por Deus como a

chave que abre a porta para infinitas possibilidades.

O nada é como esta folha em branco na qual eu estou escrevendo. Esta página deseja ser preenchida pois se ela estivesse completa, o que eu poderia escrever para tentar inventar, descobrir, descrever, narrar, contar etc.

O tudo não permite a criação pois ele já ocupou tudo e não permite a inclusão de mais nada.

Deus é tudo. Ele não precisa dos homens e por isso, Ele criou o nada como uma forma de criar espaço para que o homem possa viver e sonhar.

Deus se "ausentou" e nos deu o "livre-arbítrio" para que nós os homens possamos preencher o nada.

São Paulo 10 de fevereiro de 2022.

data

Ⓢ Ⓣ Ⓠ Ⓠ Ⓢ Ⓢ Ⓓ

20220210M

O nada existe.
O nada permite que o Universo exista.
Literalmente:

O Universo foi criado do nada.

O nada que existe, criou o Universo.

O nada criou condições para que o Universo fosse criado.

O nada criou o Universo, além dos confins do Universo, nós iremos encontrar o nada.

O nada impulsiona o Universo a preenchê-lo de forma acelerada, ou seja, quanto mais nada temos, mais rápido o Universo tentará preenchê-lo.

O nada decorre de Deus.

O nada é a tábua rasa na qual Deus, permite ao homem interagir e existir.

O nada sempre existiu, mas pela sua essência, ele sempre se transforma de infinitas formas, uma delas é o Universo que conhecemos.

O nada por si mesmo cria
condições para que algo decorra
dele.

O Universo não foi criado,
ele é a manifestação do
nada.
(uma das manifestações).

O nada existe,
somente o que existe,
poderá criar algo;
neste caso,
o Universo.

O nada também é uma forma
de energia.

Tudo é energia,
a falta de energia também
é uma forma de energia.

20220212_0003

A gravidade como força independente não existe.

A gravidade decorre da força forte (lei fundamental da física)

A curvatura do tecido espaço-tempo decorre da Força Forte.

A soma de cada Força Forte de cada átomo reunido em um determinado espaço gera por consequência a ação gravitacional. Quanto mais átomos, mais forte será a soma das Forças Fortes de todos os átomos reunidos em determinado espaço, que por sua vez, irá distorcê-lo de acordo com a reunião de todas as Forças Fortes de todos os átomos reunidos em um determinado espaço.

A curvatura do Universo existe e decorre de toda a massa deste Universo.

Onde não há massa no Universo, existe uma mínima curvatura que é decorrente da massa do Universo como um todo.

O nada existe, como o vazio do Universo também existe.

A existência destes dois gera também uma força!!!

A força gerada pelo nada e
pelo vazio decorre da simetria
intrínseca existente o Tudo (Deus)
e o nada.

A Entropia decorre desta
interação simétrica destes dois
elementos.

A falta de paridade de
aniquilação entre matéria
e anti-matéria decorre
da interação intrínseca
da ação simétrica entre
estas duas forças universais
atuantes no Universo analisado.
(em calta)

A falta desta paridade ou
simetria decorre da interação
entre o Tudo e o nada, ou seja,
não se trata de falta de paridade
mas a ação permanente do
equilíbrio entre estas duas forças
que interagem na
criação e destruição
do Universo.

entraremos no campo da filosofia e
da religião, Deus Shiva na
cultura indiana.

Le problème de Pappus

Etant donné plusieurs lignes droites dans le plan, trouver le lieu géométrique d'un point tel que les perpendiculaires — ou plus généralement les obliques abaissées de ce point sur ces droites sous des angles donnés — satisfassent à la condition que le produit de certaines d'entre elles soit dans un rapport constant avec le produit de toutes les autres.

I. — Cette question est relatée par Pappus, d'Alexandrie, qui, vers la fin du IV^e siècle de l'ère chrétienne, a rassemblé, dans ses *Collections mathématiques,* monument précieux de l'Antiquité, diverses découvertes des plus célèbres mathématiciens, ainsi que ses propres inventions. Ce fameux problème, dit *ad tres aut plures lineas,* avait exercé la sagacité d'Euclide (vers 300 av. J.-C.) et d'Apollonius (II^e siècle av. J.-C.), et Pappus le considérait comme l'écueil des Anciens. En effet, tenté par ceux-ci, il n'avait été résolu que dans des cas très particuliers, et les Anciens n'avaient pu atteindre la solution générale qui dépendait, en effet, d'une méthode nouvelle, telle que l'analyse algébrique ou l'art d'exprimer algébriquement les propriétés caractéristiques d'une courbe. Les Anciens avaient bien vu que, s'il n'y avait que trois ou quatre droites, le lieu était une section conique, mais encore ne pouvaient-ils la déterminer dans tous les cas. Et ils n'avaient pu aborder le problème lorsqu'il comportait plus de quatre droites, mais la propriété leur était connue, qui fut établie géométriquement par Newton (1642-1727) et qui constitue une propriété générale des coniques que, *quand un quadrilatère est inscrit dans une conique, le produit des distances de chaque point de la courbe à deux côtés opposés est au produit des distances du même point aux deux autres côtés dans un rapport constant.*

66

Le problème de Pappus

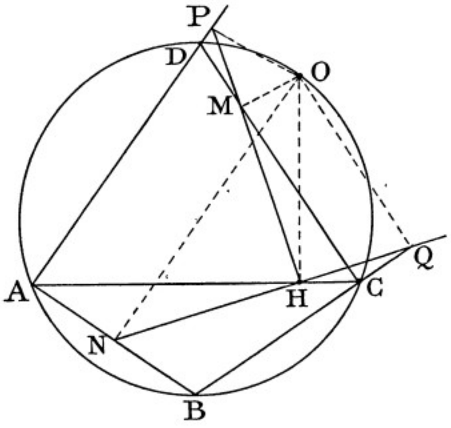
Etant donné plusieurs lignes droites dans le plan, trouver le lieu géométrique d'un point tel que les perpendiculaires — ou plus généralement les obliques abaissées de ce point sur ces droites sous des angles donnés — satisfassent à la condition que le produit de certaines d'entre elles soit dans un rapport constant avec le produit de toutes les autres.

I. — Cette question est relatée par Pappus, d'Alexandrie, qui, vers la fin du IVᵉ siècle de l'ère chrétienne, a rassemblé, dans ses *Collections mathématiques,* monument précieux de l'Antiquité, diverses découvertes des plus célèbres mathématiciens, ainsi que ses propres inventions. Ce fameux problème, dit *ad tres aut plures lineas,* avait exercé la sagacité d'Euclide (vers 300 av. J.-C.) et d'Apollonius (IIᵉ siècle av. J.-C.), et Pappus le considérait comme l'écueil des Anciens. En effet, tenté par ceux-ci, il n'avait été résolu que dans des cas très particuliers, et les Anciens n'avaient pu atteindre la solution générale qui dépendait, en effet, d'une méthode nouvelle, telle que l'analyse algébrique ou l'art d'exprimer algébriquement les propriétés caractéristiques d'une courbe. Les Anciens avaient bien vu que, s'il n'y avait que trois ou quatre droites, le lieu était une section conique, mais encore ne pouvaient-ils la déterminer dans tous les cas. Et ils n'avaient pu aborder le problème lorsqu'il comportait plus de quatre droites, mais la propriété leur était connue, qui fut établie géométriquement par Newton (1642-1727) et qui constitue une propriété générale des coniques que, *quand un quadrilatère est inscrit dans une conique, le produit des distances de chaque point de la courbe à deux côtés opposés est au produit des distances du même point aux deux autres côtés dans un rapport constant.*

Descartes (1596-1650), qui, selon l'expression de Chasles, a rendu le plus signalé service à la géométrie, par son inappréciable conception, dont on ne trouve aucun germe dans les récits des Anciens, de l'application de l'Algèbre à la théorie des courbes, créa les moyens de franchir les obstacles qui avaient arrêté les plus grands géomètres jusqu'alors, et changea véritablement la face des sciences mathématiques: Descartes a donné au problème qui nous occupe ici l'importance qu'il mérite, en même temps qu'une nouvelle célébrité, en en faisant la première application de sa *Géométrie analytique,* et en trouvant le premier, par sa nouvelle méthode, la solution générale. Le fameux problème de l'hexagone de Pascal [Pr. 55], le théorème célèbre de l'involution de Desargues [Pr. 56] peuvent être regardés comme de simples corollaires de cette proposition fondamentale.

II. — Etablissons le problème de Pappus, pour le quadrilatère ABCD inscrit dans un cercle. Il s'agit de montrer que, quelque soit le point O sur le cercle, on a :

$$OP.OQ = OM.ON.$$



En effet, si l'on joint AC diagonale et si l'on mène OH perpendiculaire à AC, les trois points P, M, H sont en ligne droite, droite de Simson du point O pour le triangle ACD; de même les points N,H,Q sont en ligne droite, droite de Simson relative à O, et au triangle ABC. L'angle en O du quadrilatère inscriptible MOPD est égal à l'angle $\widehat{ADC}$ comme ayant même supplément $\widehat{PDM}$. L'angle $\widehat{NOQ}$ du quadrilatère inscriptible NOQB est aussi égal à l'angle $\widehat{ADC}$ comme ayant même supplément $\widehat{ABC}$. Donc $\widehat{POM} = \widehat{NOQ}$. D'autre part, les angles $\widehat{PMO}$ et $\widehat{OQN}$ sont égaux car leurs compléments respectifs DMP et HQC sont égaux au même angle $\widehat{HMC}$, angle opposé pour l'un, et pour l'autre inscrit dans le cercle passant par les points O, M, H, C, Q. Les deux triangles PMO et ONQ sont donc semblables, et leurs côtés homolgues sont proportionnels; d'où :

$$\frac{OP}{OM} = \frac{ON}{OQ} \text{ soit } OP.OQ = OM.ON.$$

III. — La géométrie analytique, ou méthode de Descartes, donne ainsi la solution générale du problème :

Soient d'abord $\alpha = 0$, $\beta = 0$, $\gamma = 0$, $\delta = 0$, les équations des côtés AB, BC, CD, DA d'un quadrilatère. Les équations :

$$\alpha\gamma = 0, \beta\delta = 0,$$

représentent deux coniques particulières passant par les quatre sommets. Donc :

$$\alpha\gamma + \lambda.\beta\delta = 0,$$

λ étant un paramètre arbitraire, est l'équation générale des coniques circonscrites du quadrilatère. Et cette équation exprime que le lieu du point dont le produit des distances à deux droites est dans un rapport constant avec le produit des distances du même point à deux autres droites, est une conique passant par les points où les deux premières droites rencontrent les deux autres.

Supposons maintenant n droites $\alpha_1 = 0$, $\alpha_2 = 0 \dots \alpha_n = 0$; et p autres droites $\beta_1 = 0$, $\beta_2 = 0 \dots \beta_p = 0$; le lieu du point tel que le rapport, du produit de ses distances aux n premières droites, au produit de ses distances aux p autres droites soit constant et égal à K, est représenté par l'équation :

$$\alpha_1 \alpha_2 \dots \alpha_n = \mathrm{K} \beta_1 \beta_2 \dots \beta_p.$$

67

Le théorème des coniques d'Apollonius

Dans l'ellipse et dans l'hyperbole, le parallélogramme construit sur deux diamètres conjugués est équivalent au rectangle construit sur les deux axes.

Respectivement pour l'une et pour l'autre de ces deux coniques, la somme ou la différence des carrés des longueurs de deux diamètres conjugués est égale à la somme ou à la différence des carrés des longueurs des deux axes.

I. — Apollonius de Perge (IIᵉ siècle av. J.-C.) fut l'auteur d'un ouvrage sur les sections coniques qui est, pour ainsi dire, le couronnement de la géométrie grecque; il conçut, le premier, les sections d'un cône oblique à section circulaire, et leur donna le nom d'ellipse, d'hyperbole et de parabole. La pensée directrice de l'auteur s'y révèle sans cesse, qui tend à lier entre elles, par leurs analogues propriétés, les différentes sections du cône; et tout le traité repose presque sur une propriété unique, qui dérive directement de la nature même des coniques. Apollonius avait déjà connaissance des plus belles propriétés des coniques, et en particulier des deux théorèmes énoncés qui lui sont dus. Nous en donnerons ici une démonstration moderne, fondée sur l'emploi des invariants des formes quadratiques.

II. — Soit, tout d'abord, rappelées, quelques propriétés des formes quadratiques. Soit ainsi une transformation sans déplacement d'origine : x, y sont les coordonnées courantes d'un point M par rapport au systèmes d'axes obliques Ox, Oy, faisant entre eux l'angle θ; X, Y sont les nouvelles coordonnées du point par rapport aux axes OX, OY, faisant entre eux l'angle θ'. Les paramètres principaux de la demi-droite OX étant α, β, et ceux de OY étant α', β', on a les formules de substitution linéaire :

$$x = \alpha \mathrm{X} + \alpha' \mathrm{Y}, \quad y = \beta \mathrm{X} + \beta' \mathrm{Y},$$

et :

$$\sin \theta' = (\alpha\beta' - \beta\alpha') \sin \theta,$$

le déterminant $\alpha\beta' - \beta\alpha' = \mu = \dfrac{\sin \theta'}{\sin \theta}$ étant le module de la substitution.

Cela posé, la forme $Ax^2 + 2Bxy + Cy^2$ devient, après la transformation de coordonnées $A'X^2 + 2B'XY + C'Y^2$, de sorte que :

$$A'X^2 + 2B'XY + C'Y^2 \equiv Ax^2 + 2Bxy + Cy^2.$$

Or, lorsque deux fonctions homogènes du second degré peuvent se déduire l'une de l'autre par une substitution linéaire, le discriminant de l'une est égal au produit du discriminant de l'autre par le carré du module de la substitution. On a donc :

$$A'C' - B'^2 = (AC - B^2)\,\mu^2,$$

d'où l'invariant :

$$\frac{A'C' - B'^2}{\sin^2 \theta'} = \frac{AC - B^2}{\sin^2 \theta}.$$

On mettrait également en évidence le nouvel invariant :

$$\frac{A' + C' - 2B' \cos \theta'}{\sin^2 \theta'} = \frac{A + C - 2B \cos \theta}{\sin^2 \theta}.$$

III. — Soit :

$$\frac{x^2}{a^2} + \frac{y^2}{\varepsilon b^2} = 1,$$

l'équation, rapportée à ses axes de symétrie, d'une conique à centre; si $\varepsilon = +1$, celle-ci est une ellipse; c'est une hyperbole si $\varepsilon = -1$. Prenons pour nouveaux axes de coordonnées deux diamètres conjugués; en appelant x', y' les nouvelles coordonnées, les formules de transformation donnent :

$$\frac{x^2}{a^2} + \frac{y^2}{\varepsilon b^2} \equiv A'x'^2 + 2B'x'y' + C'y'^2,$$

A', B', C' étant des constantes. L'équation de la conique, rapportée aux nouveaux axes, est donc :

$$A'x'^2 + 2Bx'y' + C'y'^2 - 1 = 0.$$

Mais comme ces axes sont deux diamètres conjugués, $B' = 0$. Si $\varepsilon = 1$, A' et C' sont positifs, et l'on peut poser :

$$A' = \frac{1}{a'^2}\,; \quad C' = \frac{1}{b'^2}.$$

Si $\varepsilon = -1$, A' et C' sont de signe contraire; on peut supposer $A' > 0$ et $C' < 0$, d'où l'on poserait :

$$A' = \frac{1}{a'^2}\,; \quad C' = -\frac{1}{b'^2}.$$

La nouvelle équation sera donc :

$$\frac{x'^2}{a'^2} + \frac{y'^2}{\varepsilon b'^2} - 1 = 0;$$

et on a par suite :

$$\frac{x^2}{a^2} + \frac{y^2}{\varepsilon b^2} = \frac{x'^2}{a'^2} + \frac{y^{2\prime}}{\varepsilon b'^2}.$$

Mais si l'on désigne par φ l'angle des deux diamètres conjugués, l'invariance permet d'écrire :

$$\frac{1}{a^2} + \frac{1}{\varepsilon b^2} = \frac{1}{\sin^2 \varphi}\left(\frac{1}{a'^2} + \frac{1}{\varepsilon b'^2}\right).$$

et :

$$\frac{1}{a^2 b^2} = \frac{1}{\sin^2 \varphi} \cdot \frac{1}{a'^2 b'^2},$$

soit :

$$ab = a'b' \sin \varphi, \quad a^2 + \varepsilon b^2 = a'^2 + \varepsilon b'^2,$$

d'où les deux théorèmes énoncés.

IV. — Soient OM et OM′ deux demi-diamètres conjugués d'une ellipse. Rapportons celle-ci à ses deux axes de symétrie, et soient x, y les coordonnées de M, x', y' les coordonnées de M′. On a :

$$\frac{xx'}{a^2} + \frac{yy'}{b^2} = 0, \quad \text{ou} \quad \frac{y}{b} \cdot \frac{y'}{b} = -\frac{x}{a} \cdot \frac{x'}{a}.$$

Si l'on pose :

$$\frac{x'}{a} = \lambda \frac{y}{b},$$

on a, en vertu de la relation précédente :

$$\frac{y'}{b} = -\lambda \frac{x}{a};$$

d'où l'on tire :

$$\frac{x'^2}{a^2} + \frac{y'^2}{b^2} = \lambda^2 \left(\frac{x^2}{a^2} + \frac{y^2}{b^2}\right),$$

c'est-à-dire $\lambda^2 = 1$, d'où $\lambda = \pm 1$. On a ainsi les formules dues à Chasles (1793-1880) :

$$\frac{x'}{a} = \varepsilon \frac{y}{b}, \quad \frac{y'}{b} = -\varepsilon \frac{x}{a}, \quad (\varepsilon = \pm 1).$$

En particulier, si l'on suppose OM dans l'angle xOy, le coefficient de OM′ est négatif; on peut donc supposer que le demi-diamètre OM′ est situé dans l'angle $x'Oy$. Dans ces conditions, les coordonnées de M′ sont données par :

$$\frac{x'}{a} = -\frac{y}{b}, \quad \frac{y'}{b} = +\frac{x}{a}.$$

Exercice.

58. **Problème.** *Par chaque point d'une circonférence, on mène des droites parallèles sur lesquelles on prend une longueur constante* l ; *quel est le lieu des points ainsi obtenus?*

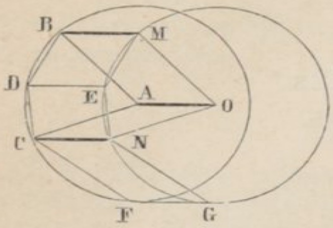

Fig. 24.

Soit CN égale et parallèle à BM.

Par le centre A menons une parallèle AO égale à l.

La figure ABMO est un parallélogramme comme ayant deux côtés opposés égaux et parallèles ; donc

$$OM = AB$$

De même $ON = AC = r$

Le lieu est donc une circonférence égale à la première.

59. **Remarque.** 1° En appliquant les conditions de l'énoncé ci-dessus à une figure quelconque, on obtiendrait aussi une figure égale.

La démonstration générale est la suivante :

Les droites BD et ME sont égales et parallèles, car BM et DE sont égales, et de même DC et EN sont égales et parallèles, et les angles BDC, MEN sont égaux comme ayant les côtés parallèles et de même sens.

Ainsi les figures BDCF, MENG sont égales comme ayant les côtés respectivement égaux et les angles égaux.

Les figures courbes sont égales comme limites de polygones égaux.

2° Dans les applications, on peut considérer la figure MENG comme ayant été obtenue par le déplacement de la figure BDCF, dont tous les sommets ont glissé sur des parallèles. Ainsi on peut dire que la figure MENG a été obtenue à l'aide de BDCF, en employant un *déplacement* ou une *translation parallèle* *.

Exercice.

60. **Problème.** *Quel est le lieu des points dont le rapport des distances à deux droites égale un rapport donné* $\frac{m}{n}$?

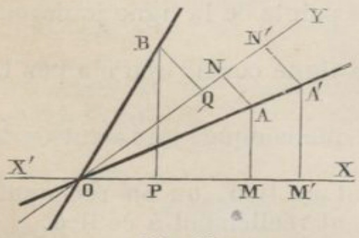

Fig. 25.

Soient OX, OY les droites données.

Le point O appartient au lieu ; soit A un point tel qu'on ait :

$$\frac{AM}{AN} = \frac{m}{n}$$

La droite AO *est le lieu demandé*, car pour tout autre point A'

on aura $$\frac{A'M'}{A'N'} = \frac{AM}{AN}$$

donc $$\frac{A'M'}{A'N'} = \frac{m}{n}$$

---

* Le terme *translation parallèle* se trouve dans un ouvrage bien remarquable : *Méthodes et théories pour la résolution des problèmes de constructions géométriques*, par JULIUS PETERSEN, professeur à l'École polytechnique de Copenhague ; traduction de M. O. CHEMIN, ingénieur des ponts et chaussées.

La droite OB *appartient aussi au lieu*, car on peut avoir

$$\frac{BP}{BQ}=\frac{m}{n}$$

Exercice.

61. Problème. *Quel est le lieu géométrique des points dont les distances à deux points donnés* A *et* B *sont dans un rapport constant* $\frac{m}{n}$?

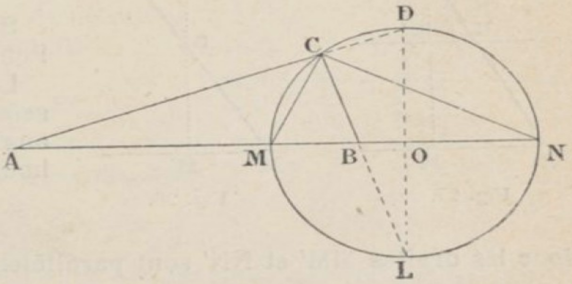

Fig. 26.

Sur la droite AB et sur son prolongement, déterminons les points M et N tels qu'on ait :

$$\frac{MA}{MB}=\frac{NA}{NB}=\frac{m}{n}$$

(G., n° 307.)

Ces deux points M et N appartiennent au lieu demandé.

Pour un autre point quelconque C du lieu, on a par hypothèse :

$$\frac{CA}{CB}=\frac{m}{n}$$

donc
$$\frac{CA}{CB}=\frac{MA}{MB}=\frac{NA}{NB}$$

Mais la bissectrice de l'angle ACB et celle de l'angle supplémentaire BCD donneraient, sur la base, deux points dont le rapport des distances aux points A et B égalerait $\frac{CA}{CB}$ ou $\frac{m}{n}$; donc les droites CM et CN sont elles-mêmes les bissectrices cherchées.

Les bissectrices des deux angles supplémentaires sont perpendiculaires l'une à l'autre ; donc l'angle MCN est droit, et le point C appartient à la circonférence décrite sur le diamètre MN.

On prouve ensuite que tout point de la circonférence appartient au lieu. (G., n° 307, 2°.)

62. Note. 1° En tenant compte des signes, on écrit :

$$\frac{MA}{MB}=-\frac{m}{n} \text{ et } \frac{NA}{NB}=\frac{m}{n}; \text{ d'où } \frac{NA}{NB}=-\frac{MA}{MB}.$$

Les quatre points A,B,M,N, forment une division harmonique. Dans la *Géométrie récente du triangle* (n^os^ 2262 et suivants) on écrit de préférence :

$$\frac{MB}{BN}=\frac{m}{n} \text{ et } \frac{MA}{AN}=-\frac{m}{n}.$$

Afin que le rapport qui correspond au point compris entre M et N soit positif.

2° Le lieu des points dont le rapport des distances à un point et à une droite est constant est une conique.

On obtient une ellipse lorsque $\frac{m}{n}$ est <1. (G., n° 846.)

— une parabole lorsque $\frac{m}{n}=1$. (G., n° 848.)

— une hyperbole pour $\frac{m}{n}>1$. (G., n° 850.)

Metric and Normed Spaces

Analysis is primarily concerned with infinite processes, including limits. So far, we have primarily done this in the setting of Euclidean spaces $\mathbb{R}^n$. We are now ready to develop a theory of limits in sets M more general than $\mathbb{R}^n$. All we need is the concept of distance as enumerated for Euclidean spaces in Section 0.5. Most of the properties of Euclidean space carry over, but not all. For example, Cauchy's inequality (Property (**E3**) of Theorem 0.6) and the Heine–Borel theorem (Theorem 0.23) do not hold in all general settings.

5.1 Metric Spaces

A **metric space** is a nonempty set M with a **distance function** or **metric** d having the following properties for all $x, y, z \in M$:

(M0) $d(x, y) \geq 0$;
(M1) $d(x, y) = 0$ if and only if $x = y$;
(M2) $d(x, y) = d(y, x)$ (symmetry);
(M3) $d(x, y) \leq d(x, z) + d(z, y)$ (triangle inequality).

Property **(M0)** can actually be proven from the others as follows:

$$0 = d(x, x) \leq d(x, y) + d(y, x) = d(x, y) + d(x, y) = 2d(x, y).$$

Here are some examples of metric spaces.

Example 5.1 The familiar Euclidean Space: Let $M = \mathbb{R}^n$, with the usual Euclidean metric as given in Section 0.5. For $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$ the metric is given by

$$d(x, y) = \sqrt{(x_1 - y_1)^2 + \cdots + (x_n - y_n)^2}.$$

Example 5.2 Discrete or Trivial Metric: Let M be any nonempty set and define

$$d(x,y) = \begin{cases} 1 & \text{if } x \neq y \\ 0 & \text{if } x = y. \end{cases}$$

The metric conditions are easily seen to be true. If you consider the discrete metric on the set $\mathbb{R}$, the distance between any two distinct points is 1, which is very different from the usual metric on $\mathbb{R}$. A major use of the discrete metric is to obtain examples to illustrate specific concepts and to create counterexamples for conjectures. When considering a conjecture about metric spaces, it is a good idea to first test it on the discrete metric.

Example 5.3 Hamming Metric: Let $n \in \mathbb{N}$ be fixed, say $n = 7$, and let M be the set of all n-tuples of 0s and 1s. For $x, y \in M$, let $d(x, y)$ be the number of places in which x and y differ. For example, $d(0010110, 1010011) = 3$. This metric is used in the decoding of messages from error correcting codes.

Example 5.4 Let M consist of the natural numbers $\mathbb{N}$ along with the object ∞. Define the metric $d(x, y)$ as follows:

$$\begin{aligned} &d(x,y) = \left|\frac{1}{x} - \frac{1}{y}\right| \qquad \text{if} \quad x, y \in \mathbb{N}, \\ &d(x,\infty) = d(\infty,x) = \frac{1}{x} \quad \text{if} \quad x \in \mathbb{N}, \\ &d(\infty,\infty) = 0. \end{aligned}$$

This metric d is bounded on $\mathbb{N}$ by $d(x, y) < 1$. Adjoining the point ∞ to the space lets the metric attain its upper bound $d(1,\infty) = 1$.

Example 5.5 The function space $C[a,b]$ of continuous functions on $[a,b]$, with $a < b$, is a metric space under the distance function

$$d(f,g) = \int_a^b |f(x) - g(x)|\, dx.$$

The properties **(M2)** and **(M3)** are easy to prove. The proof of **(M1)** is left as Exercise 5.1.14. It follows from an important property of continuous functions: If a function $h \geq 0$ is continuous and $h(x_0) > 0$ for some $x_0 \in [a,b]$, then $\int_a^b h(x)\, dx > 0$.

Example 5.6 Fréchet metric: Recall that ω is the space of all real- or complex-valued sequences. The Fréchet[1] metric on ω is defined as follows. For $x = (x_1, x_2, \ldots)$ and $y = (y_1, y_2, \ldots)$, let

$$d(x, y) = \sum_{k=1}^{\infty} \frac{|x_k - y_k|}{2^k(1 + |x_k - y_k|)}.$$

The properties **(M0)**, **(M1)**, and **(M2)** are clearly satisfied. The triangle inequality **(M3)** follows from the inequality of Lemma 5.1. The details are left to Exercise 5.1.17. A generalization of this metric is given in Exercise 5.3.6.

Lemma 5.1 *For any* $a, b \in \mathbb{C}$, *we have* $\frac{|a+b|}{1+|a+b|} \leq \frac{|a|}{1+|a|} + \frac{|b|}{1+|b|}$.

Proof Consider the function $f(t) = t/(1+t)$ on $\mathbb{R}$. For $t > -1$, we have $f'(t) = 1/(1+t)^2 > 0$. Thus means that f is increasing on $t > -1$. Applying this function to the triangle inequality for $\mathbb{R}$, we have

$$\begin{aligned}\frac{|a+b|}{1+|a+b|} &= f(|a+b|) \leq f(|a|+|b|) \\ &= \frac{|a|+|b|}{1+|a|+|b|} \leq \frac{|a|}{1+|a|} + \frac{|b|}{1+|b|}.\end{aligned}$$ ∎

Theorem 5.2 Subspace metric: *Suppose M is a metric space and N is any nonempty subset. Let the distance between elements of N be defined just as in M. Then N is also a metric space.*

The proof is left as Exercise 5.1.11.

Exercises for Section 5.1

5.1.1 Show that Euclidean space $\mathbb{R}^n$ is a metric space with the Euclidean metric.

5.1.2 **Taxicab metric:** Let $M = \mathbb{R}^2$. Show that $d_1(x, y) = |x_1 - y_1| + |x_2 - y_2|$ is a metric on M when $x = (x_1, x_2)$ and $y = (y_1, y_2)$. Example of use: Whereas the Euclidean metric is the distance "as the crow flies," the fare of a taxicab in an urban grid of streets is based on this metric d_1.

---

[1] Maurice René Fréchet (1878–1973) was a French mathematician who introduced the concept of metric spaces. He made many contributions to functional analysis, topology, probability, and statistics.

3.4 The projection operator

The real significance of traces lies in the fact that the physical content of quantum mechanics can always be expressed in terms of them. In particular, the expectation-value formula (3.13) can be expressed as a trace. For this purpose we introduce the *projection operator* $P(\psi)$ for the state ψ by means of the defining relation

$$P(\psi)\theta = \psi\int d\varsigma\, \psi^* \theta, \tag{3.25}$$

where θ is an arbitrary wave function. The projection operator derives its name from the fact that, if ψ is a member of a complete orthonormal set, then $P(\psi)$ picks out the contribution to the expansion of θ from the state ψ. By making use of the defining relation (3.25), we obtain for the (ji)th matrix element of $P(\psi)$:

$$\begin{aligned} P(\psi)_{ji} &= \int d\varsigma\, u_j^* P(\psi) u_i \\ &= \int d\varsigma\, u_j^* \psi \int d\varsigma\, \psi^* u_i \\ &= a_j a_i^*, \end{aligned} \tag{3.26}$$

where the coefficients a_i and a_j are defined by (3.6). By substituting this result in (3.13) and invoking the matrix product rule (3.11), we obtain the desired formula

$$\begin{aligned} <O> &= \sum_i \sum_j P(\psi)_{ji} O_{ij} \\ &= \sum_j (P(\psi) O)_{jj} \\ &= \mathrm{Tr}(P(\psi) O), \end{aligned} \tag{3.27}$$

which, we note, is independent of the representation.

Since it can be used to calculate expectation values, the projection operator provides a description of the physical state of the system which is completely equivalent to that provided by the wave function. For our purpose the description in terms of the projection operator is more suitable. The time-development of the system, as well as its instantaneous condition, can also be discussed in terms of the projection operator; that is to say, it is possible to derive an equation of motion for $P(\psi)$ which may be used instead of the equation of motion (3.3) for the wave function ψ (the time-dependent Schrödinger equation). It is sufficient for this purpose to suppose that the arbitrary wave function θ in (3.25) is independent of time. Then, by differentiating (3.25) with respect to time t and making use of (3.3), we obtain

$$\begin{aligned} i\hbar\, d\{P(\psi)\theta\}/dt &= i\hbar\, (d\psi/dt)\int d\varsigma\, \psi^*\theta + \psi\int d\varsigma\, i\hbar\, (d\psi^*/dt)\theta \\ &= H\psi\int d\varsigma\, \psi^*\theta - \psi\int d\varsigma\, (H\psi)^*\theta. \end{aligned} \tag{3.28}$$

Downloaded from https://www.cambridge.org/core. University of Birmingham, on 12 Aug 2017 at 19:31:32, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/CBO9781139167994.004

From the defining relation (3.25), it is evident that the first term on the second line of (3.28) is $HP(\psi)\theta$. Moreover, since energy is a real dynamical variable and therefore the corresponding operator (the Hamiltonian H) is Hermitian, we see with the aid of (3.15) that the second term on the second line of (3.28) is

$$\begin{aligned} \psi\int \mathrm{d}\varsigma\,(H\psi)^*\theta &= \psi\left(\int \mathrm{d}\varsigma\,\theta^* H\psi\right)^* \\ &= \psi\int \mathrm{d}\varsigma\,\psi^* H\theta \\ &= P(\psi)H\theta. \end{aligned} \tag{3.29}$$

Hence (3.28) becomes

$$i\hbar\,\mathrm{d}\{P(\psi)\theta\}/\mathrm{d}t = HP(\psi)\theta - P(\psi)H\theta. \tag{3.30}$$

Finally, since θ is arbitrary, it can be cancelled out of (3.30) to yield the equation of motion of the projection operator $P(\psi)$:

$$\begin{aligned} i\hbar\,\mathrm{d}\{P(\psi)\}/\mathrm{d}t &= HP(\psi) - P(\psi)H \\ &= [H, P(\psi)] \end{aligned} \tag{3.31}$$

where we have introduced the conventional bracket notation for the commutator of two operators.

3.5 The density operator

We are now in a position to introduce the density operator and determine its equation of motion. The expectation-value formula (3.2) is the basic rule for the physical interpretation of the formalism of quantum mechanics. However, in order to use it we must know the state of the system precisely so that the wave function ψ is uniquely determined (apart from a trivial phase factor). Such precise knowledge is seldom at our disposal. Let us consider, as an example, a system containing M spin-free particles. Then a precise determination of the state of the system involves the measurement of $3M$ quantities (since the system has $3M$ degrees of freedom); the quantities to be measured might, for example, be the particle momenta. For a macroscopic system comprising, for example, a 1 mm^3 cube of solid material, $M \sim 10^{20}$ typically, and the task must be abandoned as hopeless. Even in small volumes of very dilute gases, the number of entities is usually so large that one cannot expect to know the state of the system precisely. The most that can really be hoped for is statistical information. We can use whatever limited knowledge is available about the state of the system to determine the probability p_n that the system is in the state ψ_n, where n labels the different possible states in which the system might actually be. Setting $p_n = 0$ for all values of n except one, for which $p_n = 1$, gives us the exceptional case in which

>4 ; ?1 3' + . + = =

An example of the full expansion of (4.64) in the case of a four-level system is given by Bloembergen *et al* (1978).

The generalisation of the formulae (4.58), (4.63) and (4.64) to arbitrary order will become clear after we have introduced the overall permutation-symmetry property in the next section.

To derive these explicit formulae for the susceptibility tensors we have used the density-matrix approach developed in Chapter 3. We should point out, however, that this is not the only approach that can be taken. Similar results are obtained using a time-dependent perturbation analysis (Ducuing, 1969).

4.3 Overall permutation symmetry

The formulae for the susceptibility tensors derived in the previous section may be thrown into a form which reveals an important permutation-symmetry property of the tensor components. The *intrinsic* permutation-symmetry property, first introduced in §2.1 and used extensively in the previous sections of this chapter (as implied by the operator $\mathbf{S}$), indicates that $\chi^{(n)}_{\mu\alpha_1\cdots\alpha_n}(-\omega_\sigma;\omega_1,\ldots,\omega_n)$ is invariant under all $n!$ permutations of the n pairs $(\alpha_1,\omega_1),(\alpha_2,\omega_2),\ldots,(\alpha_n,\omega_n)$. *Overall* permutation symmetry, which we introduce here, is a more general property, at least in the sense that it encompasses intrinsic permutation symmetry. However, it is important to appreciate that intrinsic permutation symmetry is a completely rigorous property which arises from the principles of causality and reality, and which applies universally. The overall permutation-symmetry property, on the other hand, is an approximation which applies only under particular conditions; namely, when all of the optical frequencies involved in the susceptibility formulae (*i.e.*, the primary frequencies $\omega_\sigma,\omega_1,\ldots,\omega_n$ and the combinations of these which occur in the denominators) are far removed from molecular transition frequencies – in other words, when the medium can be assumed to be loss-free at all the relevant optical frequencies. The reasons for this restriction become clearer when, in §4.5, we introduce transition damping factors into the susceptibility formulae. The physical consequences of overall permutation symmetry are discussed in §5.1.

Here we shall simply demonstrate how overall permutation symmetry arises, and introduce a compact notation for its description. The usefulness of this notation is that it allows us to write down readily a general formula for the nth-order susceptibility tensor.

4.3.1 Compact formulae for nonresonant susceptibilities

We begin by considering the previous formula for the first-order

Downloaded from https://www.cambridge.org/core. University of Birmingham, on 12 Aug 2017 at 19:36:50, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/CBO9781139167994.005

susceptibility tensor, namely:

$$\chi^{(1)}_{\mu\alpha}(-\omega_\sigma;\omega) = \frac{N}{\varepsilon_0}\frac{e^2}{\hbar}\sum_{ab}\rho_0(a)\left[\frac{r^{\mu}_{ab}r^{\alpha}_{ba}}{\Omega_{ba}-\omega}+\frac{r^{\alpha}_{ab}r^{\mu}_{ba}}{\Omega_{ba}+\omega}\right]. \tag{4.65}$$

It will be seen that the second term in square brackets may be derived from the first by interchanging the coordinate labels μ and α and replacing $-\omega$ by ω. Consequently, if we interchange μ and α and interchange $-\omega_\sigma$ and ω in $\chi^{(1)}_{\mu\alpha}(-\omega_\sigma;\omega)$, and remembering that for the first-order susceptibility ω_σ is defined as $\omega_\sigma = \omega$, it follows that the only result is to interchange the order in which the two terms appear in the square brackets in (4.65) and their sum is unaltered. Thus we have

$$\begin{aligned}\chi^{(1)}_{\alpha\mu}(\omega;-\omega_\sigma) &= \frac{N}{\varepsilon_0}\frac{e^2}{\hbar}\sum_{ab}\rho_0(a)\left[\frac{r^{\alpha}_{ab}r^{\mu}_{ba}}{\Omega_{ba}+\omega}+\frac{r^{\mu}_{ab}r^{\alpha}_{ba}}{\Omega_{ba}-\omega}\right]\\ &= \chi^{(1)}_{\mu\alpha}(-\omega_\sigma;\omega).\end{aligned} \tag{4.66}$$

This is the overall permutation-symmetry property of the first-order susceptibility tensor. Thus (4.65) may be rewritten in a more compact form:

$$\chi^{(1)}_{\mu\alpha}(-\omega_\sigma;\omega) = \frac{N}{\varepsilon_0}\frac{e^2}{\hbar}\mathbf{S}_{\mathrm{T}}\sum_{ab}\rho_0(a)\left[\frac{r^{\mu}_{ab}r^{\alpha}_{ba}}{\Omega_{ba}-\omega}\right], \tag{4.67}$$

where the 'total symmetrisation operator' $\mathbf{S}_{\mathrm{T}}$ indicates that the expression which follows it is to be summed over all possible permutations of the pairs $(\mu,-\omega_\sigma)$ and (α,ω). There are in fact two possible permutations, which are: (i) the identity permutation $(\mu,-\omega_\sigma)\rightarrow(\mu,-\omega_\sigma)$, which merely reproduces the term stated explicitly in (4.67), *i.e.*, the first term in square brackets in (4.65); (ii) the interchange $(\mu,-\omega_\sigma)\leftrightarrow(\alpha,\omega)$, which gives the second term in square brackets in (4.65). Since $\mathbf{S}_{\mathrm{T}}$ indicates that a summation is to be made over all permutations of the pairs $(\mu,-\omega_\sigma)$ and (α,ω), it is clear that $\chi^{(1)}_{\mu\alpha}(-\omega_\sigma;\omega)$ is invariant under such permutations. This is an expression of the overall permutation-symmetry property in first order, and in this form the property generalises to all orders.

We now turn to a consideration of the formula (4.63) for the second-order susceptibility tensor. We again associate the frequency $-\omega_\sigma$ with the coordinate suffix μ. It can be seen by inspection of (4.63) that the second term in square brackets may be derived from the first by interchanging μ and α and replacing $-\omega_\sigma(=-\omega_1-\omega_2)$ by ω_1, *i.e.*, by permuting the pairs $(\mu,-\omega_\sigma)$, (α,ω_1), (β,ω_2) as follows:

$$(\mu,-\omega_\sigma),(\alpha,\omega_1),(\beta,\omega_2)\rightarrow(\alpha,\omega_1),(\mu,-\omega_\sigma),(\beta,\omega_2). \tag{4.68}$$

Downloaded from https://www.cambridge.org/core. University of Birmingham, on 12 Aug 2017 at 19:36:50, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/CBO9781139167994.005

Similarly, the last term in square brackets may be derived from the first by permuting the pairs as follows:

$$(\mu, -\omega_\sigma), (\alpha, \omega_1), (\beta, \omega_2) \rightarrow (\alpha, \omega_1), (\beta, \omega_2), (\mu, -\omega_\sigma). \tag{4.69}$$

Finally, the first term in square brackets may of course be derived from itself by applying the identity permutation

$$(\mu, -\omega_\sigma), (\alpha, \omega_1), (\beta, \omega_2) \rightarrow (\mu, -\omega_\sigma), (\alpha, \omega_1), (\beta, \omega_2). \tag{4.70}$$

Altogether there are six possible permutations of the three pairs $(\mu, -\omega_\sigma)$, (α, ω_1) and (β, ω_2). Equations (4.68), (4.69) and (4.70) specify the three permutations in which $(\mu, -\omega_\sigma)$ occupies the second, third and first place in the sequence while the order of the pairs (α, ω_1) and (β, ω_2) is left undisturbed. The other three permutations are derived from these by interchanging the pairs (α, ω_1) and (β, ω_2). Now the formula (4.63) already involves the symmetrising operation $\mathbf{S}$ which implies that the expression following it is to be summed over the two possible permutations of the pairs (α, ω_1) and (β, ω_2). Hence, when this symmetrising operation is carried out, there are six terms in the square brackets and they may all be derived from the first term by the application of the six permutations of the pairs $(\mu, -\omega_\sigma)$, (α, ω_1), (β, ω_2). Thus (4.63) may be written in the more compact form:

$$\chi^{(2)}_{\mu\alpha\beta}(-\omega_\sigma; \omega_1, \omega_2) = \frac{N e^3}{\varepsilon_0 2\hbar^2} \mathbf{S}_{\mathrm{T}} \sum_{abc} \rho_0(a) \left[\frac{r^\mu_{ab}\, r^\alpha_{bc}\, r^\beta_{ca}}{(\Omega_{ba} - \omega_1 - \omega_2)(\Omega_{ca} - \omega_2)} \right], \tag{4.71}$$

where the total symmetrisation operation $\mathbf{S}_{\mathrm{T}}$ indicates that the expression which follows it is to be summed over all six permutations of the pairs $(\mu, -\omega_\sigma)$, (α, ω_1), (β, ω_2). Since $\mathbf{S}_{\mathrm{T}}$ involves a summation over all possible permutations, it is clear that $\chi^{(2)}_{\mu\alpha\beta}(-\omega_\sigma; \omega_1, \omega_2)$ is invariant under any of them. This is the overall permutation-symmetry property in second order.

The presence of the symmetrising operation $\mathbf{S}$ in (4.63) already implies that $\chi^{(2)}_{\mu\alpha\beta}(-\omega_\sigma; \omega_1, \omega_2)$ has intrinsic permutation symmetry. The new feature introduced by the presence of the total symmetrisation operation $\mathbf{S}_{\mathrm{T}}$ in (4.71) is that the invariance is preserved under permutations involving the extra pair $(\mu, -\omega_\sigma)$. As a particular example of overall permutation symmetry in second order, we consider the permutation (4.68); thus we have

$$\chi^{(2)}_{\mu\alpha\beta}(-\omega_\sigma; \omega_1, \omega_2) = \chi^{(2)}_{\alpha\mu\beta}(\omega_1; -\omega_\sigma, \omega_2). \tag{4.72}$$

We may write down six relations of this type, one of which is an identity.

Downloaded from https://www.cambridge.org/core. University of Birmingham, on 12 Aug 2017 at 19:36:50, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/CBO9781139167994.005

The above considerations are easily extended to the formula (4.64) for the third-order susceptibility tensor $\chi^{(3)}_{\mu\alpha\beta\gamma}(-\omega_\sigma;\omega_1,\omega_2,\omega_3)$, for which ω_σ is defined to be $\omega_\sigma = \omega_1+\omega_2+\omega_2$. The four terms in the square brackets in (4.64) may all be derived from the first by application of the four permutations of the pairs $(\mu,-\omega_\sigma)$, (α,ω_1), (β,ω_2) and (γ,ω_3) in which $(\mu,-\omega_\sigma)$ appears in the first, second, third and fourth place in the sequence while the pairs (α,ω_1), (β,ω_2), and (γ,ω_3) appear in natural order. The symmetrisation operation $\mathbf{S}$ permutes the pairs (α,ω_1), (β,ω_2), and (γ,ω_3) in all six possible ways and sums the result. Hence (4.64) may be written in the compact form:

$$\chi^{(3)}_{\mu\alpha\beta\gamma}(-\omega_\sigma;\omega_1,\omega_2,\omega_3) = \frac{N}{\varepsilon_0}\frac{e^4}{3!\hbar^3}\mathbf{S}_\mathrm{T} \times \sum_{abcd}\rho_0(a)\left[\frac{r^\mu_{ab}\,r^\alpha_{bc}\,r^\beta_{cd}\,r^\gamma_{da}}{(\Omega_{ba}-\omega_1-\omega_2-\omega_3)(\Omega_{ca}-\omega_2-\omega_3)(\Omega_{da}-\omega_3)}\right], \quad (4.73)$$

where the total symmetrisation operation $\mathbf{S}_\mathrm{T}$ indicates that the expression which follows it is to be summed over all 24 permutations of the pairs $(\mu,-\omega_\sigma)$, (α,ω_1), (β,ω_2) and (γ,ω_3). Clearly, $\chi^{(3)}_{\mu\alpha\beta\gamma}(-\omega_\sigma;\omega_1,\omega_2,\omega_3)$ is invariant under all such permutations.

The generalisation of the formulae (4.67), (4.71) and (4.73) to arbitrary order is now obvious by inspection. In making this generalisation, the frequency $-\omega_\sigma$ is defined as previously, *i.e.*,

$$-\omega_\sigma = -(\omega_1+\omega_2+\cdots+\omega_n), \quad (4.74)$$

and is always associated with the cartesian coordinate μ. (We note that the pair $(\mu,-\omega_\sigma)$, and not (μ,ω_σ), is involved in overall permutation symmetry; hence the convention of writing $\chi^{(n)}_{\mu\alpha_1\cdots\alpha_n}(-\omega_\sigma;\omega_1,\dots,\omega_n)$ rather than $\chi^{(n)}_{\mu\alpha_1\cdots\alpha_n}(\omega_\sigma;\omega_1,\dots,\omega_n)$.) We thus obtain the general (but rather dense) formula:

$$\chi^{(n)}_{\mu\alpha_1\cdots\alpha_n}(-\omega_\sigma;\omega_1,\dots,\omega_n) = \frac{N}{\varepsilon_0}\frac{e^{n+1}}{n!\hbar^n}\mathbf{S}_\mathrm{T}\sum_{ab_1\cdots b_n}\rho_0(a) \times\left[\frac{r^\mu_{ab_1}\,r^{\alpha_1}_{b_1b_2}\cdots r^{\alpha_{n-1}}_{b_{n-1}b_n}\,r^{\alpha_n}_{b_na}}{(\Omega_{b_1a}-\omega_1-\cdots-\omega_n)(\Omega_{b_2a}-\omega_2-\cdots-\omega_n)\cdots(\Omega_{b_na}-\omega_n)}\right]. \quad (4.75)$$

In (4.75) $\mathbf{S}_\mathrm{T}$ is the total symmetrisation operation in *n*th order; it implies that the expression which follows it is to be summed over all $(n+1)!$ permutations of the pairs $(\mu,\omega_\sigma),(\alpha_1,\omega_1),\dots,(\alpha_n,\omega_n)$. Clearly $\boldsymbol{\chi}^{(n)}$ is invariant under all such permutations. This is the most general expression of the overall permutation-symmetry property.

Downloaded from https://www.cambridge.org/core. University of Birmingham, on 12 Aug 2017 at 19:36:50, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/CBO9781139167994.005

It will be noticed that the definition of $\mathbf{S}_\mathrm{T}$, like that of the intrinsic-permutation-symmetry operator $\mathbf{S}$ in (4.28), is different in different orders n and strictly, therefore, should carry a superscript n. However, the order will always be clear from the context and, as for $\mathbf{S}$, there is no need to complicate the notation in this way.

Lastly, it is often useful to simplify the appearance of the final formulae (4.67), (4.71), (4.73) and (4.75) by writing them in the scalar form defined by (2.58); we state below the resulting expression in nth order:

$$\chi^{(n)}(-\omega_\sigma;\omega_1,\dots,\omega_n) = \frac{N}{\varepsilon_0}\frac{e^{n+1}}{n!\hbar^n}\mathbf{S}_\mathrm{T}\sum_{ab_1\cdots b_n}\rho_0(a) \times\left[\frac{\mathbf{e}_\sigma{}^*\cdot\mathbf{r}_{ab_1}\,\mathbf{e}_1\cdot\mathbf{r}_{b_1b_2}\cdots\mathbf{e}_n\cdot\mathbf{r}_{b_na}}{(\Omega_{b_1a}-\omega_1-\cdots-\omega_n)(\Omega_{b_2a}-\omega_2-\cdots-\omega_n)\cdots(\Omega_{b_na}-\omega_n)}\right], \tag{4.76}$$

noting, once again, that the polarisation vector $\mathbf{e}_i{}^*$ is associated with the negative frequency $-\omega_i$. When expressed in this form, the total symmetrisation operation $\mathbf{S}_\mathrm{T}$ requires that the expression following it is to be summed over all permutations of the pairs $(\mathbf{e}_\sigma{}^*, -\omega_\sigma)$, $(\mathbf{e}_1, \omega_1), \dots, (\mathbf{e}_n, \omega_n)$.

The full expansion of (4.75) or (4.76), when the terms generated by $\mathbf{S}_\mathrm{T}$ are written out explicitly, contains $(n+1)!$ terms within the square brackets, although if some of the pairs $(\mathbf{e}_i, \omega_i)$ are in fact equal, then there will be fewer distinct terms. This is of no consequence, however, since the operation $\mathbf{S}_\mathrm{T}$ specifies that *all* the permutations are to be summed, regardless of whether or not they are distinct.

4.3.2 Third-harmonic generation

These points are best clarified by reference to an example, which will also demonstrate the application of the general formulae to a particular nonlinear process. The example considered here is third-harmonic generation (others occur in later sections). Third-harmonic generation can occur when an incident field at the frequency ω induces a polarisation at the frequency 3ω; the process is governed by the third-order susceptibility $\boldsymbol{\chi}^{(3)}(-3\omega;\omega,\omega,\omega)$. (The nonlinear polarisation so induced may generate a travelling wave at the third-harmonic frequency, as described in Chapter 7.) Because three of the frequency arguments of this susceptibility are identical, the 24 terms generated by $\mathbf{S}_\mathrm{T}$ in the formula (4.73) reduce to four distinct terms, each of which occurs six times. Thus, using the scalar form (4.76), we have

Downloaded from https://www.cambridge.org/core. University of Birmingham, on 12 Aug 2017 at 19:36:50, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/CBO9781139167994.005

$$\chi^{(3)}(-3\omega;\omega,\omega,\omega) = \frac{N}{\varepsilon_0}\frac{e^4}{3!\hbar^3}\sum_{abcd}\rho_0(a)$$
$$\times 6\left[\frac{\mathbf{e}_{3\omega}{}^*\cdot\mathbf{r}_{ab}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{bc}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{cd}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{da}}{(\Omega_{ba}-3\omega)(\Omega_{ca}-2\omega)(\Omega_{da}-\omega)}+\frac{\mathbf{e}_{\omega}\cdot\mathbf{r}_{ab}\,\mathbf{e}_{3\omega}{}^*\cdot\mathbf{r}_{bc}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{cd}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{da}}{(\Omega_{ba}+\omega)(\Omega_{ca}-2\omega)(\Omega_{da}-\omega)}\right.$$
$$\left.+\frac{\mathbf{e}_{\omega}\cdot\mathbf{r}_{ab}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{bc}\,\mathbf{e}_{3\omega}{}^*\cdot\mathbf{r}_{cd}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{da}}{(\Omega_{ba}+\omega)(\Omega_{ca}+2\omega)(\Omega_{da}-\omega)}+\frac{\mathbf{e}_{\omega}\cdot\mathbf{r}_{ab}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{bc}\,\mathbf{e}_{\omega}\cdot\mathbf{r}_{cd}\,\mathbf{e}_{3\omega}{}^*\cdot\mathbf{r}_{da}}{(\Omega_{ba}+\omega)(\Omega_{ca}+2\omega)(\Omega_{da}+3\omega)}\right]. \tag{4.77}$$

The singularities that occur when any of the frequency denominators in (4.77) approach zero are considered in detail in §4.5.

4.3.3 Virtual transitions and Feynman diagrams

Diagrammatic techniques can be used to keep track of the various terms in (4.75) and (4.76) which are generated by $\mathbf{S}_{\mathrm{T}}$ (Ward, 1965), and these also provide a pictorial interpretation of the matter-field interaction in terms of photon creation and annihilation (Loudon, 1983). Since we use the classical description of fields throughout this book, we should regard the polarisation vectors $\mathbf{e}_j$ and $\mathbf{e}_j{}^*$ which appear in the susceptibility formulae as commuting annihilation and creation operators, respectively. (It will be recalled that in the definition (2.58), the vector $\mathbf{e}_i{}^*$ is to be associated with a negative frequency $-\omega_i$ which appears as an argument of $\chi^{(n)}(-\omega_\sigma;\omega_1,\ldots,\omega_n)$.) To take an example, the four terms in the formula (4.77) for the third-harmonic susceptibility correspond, in order, to the four Feynman diagrams drawn in Fig. 4.1. The first diagram (a) represents the process in which a molecule, initially in a state labelled a, emits a third-harmonic photon 3ω whilst making a virtual transition to a state labelled b. By absorbing a fundamental photon ω the molecule then makes a virtual transition from b to c. The absorption of two further ω photons takes the molecule into d and finally back to the initial state a. The summation in (4.77) signifies that each of the labels a, b, c, d ranges over all of the molecular energy eigenstates, and that all combinations of the pathways $a\rightarrow b\rightarrow c\rightarrow d\rightarrow a$ contribute to the term depicted in Fig. 4.1(a). The process involves virtual transitions; the molecule undergoes no real net change of energy and is restored to its initial state when the process is complete. Energy conservation need not (and in general will not) hold at each virtual transition in the sequence depicted in the Feynman diagram. However, energy is conserved overall since $\hbar(\omega+\omega+\omega)=\hbar 3\omega$. These remarks hold for all four diagrams drawn in Fig. 4.1 in which the virtual transitions occur in various sequences corresponding to the four terms in (4.77). The factor of 6 arises from the indistinguishable permutations of the ω photons in each diagram.

Downloaded from https://www.cambridge.org/core. University of Birmingham, on 12 Aug 2017 at 19:36:50, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/CBO9781139167994.005

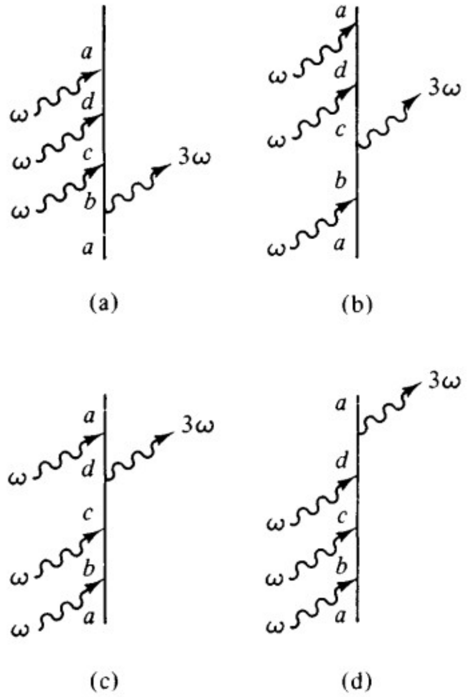

Fig. 4.1 Feynman diagrams illustrating the process of third-harmonic generation (the optical frequencies involved are assumed to be far removed from resonances). Photons (indicated by wavy lines) incident from the left represent absorption, and emission processes are represented by photons leaving to the right. The sequence of virtual molecular transitions involved in the whole process is indicated by the upward progression through states labelled a , b ,... on the vertical line.

Since energy is generally not conserved during a virtual transition (such as $a \rightarrow b$ in Fig. 4.1(a), for example), the uncertainty principle dictates that the transition is possible only if the molecule remains in the state b for a time shorter than the inverse of the detuning (which is $(\Omega_{ba} - 3\omega)^{-1}$ in this case). Virtual transitions therefore occur on an ultrafast time scale (see §6.6) and may be assumed to be instantaneous for many practical purposes.

4.4 The passage from microscopic to macroscopic formulae

In §4.1 we derived fundamental formulae for the susceptibility tensors in terms of electric-dipole operators and their matrix elements (equivalent formulae in terms of current operators and their matrix elements are derived in §4.6). The general expressions (4.28) and (4.131) for $\boldsymbol{\chi}^{(n)}$ in

CURVILINEAR DISSECTIONS

The other chapters in this book, all concerned with rectilinear dissections, can be read in deep seriousness. But this hardly applies to curvilinear dissections, whose nature fits them only for puzzles and more or less artistic designs.

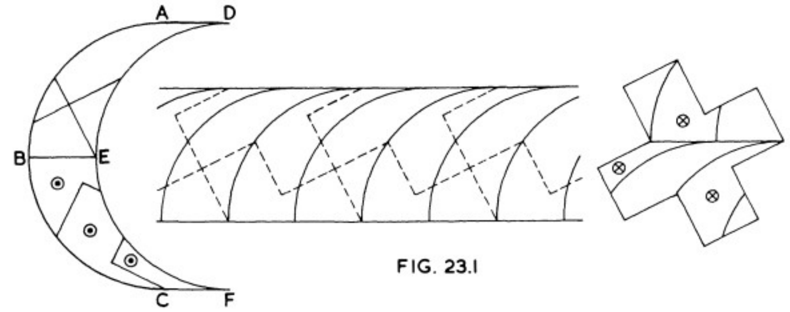

FIG. 23.1

The difficulty in finding curvilinear dissections is that to every convex edge of a figure there must nearly always correspond somewhere else concave edges of the same length and radius for it to fit into. For instance, in the dissection of crescent and

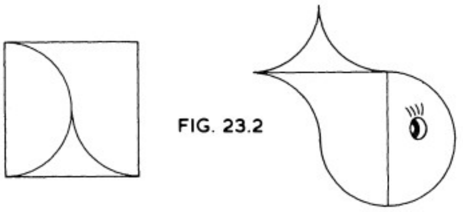

FIG. 23.2

SWEET
AND
LOVELY

Greek cross in Fig. 23.1 the edges of the former must include two equal curved portions *ABC* and *DEF,* and the remainder must be two straight lines *AD* and *CF* (if the figure is to look anything like a crescent).

Again, the shapely contour of the mermaid's rival in Fig. 23.2 has equal lengths of convex and concave curves. But Loyd exploited the difficulty by the trick shown in Fig. 23.3.

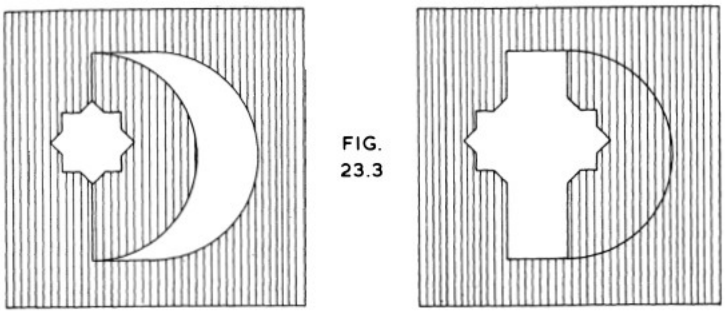

FIG. 23.3

Because of this difficulty, one cannot as a rule choose two curvilinear figures beforehand and try to dissect them; it is rather a matter of seeing what a given curvilinear figure can be dissected into. Thus it is with the circle. One might have in mind its dissection into some kind of curvilinear star, but hardly a goal more precise. And you count yourself lucky to find something as passable as Figs. 23.4-23.6.

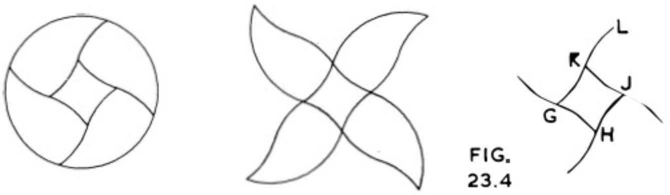

FIG. 23.4

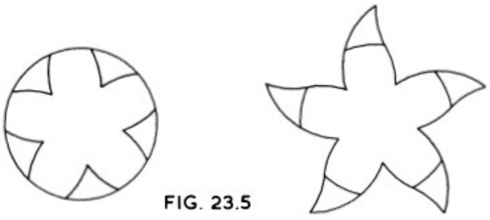

FIG. 23.5

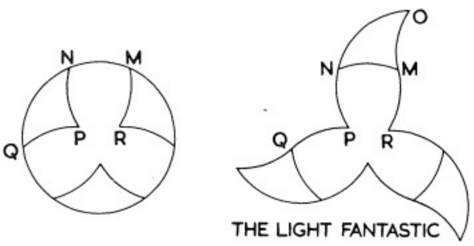
THE STARFISH

The radius of the cuts in Fig. 23.4 is arbitrary. There is less freedom in Figs. 23.5 and 23.6, in that all cuts must have the same radius as the circle.

Working out the cuts for Fig. 23.4 is quite easy. Draw curves of convenient radius joining the vertices G, H, J, K of an n-gon, making L such that GK and KL are equal and collinear; join KL by a curve of the same radius, and complete by drawing a circle through the n points like L. This construction differs from that of Fig. 19.7 only in that the lines are curved.



THE LIGHT FANTASTIC

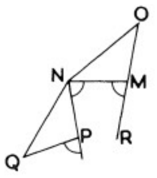


FIG. 23.6

But Figs. 23.5 and 23.6 require a more elaborate approach, to find lines that give smooth joins at points M in the star. (Points N give no trouble, for in curvilinear angles

$$\angle ONM + \angle MNP = \angle NQP + \angle MNP = \angle QNP + \angle MNP = \pi.)$$

To see one's way more clearly in considering the join at M, replace some of the curves in Fig. 23.6 by straight lines as on the right. Then a smooth join at M requires that O, M, R be collinear, whence the three marked angles must be equal. For an n-point star, since arc MNQ is $1/n$ of the circumference, it follows that

$$\angle MNP = \tfrac{2}{3}\angle MNQ = \tfrac{2}{3}(\pi - \pi/n).$$

Since also

$$QP = PN = NM = MO = MR$$

and their length can be given any convenient value, all the points named in Fig. 23.6 can be determined, and, therefore, all points in the star dissection, and the radius of the arcs is that of the circle through M, N, Q. In going about it this way, the radius of the circle is whatever it turns out to be. If on the contrary we start with a circle of given radius R, then we use the fact that

$$MN = 2R \sin \theta,$$

where

$$\cot \theta = \cot (\pi/n) + 2 \sin (\pi/3n + \pi/6)/\sin (\pi/n).$$

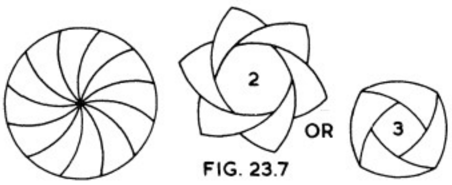

FIG. 23.7

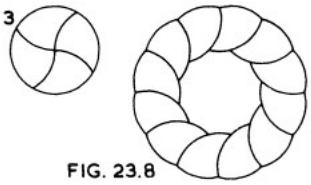

FIG. 23.8

One might also have in mind the dissection of a circle into some kind of ring. Figures 23.7 and 23.8 are typical of what can be found. There are numerous variants, depending on the number of sectors per circle and the number of rings per circle or circles per ring.

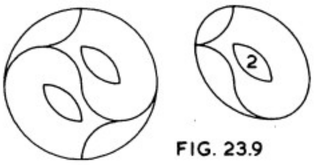

FIG. 23.9

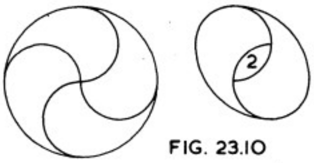

FIG. 23.10

Somewhat similar is the second of the dissections of a circle into two oval stool seats with hand-hole. (Both the dissections are by Sam Loyd—*ex ungue leonem.*) With the orientation of Figs. 23.9 and 23.10, all centers for drawing arcs are at lattice points on a grid of squares of side $\frac{1}{2}R$, where R is the radius of the circle, and their radii are either R or $\frac{1}{2}R$.

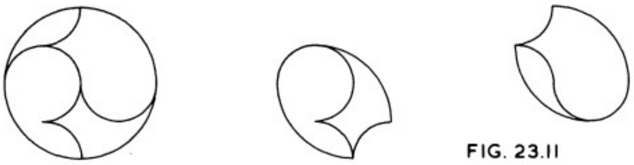

FIG. 23.11

The horseshoe dissection in Fig. 23.11 leans heavily on Fig. 23.9. But the spade-heart dissection in Fig. 23.12 is an isolated curiosity, and an outstanding one.

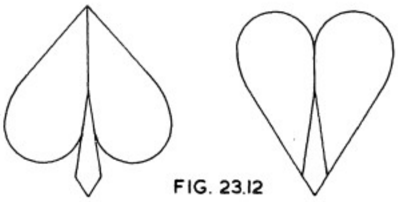

FIG. 23.12

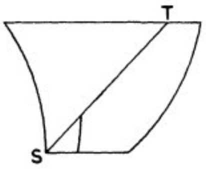

FIG. 23.13

Figure 23.1 shows that an *S*-dissection can be applied to curvilinear figures. So can the *P*-slide, as we see from Fig. 23.13; here the transverse cut *ST* also can be curved. Perhaps a good dissection based on this can be found.

Chapter 16

Symmetries

The complexity of a general problem may be drastically reduced if we are able to recognize inherent symmetries or if a classification according to an already known symmetry is possible.

If, e.g. a symmetric hexagon is inscribed into a circle, a clockwise rotation of 60° about the center leaves its form invariant. The same result follows from any multiple of 60°. Furthermore two consecutive rotations may be described by a single one with 120°. The same holds for counter clockwise rotations. From the listed properties we may combine all these rotations into one discrete rotation group.

There are additional discrete operations which leave the shape of the hexagon invariant e.g. reflections at a symmetry axis.

Consequently we may describe a hexagon only by its symmetry properties.

If we fix the hexagon at its boundaries and investigate the vibrational characteristics of this hexagonal membrane, we have to solve a second order differential equation. We expect, that the symmetry properties mentioned above are still valid for the fundamental mode. This means, that the solution of the wave equation is invariant for rotations about 60°.

Considerations of this type are very important, since they reduce the complexity of a given problem and in many cases are necessary to obtain a valid solution.

The extension from discrete to continuous symmetries, e.g. a rotation with arbitrary angle, a shift with arbitrary length parameter or a measurement at any time leads to the concept of continuous groups, which are called Lie groups [Greiner and Müller (1994)], [Steeb (2007)].

Prominent examples are the components of the classical angular momentum $\vec{L} = \{L_x, L_y, L_z\}$, which are defined as

$$\vec{L} = \vec{r} \times \vec{p} \tag{16.1}$$

They obey the commutation relations

$$[L_x, L_y] = L_z \quad [L_x, L_z] = -L_y \quad [L_y, L_z] = L_x \tag{16.2}$$

and consequently form a non-Abelian group.

The Casimir operator Operator Λ_3^2 commutes with all elements of this group simultaneously:

$$\Lambda_3^2 = L_x^2 + L_y^2 + L_z^2 \tag{16.3}$$

$$[\Lambda_3^2, L_x] = 0 \quad [\Lambda_3^2, L_y] = 0 \quad [\Lambda_3^2, L_z] = 0 \tag{16.4}$$

16.1 Characteristics of fractional group theory

The transition from classical mechanics to quantum mechanics is realized within the framework of canonical quantization by replacing the classical observables $\{x, p\}$ by the corresponding quantum mechanical observables $\{\hat{x}, \hat{p}\}$, which are realized as derivative operators.

In quantum mechanics, calculations are performed using these operators. For example, we obtain for the commutation relation $[\hat{x}, \hat{p}]$

$$\begin{aligned} [\hat{x}, \hat{p}] &= [x, -i\hbar\partial_x] \\ &= -i\hbar(x\partial_x - \partial_x x) \\ &= -i\hbar(x\partial_x - 1 - x\partial_x) \\ &= i\hbar \end{aligned} \tag{16.5}$$

where we have used the Leibniz' product rule.

We want to emphasize that the commutation relations were calculated independently of a specific function set $|\nu\rangle$ they are acting on. Therefore we obtain results, which are valid in general for any reasonable realization of the underlying Hilbert space.

In order to realize the transition to fractional quantum mechanics within the framework of canonical quantization the classical observables $\{x, p\}$ are replaced by (11.10) and (11.11). For the commutation relations $[\hat{X}, \hat{P}]$ are given as

$$[\hat{X}, \hat{P}] = -i\hbar[\hat{x}^\alpha, \hat{D}^\alpha] \tag{16.6}$$

In the following we will show, that commutation relations may not be calculated independently of a specific function set any more. Instead, the results derived are only valid for a given function set, the operators act on.

As an illustrative example we will apply the fractional derivative according to Riemann and will calculate the explicit action of the commutation relations on the specific function set $|\nu\rangle = \hat{x}^{\alpha\nu}$. We obtain:

$$\begin{aligned} -i\hbar[\hat{x}^\alpha, {}_{\mathrm{R}}\hat{D}^\alpha]|\nu\rangle &= -i\hbar \left(\hat{x}^\alpha \frac{\Gamma(1+\nu\alpha)}{\Gamma(1+(\nu-1)\alpha)} |\nu-1\rangle - {}_{\mathrm{R}}\hat{D}^\alpha |\nu+1\rangle \right) \\ &= -i\hbar \left(\frac{\Gamma(1+\nu\alpha)}{\Gamma(1+(\nu-1)\alpha)} - \frac{\Gamma(1+(\nu+1)\alpha)}{\Gamma(1+\nu\alpha)} \right) |\nu\rangle \end{aligned} \tag{16.7}$$

With the abbreviation

$$ {}_{\mathrm{R}}c(\nu,\alpha) = \frac{\Gamma(1+(\nu+1)\alpha)}{\Gamma(1+\nu\alpha)} - \frac{\Gamma(1+\nu\alpha)}{\Gamma(1+(\nu-1)\alpha)} \tag{16.8}$$

the commutation relations (16.6) based on the fractional derivative according to Riemann result as:

$$[\hat{X}, {}_{\mathrm{R}}\hat{P}]\, |\nu\rangle = i\hbar_{\mathrm{R}} c(\nu,\alpha)\, |\nu\rangle \tag{16.9}$$

We obtain the important result that, in contrast to classical quantum mechanics, within the framework of fractional quantum mechanics all calculations depend on the specific representation of the Hilbert space, the fractional operators act on.

The minimum requirement for a fractional operator algebra is the explicit knowledge of the corresponding set of eigenfunctions.

Hence if we present the result of our derivation as

$$[\hat{X}, {}_{\mathrm{R}}\hat{P}] = i\hbar_{\mathrm{R}} c(\nu,\alpha) \tag{16.10}$$

this relation is valid only on the set of square integrable eigenfunctions $|\nu\rangle$.

For the same commutation relations with the Liouville definition of the fractional derivative on the set of eigenfunctions $|\nu\rangle = |x|^{-\alpha\nu}, x < 0$ we obtain:

$$\begin{aligned} -i\hbar[\hat{x}^\alpha, {}_{\mathrm{L}}\hat{D}^\alpha]|\nu\rangle &= -i\hbar \left(\hat{x}^\alpha \frac{\Gamma((\nu+1)\alpha)}{\Gamma(\nu\alpha)} |\nu+1\rangle - {}_{\mathrm{L}}\hat{D}^\alpha |\nu-1\rangle \right) \\ &= -i\hbar \operatorname{sign}(x) \left(|x|^\alpha \frac{\Gamma((\nu+1)\alpha)}{\Gamma(\nu\alpha)} |\nu+1\rangle - {}_{\mathrm{L}}\hat{D}^\alpha |\nu-1\rangle \right) \\ &= -i\hbar \operatorname{sign}(x) \left(\frac{\Gamma((\nu+1)\alpha)}{\Gamma(\nu\alpha)} - \frac{\Gamma(\nu\alpha)}{\Gamma((\nu-1)\alpha)} \right) |\nu\rangle \end{aligned} \tag{16.11}$$

and hence

$$
{}_{\mathrm{L}}c(\nu,\alpha) = \mathrm{sign}(x)\left(\frac{\Gamma(\nu\alpha)}{\Gamma((\nu-1)\alpha)} - \frac{\Gamma((\nu+1)\alpha)}{\Gamma(\nu\alpha)}\right) \quad x<0 \tag{16.12}
$$

$$
= \frac{\Gamma((\nu+1)\alpha)}{\Gamma(\nu\alpha)} - \frac{\Gamma(\nu\alpha)}{\Gamma((\nu-1)\alpha)} \tag{16.13}
$$

Finally, applying the fractional derivative according to Caputo the eigenfunctions of the commutation relations are given by $|\nu\rangle = x^{\nu\alpha}$ and therefore we may proceed

$$
{}_{\mathrm{C}}c(\nu,\alpha) = \begin{cases} \frac{\Gamma(1+(\nu+1)\alpha)}{\Gamma(1+\nu\alpha)} - \frac{\Gamma(1+\nu\alpha)}{\Gamma(1+(\nu-1)\alpha)} & \nu \neq 0 \\ \frac{\Gamma(1+(\nu+1)\alpha)}{\Gamma(1+\nu\alpha)} & \nu = 0 \end{cases} \tag{16.14}
$$

Obviously the sets of eigenfunctions for the different commutation relations are eigenfunctions of the fractional one dimensional Euler operator $j_1^{\mathrm{E}} = \hat{x}^\alpha \hat{D}^\alpha$ as well. The corresponding eigenvalues follow as:

$$
{}_{\mathrm{R}}j_1^{\mathrm{E}} = \frac{\Gamma(1+\nu\alpha)}{\Gamma(1+(\nu-1)\alpha)} \tag{16.15}
$$

$$
{}_{\mathrm{C}}j_1^{\mathrm{E}} = \begin{cases} \frac{\Gamma(1+\nu\alpha)}{\Gamma(1+(\nu-1)\alpha)} & \nu \neq 0 \\ 0 & \nu = 0 \end{cases} \tag{16.16}
$$

$$
{}_{\mathrm{L}}j_1^{\mathrm{E}} = -\frac{\Gamma((\nu+1)\alpha)}{\Gamma(\nu\alpha)} \tag{16.17}
$$

We conclude that an extension from standard group theory to fractional group theory is confronted with some additional difficulties. Despite this fact a group theoretical approach for a classification of multiplets of fractional extensions of standard groups will turn out to be a powerful tool to solve problems.

Especially nontrivial symmetries in multi-dimensional spaces, like fractional rotational symmetry in $\mathbb{R}^3$ may successfully be investigated. Instead of solving the fractional Schrödinger equation in hyper-spherical coordinates directly, group theoretical methods provide elegant methods and strategies, to determine the eigenvalue spectrum of such highly symmetric problems analytically.

This will be explicitly shown in the next section.

16.2 The fractional rotation group SO_N^α

The components of the classical angular momentum in $\mathbb{R}^3$ are given by

$$
L_{ij} = x_i p_j - x_j p_i \qquad i,j = 1,2,3 \tag{16.18}
$$

Symmetry involves finding or imposing order in a concrete way, for example, by reflection. Other tactics find or exploit order, but in more abstract, almost "metaphorical" ways. We shall discuss three such methods of "pseudosymmetry." All of them rely on very simple observations that sometimes yield amazingly useful information. The first tactic, the *extreme principle*, which we encountered with the Affirmative Action problem (Example 2.1.9 on page 19), works by focusing on the largest and smallest entities within a problem. Next, the *pigeonhole principle* stems from the nearly vacuous observation that if you have more guests than spare rooms, some of the guests will have to share rooms. Our final tactic, the concept of *invariants*, shows how much information comes your way when you restrict your attention to a narrow aspect of your problem that does not change (such as parity). This is an extremely powerful idea, fundamental to mathematics, that underlies many seemingly different tactics and tools.

3.1 Symmetry

We all have an intuitive idea of symmetry; for example, everyone understands that circles are symmetrical. It is helpful, however, to define symmetry in a formal way, if only because this will expand our notion of it. We call an object *symmetric* if there are one or more non-trivial "actions" that leave the object unchanged. We call the actions that do this the *symmetries* of the object.[1]

We promised something formal, but the above definition seems pretty vague. What do we mean by an "action"? Almost anything! We are being deliberately vague, because our aim is to let you see symmetry in as many situations as possible. Here are a few examples.

Example 3.1.1 A square is symmetric with respect to reflection about a diagonal. The reflection is one of the several symmetries of the square. Other symmetries include rotation clockwise by 90 degrees and reflection about a line joining the midpoints of two opposite sides.

Example 3.1.2 A circle has infinitely many symmetries, for example, rotation clockwise by α degrees for any α.

Example 3.1.3 The doubly infinite sequence

$$\ldots, 3, 1, 4, 3, 1, 4, 3, 1, 4, \ldots$$

is symmetrical with respect to the action "shift everything three places to the right (or left)."

Why is symmetry important? Because it gives you "free" information. If you know that something is, say, symmetric with respect to 90-degree rotation about some point, then you only need to look at one-quarter of the object. And you also know that the center of rotation is a "special" point, worthy of close investigation. You will see these ideas in action below, but before we begin, let us mention two things to keep in mind as you ponder symmetry:

- The strategic principles of peripheral vision and rule-breaking tell us to look for symmetry in unlikely places, and not to worry if something is almost, but not quite symmetrical. In these cases, it is wise to proceed as if symmetry is present, since we will probably learn something useful.

---

[1] We deliberately avoid the language of transformations and automorphisms that would be demanded by a mathematically precise definition.

- An informal alternate definition of symmetry is “harmony.” This is even vaguer than our “formal” definition, but it is not without value. Look for harmony, and beauty, whenever you investigate a problem. If you can do something that makes things more harmonious or more beautiful, *even if you have no idea how to define these two terms*, then you are often on the right track.

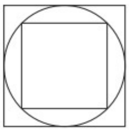
Geometric Symmetry

Most geometric investigations profit by a look at symmetry. Ask these questions about symmetry:

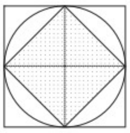
- Is it present?
- If not, can it be imposed?
- How can it then be exploited?

Here is a simple but striking example.

Example 3.1.4 A square is inscribed in a circle that is inscribed in a square. Find the ratio of the areas of the two squares.



Solution: The problem can certainly be solved algebraically (let x equal the length of the small square, then use the Pythagorean theorem, etc.), but there is a nicer approach. The original diagram is full of symmetries. We are free to rotate and/or reflect many shapes and still preserve the areas of the two squares. How do we choose from all these possibilities? We need to use the hypothesis that the objects are inscribed in one another. If we rotate the small square by 45 degrees, its vertices now line up with the points of tangency between the circle and the large square, and instantly the solution emerges.

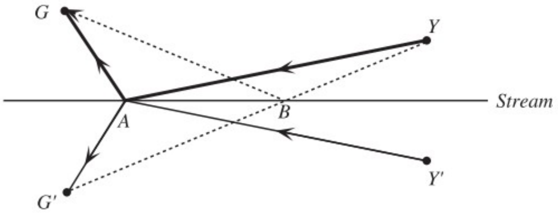


The small square obviously has half the area of the larger! ■

The simplest geometric symmetries are rotational and reflectional. Always check to see if rotations or reflections will impose order on your problem. The next example shows the power of imposing reflectional symmetry.

Example 3.1.5 Your cabin is two miles due north of a stream that runs east-west. Your grandmother's cabin is located 12 miles west and one mile north of your cabin. Every day, you go from your cabin to Grandma's, but first visit the stream (to get fresh water for Grandma). What is the length of the route with minimum distance?

Solution: First, *draw a picture*! Label your location by Y and Grandma's by G. Certainly, this problem can be done with calculus, but it is very ugly (you need to differentiate the sum of two radicals, for starters). The problem appears to have no symmetry in it, but the stream is practically begging you to reflect across it! Draw a sample path (shown below as YA followed by AG) and look at its reflection. We call the reflections of your house and Grandma's house Y' and G', respectively.

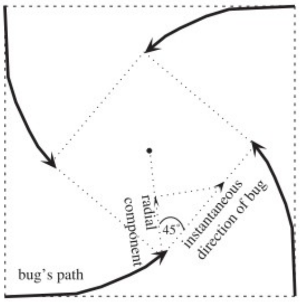


While you are carrying water to Grandma, your duplicate in an alternate universe is doing the same, only south of the stream. Notice that $AG = AG'$, so the length of your path would be *unchanged* if you visited the reflected Grandma instead of the real one. Since the shortest distance between two points is the straight line YBG', the optimal path will be YB followed by BG. Its length is the same as the length of YBG', which is just the hypotenuse of a right triangle with legs 5 and 12 miles. Hence our answer is 13 miles. ■

When pondering a symmetrical situation, you should always focus briefly on the "fixed" objects that are unchanged by the symmetries. For example, if something is symmetric with respect to reflection about an axis, that axis is fixed and worthy of study (the stream in the previous problem played that role). Here is another example, a classic problem that exploits rotational symmetry along with a crucial fixed point.

Example 3.1.6 Four bugs are situated at each vertex of a unit square. Suddenly, each bug begins to chase its counterclockwise neighbor. If the bugs travel at 1 unit per minute, how long will it take for the four bugs to crash into one another?

Solution: The situation is rotationally symmetric in that there is no one "distinguished" bug. If their starting configuration is that of a square, then they will always maintain that configuration. This is the key insight, believe it or not, and it is a very profitable one!



As time progresses, the bugs form a shrinking square that rotates counterclockwise. The center of the square does not move. This center, then, is the only "distinguished" point, so we focus our analysis on it. Many otherwise intractable problems become easy once we shift our focus to the natural frame of reference; in this case we should consider a *radial* frame of reference, one that rotates with the square. For example, pick one of the bugs (it doesn't matter which one!), and look at the line segment from the center of the square to the bug. This segment will rotate counterclockwise, and (more importantly) shrink. When it has shrunk to zero, the bugs will have crashed into one another. How fast is it shrinking? Forget about the fact that the line is rotating. *From the point of view of this radial line,* the bug is always traveling at a 45° angle. Since the bug travels at unit speed, its radial velocity component is just $1 \cdot \cos 45° = \sqrt{2}/2$ units per minute, i.e., the radial line shrinks at this speed. Since the original length of the radial line was $\sqrt{2}/2$, it will take just 1 minute for the bugs to crash. ■

Here is a simple calculus problem that can certainly be solved easily in a more conventional way. However, our method below illustrates the power of the Draw a Picture strategy coupled with symmetry, and can be applied in many harder situations.

Example 3.1.7 Compute $\int_0^{\frac{1}{2}\pi} \cos^2 x\, dx$ in your head.

Solution: Mentally draw the sine and cosine graphs from 0 to $\frac{1}{2}\pi$, and you will notice that they are symmetric with respect to reflection about the vertical line $x = \frac{1}{4}\pi$. Thus

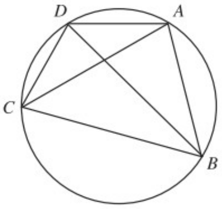
$$\int_0^{\frac{1}{2}\pi} \cos^2 x\, dx = \int_0^{\frac{1}{2}\pi} \sin^2 x\, dx.$$

Consequently, the value that we seek is

$$\frac{1}{2}\int_0^{\frac{1}{2}\pi} (\cos^2 x + \sin^2 x)\, dx = \frac{1}{2}\int_0^{\frac{1}{2}\pi} 1 \cdot dx = \frac{\pi}{4}.$$ ■

The next problem, from the 1995 IMO, is harder than the others, but only in a "technical" way. In order to solve it, you need to be familiar with *Ptolemy's Theorem*, which states

> *Let $ABCD$ be a cyclic quadrilateral, i.e., a quadrilateral whose vertices lie on a circle. Then*
> $$AB \cdot CD + AD \cdot BC = AC \cdot BD.$$



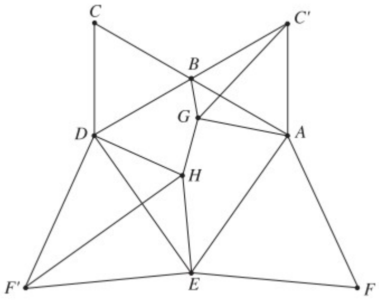
See Problems 8.4.29 and 8.5.49 for different ideas for a proof. A key feature of cyclic quadrilaterals is the easily verified fact (see page 267) that

> *A quadrilateral is cyclic if and only if its opposite angles are supplementary (add up to 180 degrees).*

Example 3.1.8 Let $ABCDEF$ be a convex hexagon with $AB = BC = CD$ and $DE = EF = FA$, such that $\angle BCD = \angle EFA = \pi/3$. Suppose G and H are points in the interior of the hexagon such that $\angle AGB = \angle DHE = 2\pi/3$. Prove that

$$AG + GB + GH + DH + HE \geq CF.$$

Solution: First, as for all geometry problems, draw an accurate diagram, using pencil, compass and ruler. Look for symmetry. Note that BCD and EFA are equilateral triangles, so that $BD = BA$ and $DE = AE$. By the symmetry of the figure, it is seems profitable to reflect about BE. Let C' and F' be the reflections of C and F respectively.



A tactic that often works for geometric inequalities is to look for a way to compare the sum of several lengths with a single length, since the shortest distance between two points is a straight line. Quadrilaterals $AGBC'$ and $HEF'D$ are cyclic, since the opposite angles add up to 180 degrees. Ptolemy's Theorem then implies that $AG \cdot BC' + GB \cdot AC' = C'G \cdot AB$. Since ABC' is equilateral, this implies that $AG + GB = C'G$. Similarly, $DH + HE = HF'$. The shortest path between two points is a straight line. It follows that

$$CF = C'F' \leq C'G + GH + HF' = AG + GB + GH + DH + HE,$$

with equality if and only if G and H both lie on $C'F'$. ■

Algebraic Symmetry

Don't restrict your notions of symmetry to physical or geometric objects. For example, sequences can have symmetry, like this row of Pascal's Triangle:

$$1, 6, 15, 20, 20, 15, 6, 1.$$

That's only the beginning. In just about any situation where you can imagine "pairing" things up, you can think about symmetry. And thinking about symmetry almost always pays off.

The Gaussian Pairing Tool

Carl Friedrich Gauss (1777–1855) was certainly one of the greatest mathematicians of all times. Many stories celebrate his precocity and prodigious mental power. No one knows how true these stories are, because many of them are attributable only to Gauss himself. The following anecdote has many variants. We choose one of the simplest.

When Gauss was 10, his teacher punished his class with a seemingly tedious sum:

$$1 + 2 + 3 + \cdots + 98 + 99 + 100.$$

While the other students slowly added the numbers, little Carl discovered a shortcut and immediately arrived at the answer of 5,050. He was the only student to find the correct sum. His insight was to notice that 1 could be paired with 100, 2 with 99, 3 with 98, etc. to produce 50 identical sums of 101. Hence the answer of $101 \cdot 50 = 5050$. Another, more formal way of doing this is to write the sum in question twice, first forward, then backward:

$$\begin{array}{ccccccccc} S & = & 1 & + & 2 & +\cdots+ & 99 & + & 100, \\ S & = & 100 & + & 99 & +\cdots+ & 2 & + & 1. \end{array}$$

Then, of course, $2S = 100 \cdot 101$. The advantage of this method is that it does not matter whether the number of terms was even or odd (notice that this is an issue with the original pairing method).

This is a pretty good trick, especially for a 10-year-old, and it has many applications. Don't be restricted to sums. Look for any kind of *symmetry* in a problem and then investigate whether a clever pairing of items can simplify things. First, let's tackle the "Locker problem," which we first encountered in Example 2.2.3 on page 26. Recall that we reduced this problem to

Prove that $d(n)$ is odd if and only if n is a perfect square, where $d(n)$ denotes the number of divisors of n, including 1 and n. Now we can use the Gaussian pairing tool. The symmetry here is that one can always pair a divisor d of n with n/d. For example, if $n = 28$, it is "natural" to pair the divisor 2 with the divisor 14. Thus, as we go through the list of divisors of n, each divisor will have a unique "mate" *unless n is a perfect square*, in which case $\sqrt{n}$ is paired with itself. For example, the divisors of 28 are $1, 2, 4, 7, 14, 28$, which can be rearranged into the pairs $(1, 28)$, $(2, 14)$, $(4, 7)$, so clearly $d(28)$ is even. On the other hand, the divisors of the perfect square 36 are $1, 2, 3, 4, 6, 9, 12, 18, 36$, which pair into $(1, 36)$, $(2, 18)$, $(3, 12)$, $(4, 9)$, $(6, 6)$. Notice that 6 is paired with itself, so the actual count of divisors is odd (several true pairs plus the 6, which can only be counted once). We can conclude that $d(n)$ is odd if and only if n is a perfect square.[2] ■

The argument used can be repeated almost identically, yet in a radically different context, to prove a well-known theorem in number theory.

Example 3.1.9 *Wilson's Theorem.* Prove that for all primes p,

$$(p-1)! \equiv -1 \pmod{p}.$$

Solution: First try an example. Let $p = 13$. Then the product in question is $1 \cdot 2 \cdot 3 \cdot 4 \cdot 5 \cdot 6 \cdot 7 \cdot 8 \cdot 9 \cdot 10 \cdot 11 \cdot 12$. One way to evaluate this product modulo 13 would be to multiply it all out, but that is not the problem solver's way! We should look for smaller subproducts that are easy to compute modulo p. The easiest numbers to compute with are $0, 1$, and -1. Since p is a prime, none of the factors $1, 2, 3, \ldots p-1$ are congruent to 0 modulo p. Likewise, no subproducts can be congruent to 0. On the other hand, the primality of p implies that every non-zero number has a *unique* multiplicative inverse modulo p; i.e., if x is not a multiple of p then there is a unique $y \in \{1, 2, 3, \ldots, p-1\}$ such that $xy \equiv 1 \pmod{p}$. (Recall the proof of this assertion in Example 2.3.4 on page 41.)

Armed with this information, we proceed as in the locker problem: Pair each x between 1 and $p-1$ with its "natural" mate y between 1 and $p-1$ such that $xy \equiv 1 \pmod{p}$. For example, if $p = 13$, the pairs are

$$(1,1), (2,7), (3,9), (4,10), (5,8), (6,11), (12,12),$$

and we can rewrite

$$12! = 1 \cdot 2 \cdot 3 \cdot 4 \cdot 5 \cdot 6 \cdot 7 \cdot 8 \cdot 9 \cdot 10 \cdot 11 \cdot 12$$

as

$$1 \cdot (2 \cdot 7)(3 \cdot 9)(4 \cdot 10)(5 \cdot 8)(6 \cdot 11) \cdot 12 \equiv 1 \cdot 1 \cdot 1 \cdot 1 \cdot 1 \cdot 1 \cdot 12 = -1 \pmod{13}.$$

Notice that 1 and 12 were the only elements that paired with themselves. Notice also that $12 \equiv -1 \pmod{13}$. We will be done in general if we can show that x is its own multiplicative inverse modulo p if and only if $x = \pm 1$. But this is easy: If $x^2 \equiv 1 \pmod{p}$, then

$$x^2 - 1 = (x-1)(x+1) \equiv 0 \pmod{p}.$$

Because p is prime, this implies that either $x - 1$ or $x + 1$ is a multiple of p; i.e., $x \equiv \pm 1 \pmod{p}$ are the *only* possibilities. ■

---

[2] A completely different argument uses basic counting methods and parity. See Problem 6.1.21 on page 196.

Symmetry in Polynomials and Inequalities

Algebra problems with many variables or of high degree are often intractable unless there is some underlying symmetry to exploit. Here is a lovely example.

Example 3.1.10 Solve $x^4 + x^3 + x^2 + x + 1 = 0$.

Solution: While there are other ways of approaching this problem (see page 122), we will use the symmetry of the coefficients as a starting point to impose yet more symmetry, on the degrees of the terms. Simply divide by x^2:

$$x^2 + x + 1 + \frac{1}{x} + \frac{1}{x^2} = 0.$$

This looks no simpler, but note that now there is more symmetry, for we can collect "like" terms as follows:

$$x^2 + \frac{1}{x^2} + x + \frac{1}{x} + 1 = 0. \tag{3.1.1}$$

Now make the *substitution* $u := x + \frac{1}{x}$. Note that

$$u^2 = x^2 + 2 + \frac{1}{x^2},$$

so (3.1.1) becomes $u^2 - 2 + u + 1 = 0$, or $u^2 + u - 1 = 0$, which has solutions

$$u = \frac{-1 \pm \sqrt{5}}{2}.$$

Solving $x + \frac{1}{x} = u$, we get $x^2 - ux + 1 = 0$, or

$$x = \frac{u \pm \sqrt{u^2 - 4}}{2}.$$

Putting these together, we have

$$x = \frac{\frac{-1 \pm \sqrt{5}}{2} \pm \sqrt{\left(\frac{-1 \pm \sqrt{5}}{2}\right)^2 - 4}}{2} = \frac{-1 \pm \sqrt{5} \pm i\sqrt{10 \pm 2\sqrt{5}}}{4}. \qquad \blacksquare$$

The last few steps are mere "technical details." The two crux moves were to increase the symmetry of the problem and then make the symmetrical substitution $u = x + x^{-1}$.

In the next example, we use symmetry to reduce the complexity of an inequality.

Example 3.1.11 Prove that

$$(a + b)(b + c)(c + a) \geq 8abc$$

is true for all positive numbers a, b, and c, with equality only if $a = b = c$.

Solution: Observe that the alleged inequality is symmetric, in that it is unchanged if we permute any of the variables. This suggests that we not multiply out the left side (rarely a wise idea!) but instead look at the factored parts, for the sequence

$$a+b, \quad b+c, \quad c+a$$

can be derived by just looking at the term $a+b$ and then performing the *cyclic permutation* $a \mapsto b$, $b \mapsto c$, $c \mapsto a$ once and then twice.

The simple two-variable version of the *Arithmetic-Geometric-Mean* inequality (see Section 5.5 for more details) implies

$$a+b \geq 2\sqrt{ab}.$$

Now, just perform the cyclic permutations

$$b+c \geq 2\sqrt{bc}$$

and

$$c+a \geq 2\sqrt{ca}.$$

The desired inequality follows by multiplying these three inequalities. ■

It is worth exploring the concept of cyclic permutation in more detail. Given an n-variable expression $f(x_1, x_2, \ldots, x_n)$, we will denote the *cyclic sum* by

$$\sum_\sigma f(x_1, x_2, \ldots, x_n) := f(x_1, x_2, \ldots, x_n) + f(x_2, x_3, \ldots, x_n, x_1) + \cdots + f(x_n, x_1, \ldots, x_{n-1}).$$

For example, if our variables are x, y, and z, then

$$\sum_\sigma x^3 = x^3 + y^3 + z^3 \quad \text{and} \quad \sum_\sigma xz^2 = xz^2 + yx^2 + zy^2.$$

Let us use this notation to factor a symmetric cubic in three variables.

Example 3.1.12 Factor $a^3 + b^3 + c^3 - 3abc$.

Solution: We hope for the best and proceed naively, making sure that our guesses stay symmetric. The simplest guess for a factor would be $a+b+c$, so let us try it. Multiplying $a+b+c$ by $a^2+b^2+c^2$ would give us the cubic terms, with some error terms. Specifically, we have

$$\begin{aligned}a^3+b^3+c^3-3abc &= (a+b+c)(a^2+b^2+c^2)-\sum_\sigma(a^2b+b^2a)-3abc\\ &= (a+b+c)(a^2+b^2+c^2)-\sum_\sigma(a^2b+b^2a+abc)\\ &= (a+b+c)(a^2+b^2+c^2)-\sum_\sigma(ab(a+b+c))\\ &= (a+b+c)\left(a^2+b^2+c^2-\sum_\sigma ab\right)\\ &= (a+b+c)(a^2+b^2+c^2-ab-bc-ac).\end{aligned}$$

Notice how the $\sum_\sigma$ notation saves time and, once you get used to it, reduces the chance for an error.

Problems and Exercises

3.1.13 Find the length of the shortest path from the point (3,5) to the point (8,2) that touches the x-axis and also touches the y-axis.

3.1.14 In Example 1.2.1 on page 4, we saw that the product of four consecutive integers is always one less than a square. What can you say about the product of four consecutive terms of an arbitrary arithmetical progression, e.g., $3\cdot 8\cdot 13\cdot 18$?

3.1.15 Find (and prove) a nice formula for the product of the divisors of any integer. For example, if $n=12$, the product of its divisors is

$$1\cdot 2\cdot 3\cdot 4\cdot 6\cdot 12=1728.$$

You may want use the $d(n)$ function (defined in the solution to the Locker problem on page 64) in your formula.

3.1.16 How many subsets of the set $\{1,2,3,4,\ldots,30\}$ have the property that the sum of the elements of the subset is greater than 232?

3.1.17 (Putnam 1998) Given a point (a,b) with $0<b<a$, determine the minimum perimeter of a triangle with one vertex at (a,b), one on the x-axis, and one on the line $y=x$. You may assume that a triangle of minimum perimeter exists.

3.1.18 A polynomial in several variables is called *symmetric* if it is unchanged when the variables are permuted. For example,

$$f(x,y,z):=x^2+y^2+z^2+xyz$$

is symmetric, since

$$\begin{aligned}f(x,y,z) &= f(x,z,y)=f(y,x,z)=f(y,z,x)\\ &= f(z,x,y)=f(z,y,x).\end{aligned}$$

A polynomial in several variables is called *homogeneous* of degree r if all of the terms are degree r. For example, $g(x,y):=x^2+5xy$ is homogeneous of degree 2. (The $5xy$ term is considered to have degree 2, since it is the product of two degree-1 terms.) In general, the k-variable polynomial $g(x_1,x_2,\ldots,x_k)$ is homogeneous of degree r if for all t, we have

$$g(tx_1,tx_2,\ldots,tx_k)=t^r g(x_1,x_2,\ldots,x_k).$$

Given three variables x,y,z, we define the *elementary symmetric functions*

$$\begin{aligned}s_1 &:= x+y+z,\\ s_2 &:= xy+yz+zx,\\ s_3 &:= xyz.\end{aligned}$$

The elementary symmetric function s_k is symmetric, homogeneous of degree k, and all its coefficients are equal to 1. Elementary symmetric functions can be defined for any number of variables. For example, for four variables x,y,z,w, they are

$$\begin{aligned}s_1 &:= x+y+z+w,\\ s_2 &:= xy+xz+xw+yz+yw+zw,\\ s_3 &:= xyz+xyw+xzw+yzw,\\ s_4 &:= xyzw.\end{aligned}$$

Chapter 4

Approaching general relativity: introducing curvilinear coordinate systems

Cartesian coordinate systems have straight coordinate lines orthogonal to each other. The coordinate basis vector fields are constant, and all the vectors of each field are unit vectors with the same direction. This is the simplest coordinate system that one can imagine. It seems strange that it can be advantageous to introduce coordinate systems with coordinate curves which are not straight lines, so-called curvilinear coordinate systems. But in fact some objects of investigation have certain symmetries, for example cylindrical or spherical symmetry that makes it advantageous to introduce curvilinear coordinates. In a flat space, however, every coordinate system can be transformed into a Cartesian system, so that in principle one could solve every problem with reference to Cartesian coordinates.

In general relativity it is necessary to introduce curvilinear coordinate systems. According to this theory spacetime[1] is curved and four-dimensional with three space dimensions and one time dimension. This curved four-dimensional spacetime seems to be the easiest way of taking into account the results from careful experimental investigations of electromagnetism and gravitation.

In fact, already about 1920, the general theory of relativity was generalized to describe spacetime with more than three spatial dimensions. More than one time dimension is problematic, however, because it leads to certain strange possibilities of backward time travel, which belongs to science fiction. These generalized versions of general relativity are called Kaluza–Klein theories, and have been thoroughly investigated recently. They lead to the possibility of giving a unified geometrical description of classical (i.e. non-quantum) electromagnetism and gravity. The problem of creating a coherent single theory for gravitation and quantum theory is still unsolved. The most recent effort is called superstring theory and involves ten-dimensional spacetime. In this book we shall be concerned with four-dimensional spacetime.

Consider hypothetical two-dimensional creatures living in a two-dimensional space made up of the surface of a sphere. They would have to describe their world with reference to the curved surface. No three-dimensional space exists for these creatures. And the spherical surface *cannot* be covered by a two-dimensional Cartesian coordinate system. (Look at a globus!). The situation is similar in the case of curved spaces of higher dimensions, such as our spacetime. It cannot be covered by a Cartesian coordinate system. As long as we insist that the spacetime may be curved and four-dimensional, and that the description of our universe shall be referred to a coordinate system with four dimensions only, there is no other way than introducing curvilinear coordinate systems.

---

[1] See Sect. 1.7 and Ch. 5.

The simplest curvilinear coordinate system is a system of concentric circles and straight radial lines out from the common centre of the circles. The coordinates of this system are called *plane polar coordinates*. In this chapter we shall consider the main properties of such a coordinate system. Some knowledge of trigonometric functions is then indispensable.

4.1 Trigonometric functions

We shall now introduce three so-called *trigonometric* functions, named *sinus*, *cosinus*, and *tangens*. They are widely used in physics, meteorology and astronomy—everywhere.

Consider a circle with radius r and centre at the origin of a Cartesian coordinate system, as shown in Fig. 4.1. The radial line OP makes an angle θ with the positive x-axis. The point P has coordinates (x, y).

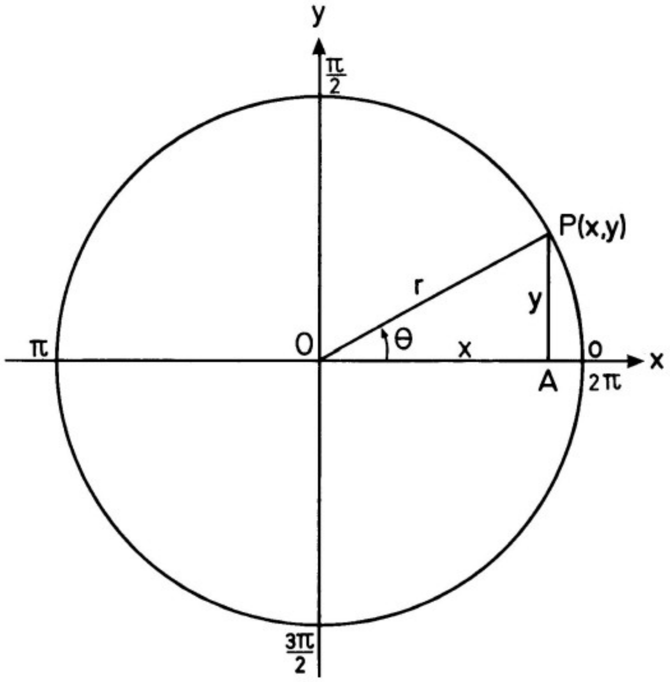

Figure 4.1: Circle of radius r centered at the origin

.

Before we define the functions sinus, cosinus and tangens, we shall have to know how we measure angles. There are two common angular measures. In daily life we measure angles in *degrees*. For example the latitude and longitude of the position of a mountain are given in degrees. One degree may be defined in the following way: divide a circle in 360 parts by marking 360 equidistant points. Draw radial lines from the centre of the circle to all of the dividing points. One degree is the angle between two neighbouring radial lines. Thus the angle around the full circle is 360 degrees. Since there are four right angles around a circle, a right angle is equal to 90 degrees, and a half circle is 180 degrees.

The other angular measure, which is used in connection with the trigonometric functions, is called a *radian*. With reference to Fig. 4.1 we formulate the following definition: the angle, θ, i.e. the *number of radians*, is defined as the length of the circular arc between 0 and P divided by the radius. Note that this ratio is independent of the radius of the circle. The sign π is the symbol for the number of radians of a 180 degree angle. Its value is $3.141592\ldots$. It follows that the length of a circle with radius r is $2\pi r$. The angle around a circle, as measured in radians, is 2π, and a right angle is equal to $2\pi/4 = \pi/2$. Increasing an angle by 2π corresponds to going one time around a circle.

The functions $\text{sinus}(\theta)$ and $\text{cosinus}(\theta)$ are denoted by $\sin\theta$ and $\cos\theta$. They are defined with reference to Fig. 4.1 by the equations

$$\sin\theta \equiv \frac{y}{r} \quad \text{and} \quad \cos\theta \equiv \frac{x}{r}, \tag{4.1a}$$

where $r = (x^2 + y^2)^{1/2}$ according to the Pythagorean theorem. Note that if $r = 1$ then $\sin\theta = y$ and $\cos\theta = x$. For θ outside the range $[0, 2\pi\rangle$ the definition implies

$$\sin(\theta + 2\pi) = \sin\theta \quad \text{and} \quad \cos(\theta + 2\pi) = \cos\theta. \tag{4.1b}$$

Equation (4.1b) shows that $\sin\theta$ and $\cos\theta$ are periodic functions with period 2π. This corresponds to the fact that if P on Fig. 4.1 is moved around the circle, so that θ passes 2π, then x and y, and thus $\sin\theta$ and $\cos\theta$ obtain just the same values as one round earlier.

The function tangens(θ) is denoted by $\tan\theta$, and is defined by

$$\tan\theta \equiv \frac{\sin\theta}{\cos\theta}. \tag{4.2}$$

Substituting for $\sin\theta$ and $\cos\theta$ from the definitions in Eqs. (4.1) leads to

$$\tan\theta = \frac{y}{x}. \tag{4.3}$$

The function $\tan\theta$ is in principle superfluous. We can always use $\sin\theta$ and $\cos\theta$. However, the function $\tan\theta$ simplifies some calculations, as will be seen in our description of plane curves in Sect. 9.1.

It will be useful to formulate the expressions for the trigonometric functions without reference to a Cartesian coordinate system; only referring to a right angled triangle, such as OAP in Fig. 4.1. Note that in relation to the angle θ the base x is the side adjacent to θ, and the height

y is the side opposite to θ. Using these terms the expressions for $\sin\theta$ and $\cos\theta$ can be formulated in the following way.

$$\sin\theta = \frac{\text{the length of the side opposite to }\theta}{\text{the length of the hypotenuse}},$$

$$\cos\theta = \frac{\text{the length of the side adjacent to }\theta}{\text{the length of the hypotenuse}},$$

and

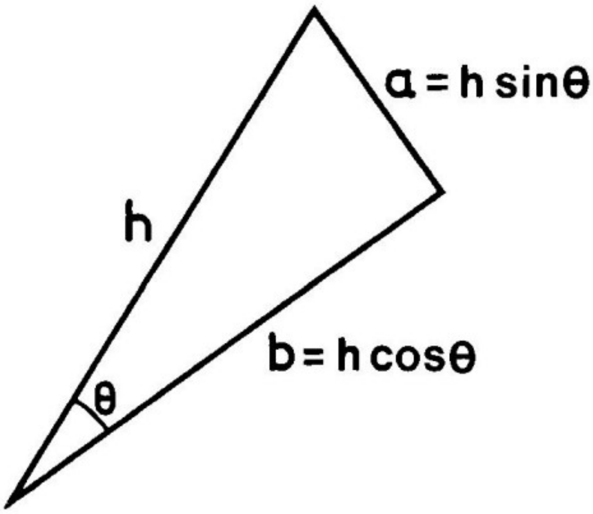
$$\tan\theta = \frac{\text{the length of the side opposite to }\theta}{\text{the length of the side adjacent to }\theta}.$$

These formulations permit us to find expressions for the trigonometric functions by reference to a right angled triangle with arbitrary orientation, not referring to any coordinate system, see Fig. 4.2.

From Fig. 4.2 and the expressions (4.1) we get $\sin\theta = a/h$ and $\cos\theta = b/h$. Multiplying by h we can express the magnitude of the side opposite to θ and the side adjacent to θ, by θ and the hypotenuse h of the right angled triangle,

$$a = h\sin\theta \quad \text{and} \quad b = h\cos\theta. \tag{4.4}$$

Consider Fig. 4.3. The part CQD of the figure is obtained by turning the part APB an angle 90 degrees to the left. Thus the angles CQD and APB are equal. We obtain



a = h sinθ
h
b = h cosθ
θ

Figure 4.2: A right-angled triangle

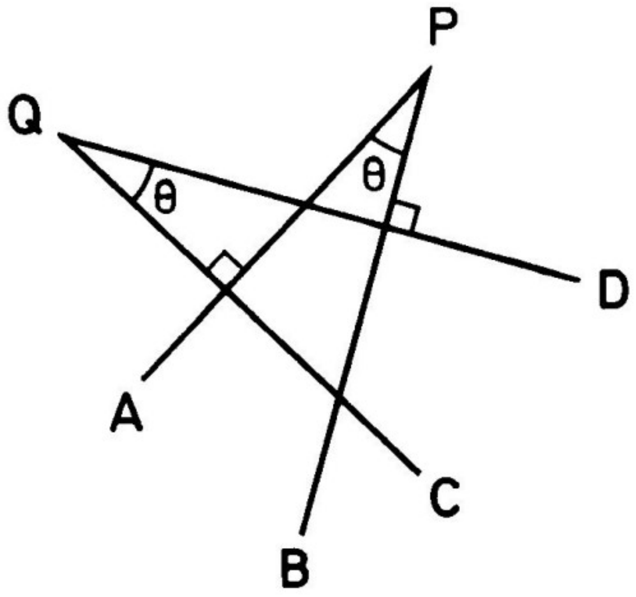


Figure 4.3: Angles with pairwise normal legs

the following sentence: two angles with pairwise normal legs, are equal.

In Eq. (1.8) we have written the dot product of two vectors $\vec{A}$ and $\vec{B}$ as 'the magnitude of $\vec{A}$ times the magnitude of $\vec{B}$'s projection, $\vec{B}_{\|}$, along $\vec{A}$'. This may now be expressed in terms of the angle α between $\vec{A}$ and $\vec{B}$.

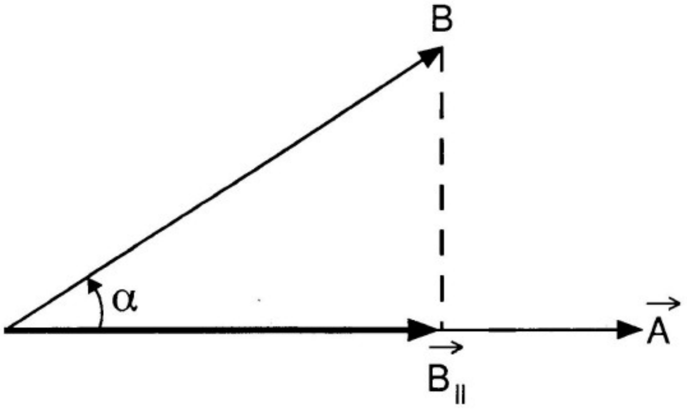

Figure 4.4: Angle α between $\vec{A}$ and $\vec{B}$

From Fig. 4.4 is seen that $|\vec{B}_{\|}| = \cos\alpha$. In general

$$|\vec{B}_{\|}| = \begin{cases} |\vec{B}|\cos\alpha & \text{for} \quad -\frac{\pi}{2} \leq \alpha < \frac{\pi}{2} \\ -|\vec{B}|\cos\alpha & \text{for} \quad \frac{\pi}{2} \leq \alpha < \frac{3\pi}{2}. \end{cases} \tag{4.5}$$

Inserting this into Eq. (1.8) gives

$$\vec{A} \cdot \vec{B} = |\vec{A}||\vec{B}|\cos\alpha \tag{4.6}$$

where the sign ambiguity in Eq. (1.8) is taken care of automatically. Since the angle that a vector makes with itself is zero, and $\cos 0 = 1$, it follows that the square of the magnitude of a vector is

$$|\vec{A}|^2 = \vec{A} \cdot \vec{A}. \tag{4.7}$$

We shall now deduce a geometrical identity that will be used in Ch. 5. The square of $|\vec{A} - \vec{B}|$ is

$$\begin{aligned} |\vec{A} - \vec{B}|^2 &= (\vec{A} - \vec{B}) \cdot (\vec{A} - \vec{B}) = \vec{A} \cdot \vec{A} - 2\vec{A} \cdot \vec{B} + \vec{B} \cdot \vec{B} \\ &= |\vec{A}|^2 + |\vec{B}|^2 - 2\vec{A} \cdot \vec{B}. \end{aligned} \tag{4.8}$$

Substituting the expression (4.6) for the dot product $\vec{A} \cdot \vec{B}$ leads to

$$|\vec{A} - \vec{B}|^2 = |\vec{A}|^2 + |\vec{B}|^2 - 2|\vec{A}||\vec{B}| \cos \alpha. \tag{4.9}$$

Look at Fig. 1.9. Let the angle between the vectors $\vec{A}$ and $\vec{B}$ be α, the length of $\vec{A}$ be L_1, the length of $\vec{B}$ be L_2, and the length of $\vec{A} - \vec{B}$ be L. Then Eq. (4.9) may be written

$$L^2 = L_1^2 + L_2^2 - 2L_1L_2 \cos \alpha. \tag{4.10}$$

This is an extension of the Pythagorean theorem to the case when the triangle has no 90 degree angle. It might have been named 'The extended Pythagorean theorem', but is usually called 'the law of cosines'. In Fig. 4.5 we have redrawn Fig. 1.9, but this time with the quantities L, L_1, L_2, and α which appear in Eq. (4.10).

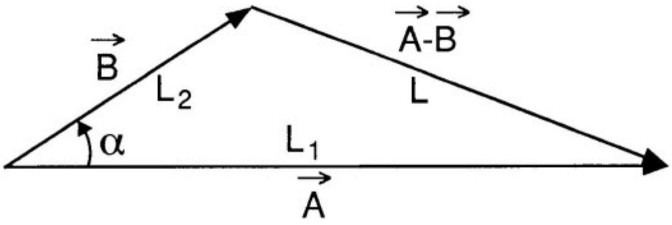

Figure 4.5: The triangle of Eq. (4.10)

The magnitudes of $\sin\theta$ and $\cos\theta$ when θ increases from 0 to 2π are seen from Fig.4.1 by letting P start at the positive x-axis and then move around the circle. At the x-axis, $x = r$ and $y = 0$, giving and $\cos 0 = 1$. Moving on to the y-axis, x decreases towards zero and y increases towards r. When P is at the y-axis the angle $\theta$is equal to $\pi/2$. Thus $\sin(\pi/2) = 1$ and $\cos(\pi/2) = 0$. As P comes to the negative x-axis, $x = -r$ and $y = 0$, while $\theta = \pi$, so $\sin\pi = 0$ and $\cos\pi = -1$. Letting P move further to the negative y-axis, the angle θ reaches $3\pi/2$, while $x = 0$ and $y = -r$, giving $\sin(3\pi/2) = -1$ and $\cos(3\pi/2) = 0$. We may now draw the diagrams representing $y = \sin\theta$ and $y = \cos\theta$ (in Fig. 4.6), with y along a vertical axis and θ along a horizontal axis.

An important relation between $\sin\theta$ and $\cos\theta$ should

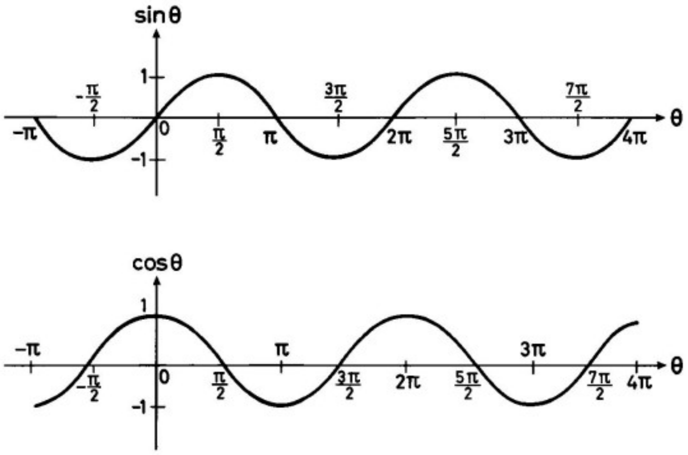

Figure 4.6: The function $\sin\theta$ and $\cos\theta$

be noted. Using Eqs. (4.1) we get

$$\sin^2\theta + \cos^2\theta = \frac{x^2}{r^2} + \frac{y^2}{r^2} = \frac{x^2+y^2}{r^2} = \frac{r^2}{r^2} = 1. \qquad (4.11)$$

This equation is valid for every value of the angle θ.

We shall need to calculate cosinus to the sum (or difference) of two angles. The formulae both for sinus and cosinus to a sum of two angles are found from Fig. 4.7. You will find a lot of information written on the figure. These are results that we shall now deduce. Consider first the angle DPC. PC is normal to OC and PD is normal to OA. According to Fig. 4.3 two angles with pairwise normal legs are equal. Hence, we conclude that the angle DPC is equal to the angle POC, i.e. it is equal to u.

cos u cos v

Figure 4.7: Sum of angles

Next we shall utilize Eq. (4.4) which is related to Fig. 4.2. Consider the triangle OCP which is similar to the triangle of Fig. 4.2. Using Eq. (4.4) we find

$$\mathrm{OC} = \cos u \quad \text{and} \quad \mathrm{PC} = \sin u. \tag{4.12}$$

Looking at the triangle DCP we find

$$\begin{aligned} \mathrm{DC} &= \mathrm{PC} \sin v = \sin u \sin v, \\ \mathrm{PD} &= \mathrm{PC} \cos v = \sin u \cos v. \end{aligned} \tag{4.13}$$

From the triangle OBC we get

$$\begin{aligned} \mathrm{OB} &= \mathrm{OC} \cos v = \cos u \cos v, \\ \mathrm{BC} &= \mathrm{OC} \sin v = \cos u \sin v, \end{aligned} \tag{4.14}$$

and from the triangle OAP we have

$$\mathrm{OA} = \cos(u+v) \quad \text{and} \quad \mathrm{AP} = \sin(u+v). \tag{4.15}$$

Looking at Fig. 4.7 we now find

$$\sin(u+v) = \mathrm{PD} + \mathrm{AD} = \mathrm{PD} + \mathrm{BC}. \tag{4.16}$$

Inserting the expressions for PD and BC from Eqs. (4.13) and (4.14), respectively, we get

$$\sin(u+v) = \sin u \, \cos v + \cos u \, \sin v \tag{4.17}$$

and

$$\cos(u+v) = \mathrm{OB} - \mathrm{AB} = \mathrm{OB} - \mathrm{DC}. \tag{4.18}$$

Inserting the expressions for OB and DC from Eqs. (4.14) and (4.13), respectively, leads to

$$\cos(u+v) = \cos u\,\cos v - \sin u\,\sin v. \tag{4.19}$$

We shall now deduce a formula which will be needed in chapter 14. Using Eq. (4.17) we get

$$\begin{aligned}\sin 2\theta &= \sin(\theta+\theta)\\ &= \sin\theta\,\cos\theta + \cos\theta\,\sin\theta = 2\sin\theta\,\cos\theta.\end{aligned} \tag{4.20}$$

From Eq. (4.19) we have

$$\cos 2\theta = \cos(\theta+\theta) = \cos^2\theta - \sin^2\theta.$$

Using Eq. (4.11) this may be written alternatively as

$$\cos 2\theta = 2\cos^2\theta - 1 = 1 - 2\sin^2\theta.$$

4.1.1 Differentiation of trigonometric functions

In our analysis of curved coordinate systems we shall have to differentiate the functions $\sin\theta$ and $\cos\theta$. A geometrical deduction of the expressions for the derivatives of these functions shall now be given.

Figure 4.8: Changes in position on the unitunit!circle circle when incrementing θ by Δθ

Consider Fig. 4.8. A circle with radius 1 is drawn about the origin O of a Cartesian coordinate system. The radii OP and OQ make angles θ and $\theta + \Delta\theta$, respectively, with the positive x axis. The point P has coordinates (x, y) and the point Q $(x - \Delta x, y + \Delta y)$. For a small angle $\Delta\theta$, the direction of the line PQ is very close to that of the tangent at P. Then PQ is normal to the radial line OP. Thus the legs PQ and QR of the angle PQR are pairwise normal to the legs OP and OA. Since the angle POA is equal to θ, the angle PQR must also be equal to θ. From the triangle PQR we then have

$$\sin\theta = \frac{\Delta x}{\Delta\theta} \quad \text{and} \quad \cos\theta = \frac{\Delta y}{\Delta\theta}. \tag{4.21}$$

Note that the line PQ equals $\Delta\theta$ because the radius is equal to 1. Also from the triangles OAP and OBQ we get

$$\sin\theta = y \quad \text{and} \quad \cos\theta = x, \tag{4.22}$$

and

$$\sin(\theta + \Delta\theta) = y + \Delta y \quad \text{and} \quad \cos(\theta + \Delta\theta) = x - \Delta x. \tag{4.23}$$

The expressions for the derivatives of $\sin\theta$ and $\cos\theta$ can now be deduced directly from the general definition of the derivative of a function, Eq. (2.4).

$$\begin{aligned}(\sin\theta)' &= \lim_{\Delta\theta\to 0}\frac{\sin(\theta+\Delta\theta)-\sin\theta}{\Delta\theta} = \lim_{\Delta\theta\to 0}\frac{y+\Delta y-y}{\Delta\theta}\\ &= \lim_{\Delta\theta\to 0}\frac{\Delta y}{\Delta\theta} = \cos\theta\end{aligned} \tag{4.24}$$

and

$$\begin{aligned}(\cos\theta)' &= \lim_{\Delta\theta\to 0}\frac{\cos(\theta+\Delta\theta)-\cos\theta}{\Delta\theta} = \lim_{\Delta\theta\to 0}\frac{x-\Delta x-x}{\Delta\theta}\\ &= \lim_{\Delta\theta\to 0}\left(-\frac{\Delta x}{\Delta\theta}\right) = -\sin\theta.\end{aligned} \tag{4.25}$$

where we have used Eqs. (4.21)–(4.23).

In order to calculate, in chapter 9, the curvature of a curve, we shall need the derivative of $\tan\theta$. This is most simply deduced by applying the formula (2.46) for differentiating a fraction of functions. Inserting $u = \sin\theta$ and $v = \cos\theta$ and using Eqs. (4.2),(4.24), and (4.25) we find

$$\begin{aligned}(\tan\theta)' &= \left(\frac{\sin\theta}{\cos\theta}\right)' = \frac{\cos\theta\cos\theta-\sin\theta\,(-\sin\theta)}{\cos^2\theta}\\ &= \frac{\cos^2\theta+\sin^2\theta}{\cos^2\theta} = \frac{1}{\cos^2\theta}.\end{aligned} \tag{4.26}$$

Alternatively, from the next last expression in Eq. (4.26), we get

$$(\tan\theta)' = 1 + \frac{\sin^2}{\cos^2\theta} = 1 + \tan^2\theta, \qquad (4.27)$$

where we have used the definition of $\tan\theta$ in Eq. (4.2).

In Sect. 9.2 we shall need to know the MacLaurin series for $\sin\theta$. In order to collect the necessary theory of trigonometry at one place, we shall immediately deduce the form of this series.

The MacLaurin series of a function $f(\theta)$ is given in Eq. (2.84) as

$$f(\theta) = f(0) + f'(0)\,\theta + \frac{f''(0)}{2}\,\theta^2 + \frac{f'''(0)}{6}\,\theta^3 + \cdots . \qquad (4.28)$$

In the case that $f(\theta) = \sin\theta$ we get

$$\begin{array}{lcl} f(\theta) = \sin\theta & \Rightarrow & f(0) = 0 \\ f'(\theta) = \cos\theta & \Rightarrow & f'(0) = 1 \\ f''(\theta) = -\sin\theta & \Rightarrow & f''(0) = 0 \\ f'''(\theta) = -\cos\theta & \Rightarrow & f'''(0) = -1. \end{array}$$

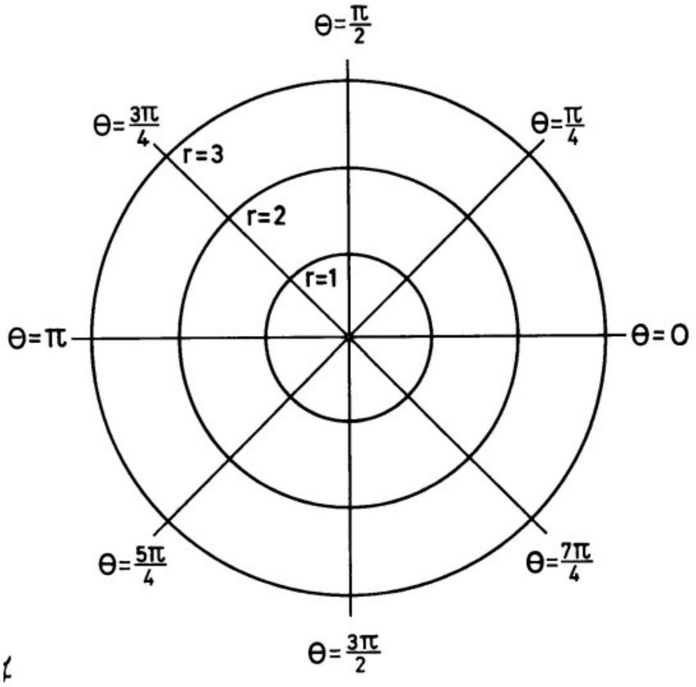
Substitution into Eq. (4.28) gives

$$\sin\theta = \theta - \frac{1}{6}\theta^3 + \cdots . \qquad (4.29)$$

These are the first terms of the MacLaurin series for $\sin\theta$.

4.2 Plane polar coordinates

A coordinate system with plane polar coordinates, r and θ, is shown in Fig. 4.9.



$\theta=\frac{\pi}{2}$
$\theta=\frac{3\pi}{4}$
$\theta=\frac{\pi}{4}$
$r=3$
$r=2$
$r=1$
$\theta=\pi$
$\theta=0$
$\theta=\frac{5\pi}{4}$
$\theta=\frac{7\pi}{4}$
$\theta=\frac{3\pi}{2}$

Figure 4.9: Plane polar coordinates, r and θ

Instead of vertical and horizontal coordinate lines, such as in a Cartesian coordinate system, the coordinate curves in a system with plane polar coordinates are concentric circles and radial lines. The Cartesian coordinates

x and y are the horizontal and vertical distances from the origin. The plane polar coordinate r of an arbitrary point P, is the distance from the origin to P. The plane polar coordinate θ is the angle of the radial line from the origin to P with respect to a horizontal line.

Just as there are horizontal and a vertical basis vectors, $\vec{e}_x$ and $\vec{e}_y$, at every point in a Cartesian coordinate system, there are radial, and a tangential basis vectors, $\vec{e}_r$ and $\vec{e}_\theta$, at every point in a polar coordinate system. These basis vectors at an arbitrary point P are shown in Fig. 4.10. The point O is the origin of the coordinate system. The point P has coordinates r and θ. The basis vectors at P have been denoted by $(\vec{e}_r)_P$ and $(\vec{e}_\theta)_P$ to indicate that their di-

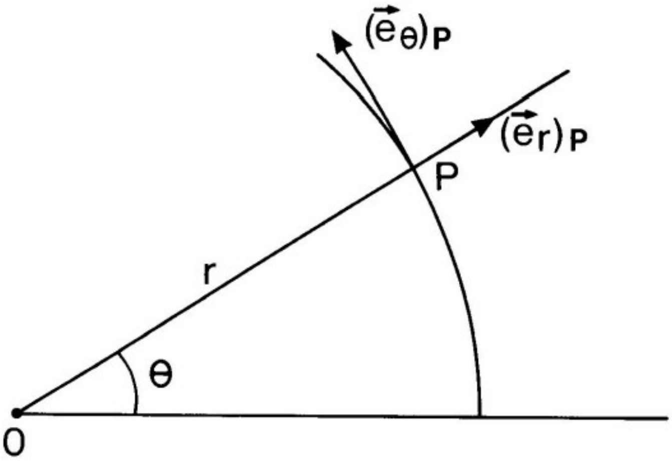


Figure 4.10: Radial and tangential basis vectors

rections and magnitudes depend upon the point at which they are drawn. The Cartesian basis vectors, $\vec{e}_x$ and $\vec{e}_y$, on the other hand, are the same everywhere.

The simple relation between a Cartesian coordinate system and a polar coordinate system with the same origin, and with the direction $\theta = 0$ corresponding to the x-axis, is shown in Fig. 4.11.

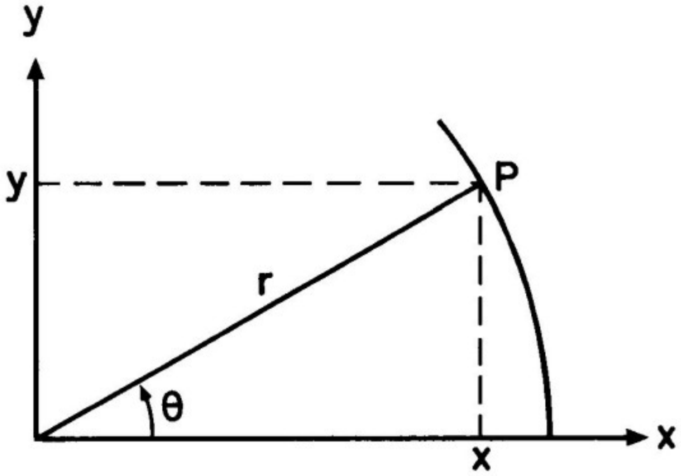

Figure 4.11: Relation between Cartesian and polar coordinates

From the figure is seen that

$$\cos\theta = \frac{x}{r} \quad \text{and} \quad \sin\theta = \frac{y}{r} \tag{4.30}$$

which gives

$$x = r\cos\theta \quad \text{and} \quad y = r\sin\theta. \tag{4.31}$$

This is our first example of a coordinate transformation equation.

Some curves have a simpler equation in polar coordinates than in Cartesian coordinates. The equation of a circle with centre at the origin and radius R is in Cartesian coordinates

$$x^2 + y^2 = R^2. \tag{4.32}$$

The equation of the same circle in polar coordinates is

$$r = R. \tag{4.33}$$

The position vector of an arbitrary point P with Cartesian coordinates (x, y) is

$$\vec{r} = x\vec{e}_x + y\vec{e}_y. \tag{4.34}$$

The Cartesian components of $\vec{r}$ are $r^x = x$ and $r^y = y$, and may be expressed by the coordinates r and θ by means of Eq. (4.31), giving

$$\vec{r} = r\cos\theta\,\vec{e}_x + r\sin\theta\,\vec{e}_y. \tag{4.35}$$

We now calculate the magnitude of the basis vectors $\vec{e}_r$ and $\vec{e}_\theta$. Using a concept introduced in section 3.3 we may say that the basis vector field $\vec{e}_r$ is a tangent vector field to the radial lines. The coordinate θ is constant along a radial line, while r increases along it. Thus r can be used as a parameter for such a line. The parametric equation for a radial line is then

$$x = r\cos\theta \quad \text{and} \quad y = r\sin\theta$$

where θ is a constant, specific for each line. Equation (3.19) with $\vec{u} = \vec{e}_r$, $t = r$, and replacing dx/dt with $\partial x/\partial r$, and dy/dt with $\partial y/\partial r$, gives

$$\vec{e}_r = \frac{\partial x}{\partial r}\vec{e}_x + \frac{\partial y}{\partial r}\vec{e}_y, \tag{4.36}$$

which shows that

$$(\vec{e}_r)^x = \frac{\partial x}{\partial r} \quad \text{and} \quad (\vec{e}_r)^y = \frac{\partial y}{\partial r}. \tag{4.37}$$

Differentiating Eq. (4.31) with respect to r, (remember that θ is constant when we differentiate partially with respect to r), we get

$$\frac{\partial x}{\partial r} = \cos\theta \quad \text{and} \quad \frac{\partial y}{\partial r} = \sin\theta. \tag{4.38}$$

Thus

$$(\vec{e}_r)^x = \cos\theta \quad \text{and} \quad (\vec{e}_r)^y = \sin\theta \tag{4.39}$$

showing that

$$\vec{e}_r = \cos\theta\,\vec{e}_x + \sin\theta\,\vec{e}_y. \tag{4.40}$$

The magnitude of $\vec{e}_r$, as calculated by means of Eqs. (1.5) and (4.39) is

$$|\vec{e}_r| = \cos^2\theta + \sin^2\theta = 1, \tag{4.41}$$

which shows that $\vec{e}_r$ is an unit vector independent of its position. But $\vec{e}_r$ changes with θ. Since the magnitude of $\vec{e}_r$ is constant and equal to unity, the change of $\vec{e}_r$ with θ is only a change of direction.

The basis vector fields $\vec{e}_\theta$ are tangent vector fields to the circles about the origin. The coordinate r is constant along a circle, while θ increases along it. So θ can be used as a parameter for such a circle. The parametric equation for a circle about the origin is again Eq. (4.31), but this time with $r =$ constant for each circle, and with θ as variable.

Equation (3.17) with $\vec{u} = \vec{e}_\theta$, $t = \theta$, and first $i = x$, so $i = y$, then gives

$$(\vec{e}_\theta)^x = \frac{\partial x}{\partial \theta} = -r\sin\theta \quad \text{and} \quad (\vec{e}_\theta)^y = \frac{\partial y}{\partial \theta} = r\cos\theta, \tag{4.42}$$

which leads to

$$\vec{e}_\theta = -r\sin\theta\,\vec{e}_x + r\cos\theta\,\vec{e}_y. \tag{4.43}$$

The magnitude of $\vec{e}_\theta$ is found from Eqs. (1.5) and (4.43) as

$$\begin{aligned} |\vec{e}_\theta| &= \left[(-r\sin\theta)^2 + (r\cos\theta)^2\right]^{1/2} \\ &= r(\sin^2\theta + \cos^2\theta)^{1/2} = r. \end{aligned} \tag{4.44}$$

This equation shows that the magnitude of $\vec{e}_\theta$ increases proportionally to the distance from the origin. This is not a unit vector field. However, one could define a corresponding unit vector field $\vec{e}_{\hat{\theta}}$ by

$$\vec{e}_{\hat{\theta}} = \frac{\vec{e}_\theta}{|\vec{e}_\theta|} = \frac{1}{r}\vec{e}_\theta. \tag{4.45}$$

Here the hat above the index denotes that the vector has unit length.

Note that the calculation above has provided us with a method for transforming basis vectors. Using Eq. (3.19) we find the transformation of the basis vectors from a knowledge of the corresponding coordinate transformation.

We have seen that in general the coordinate basis vectors are not unit vectors. And the corresponding unit vectors, such as $\vec{e}_{\hat{\theta}}$, will in general not be coordinate basis vectors. Still they are basis vectors, in the sense that an arbitrary vector can be decomposed along the basis vectors.

Chapter 5

The metric tensor

The metric tensor is perhaps the most important mathematical quantity in the theory of relativity. From a knowledge of the metric tensor one may compute the geometry of spacetime and for example the motion of the planets in the solar system. In this chapter we shall give a thorough introduction to the metric tensor and its physical significance in the theory of relativity.

5.1 Basis vectors and the dimension of a space

In Chapter 1 basis vectors were introduced as reference vectors for directions (in flat space), and it was mentioned that at every point of an n-dimensional space there are n basis vectors. One could say that there are n independent

Chapter 3
The Equivalence Principle

3.1 Inertial and Gravitational Masses

In this section we discuss the *principle of equivalence*. We shall see that, besides allowing the extension of the principle of relativity to *a generic*, not necessarily inertial, frame of reference, it allows to define gravity, in a relativistic framework, as a property of the four-dimensional space–time geometry.

The *principle of equivalence*, in the so-called *weak* form, asserts the *exact equivalence between the inertial mass* m_I *and the gravitational one* m_G. We recall that the inertial mass m_I is defined through Newton's second law of dynamics:

$$\mathbf{F} = m_I \mathbf{a}. \tag{3.1}$$

Its physical meaning is, as is well known, that of *inertia* of a body, that is its reluctance to be set in motion or, more generally, to change its velocity. The gravitational mass m_G, on the other hand, enters the definition of Newton's universal law of gravitation according to:

$$\mathbf{F} = -G\frac{m_G M_G}{r^2}\mathbf{u_r} \tag{3.2}$$

where $G = 6.6732 \times 10^{-11}\ \mathrm{Nm}^2/\mathrm{Kg}^2$ is the gravitational constant, m_G and M_G are the gravitational masses of the two attracting bodies.[1] For definiteness we refer to the situation where the mass M_G attracts the mass m_G. We see that the gravitational mass sets the strength of the gravitational force that, *ceteris paribus,* a given body exerts on another one. In this sense it would better deserve the name of *gravitational charge*, in analogy with Coulomb's law of the electrostatic interaction, where the electric charge sets the strength of the electric interaction, the mathematical structures of the two laws being exactly the same.

---

[1] It goes without saying that we are referring to two spherical bodies or to bodies whose dimensions are negligible with respect to their distance r.

R. D'Auria and M. Trigiante, *From Special Relativity to Feynman Diagrams*,
UNITEXT, DOI: 10.1007/978-88-470-1504-3_3,
© Springer-Verlag Italia 2012

However, besides the enormous *quantitative* difference between the *strengths* of *gravitational* and *electrostatic* forces[2] there is a major qualitative difference between them: While any two bodies have mass, they do not necessarily have charge. As a consequence the gravitational force is *universal*, while the electric force is not.

It is important to note that the equality between inertial and gravitational mass, expressed by the principle of equivalence, is in some sense surprising, given the substantial difference between these two physical concepts, which reflects into different operational definitions of their respective measures.

It is, however, one of the best established results from the experimental point of view.

Indeed a large number of experiments were devised, since Newton's times, to ascertain the validity of this unexpected coincidence; among them, of particular importance from a historical point of view is the *Eötvos experiment*, of which we give a short description in Appendix A. The precision reached in this experiment is such that $\frac{\Delta m}{m_I} \equiv \frac{|m_G - m_I|}{m_I}$, is less than 2×10^{-3}. Thanks to the advanced technological features of modern experimental physics, the above ratio has been pushed to less than 10^{-15}. This justifies the theoretical assumption of the exact equality between inertial and gravitational mass:

$$m_I = m_G, \tag{3.3}$$

that is the *principle of equivalence in its weak form*, can be safely assumed as one of the experimentally best established principles of theoretical physics.

The great intuition Einstein had at the beginning of last century, was to realize the considerable importance of this seemingly curious "coincidence", since it implies that *locally, it is impossible to distinguish between the effects of a gravitational field and those of an accelerated frame of reference.*

To justify such a conclusion we illustrate a so-called "Gedankenexperiment", that is a conceptual experiment, originally formulated by Einstein to be performed in a frame of reference attached to an elevator; in our era of space journeys, it seems however more appropriate to update this experiment by replacing Einstein's elevator with a spaceship. Note that the time duration of the experiment inside the spaceship, together with its spatial extension, define a four-dimensional region of space–time. In the following we shall moreover restrict ourselves to the framework of the Newtonian theory of gravitation.

Let us now describe this conceptual experiment, in the following four steps:

(i) Suppose the spaceship, to be simply referred to by $\mathcal{A}$, is initially placed, with the engines turned off, in a region of space which is far enough from any celestial body for the net gravitational force acting on it to be negligible. By definition this is an *inertial frame of reference.* If a physicist performs experiments within the spaceship, he will find that all bodies (if not subject to other kind of forces) move in a rectilinear uniform motion, according to Galileo's principle of inertia.

---

[2] We recall that the ratio between the electric and gravitational forces between two protons is of the order of 10^{38}.

(ii) Let us assume next that, at some stage, the spaceship reaches the proximity of a planet, and thus becomes subject to a gravitational acceleration of the form:

$$\mathbf{g}(\mathbf{r}) = -G\frac{M}{r^2}\mathbf{u_r}, \tag{3.4}$$

M being the (gravitational) mass of the planet.

In the presence of such an attraction $\mathcal{A}$ starts orbiting around the planet, thus becoming an *accelerated frame of reference*. The accelerated frame of reference defined by *any* massive body which is not subject to forces other than gravity is usually referred to as a *free falling frame*. Our spaceship $\mathcal{A}$ orbiting around the planet, is an example of a free falling frame. In this situation an observer inside $\mathcal{A}$ still finds that all bodies execute an *inertial motion*: Indeed, the same acceleration $\mathbf{g}(\mathbf{r})$, acting on the frame $\mathcal{A}$, also acts on each body inside of it. It follows that the motion of bodies in $\mathcal{A}$ is inertial with respect to the spaceship itself, since their relative acceleration with respect to $\mathcal{A}$ is zero.

Since in both cases (i) and (ii) the motion inside $\mathcal{A}$ is of the same kind, that is inertial, there is no way an observer in the spaceship can distinguish between the two situations. We conclude that:

It is not possible through experiments performed in the interior of $\mathcal{A}$ to tell whether it is a free falling frame or an inertial one.[3]

(iii) Consider again the spaceship $\mathcal{A}$ in a region far from any celestial body, and suppose that now, in contrast to case (i), its engines are turned on, thus producing an acceleration $\mathbf{a_R}$ which is uniform all over the spaceship and constant in time. Since now $\mathcal{A}$ is accelerated, all bodies inside of it fall with the same acceleration $\mathbf{a}' = -\mathbf{a}_R$, where $\mathbf{a}'$ and $\mathbf{a}_R$ are the accelerations with respect to $\mathcal{A}$ and the relative acceleration of $\mathcal{A}$ with respect to an inertial system, respectively.

(iv) Finally consider the situation in which the spaceship is at rest on a massive body (for example the earth) which creates a gravitational field of acceleration $\mathbf{g}$; because of the equality between inertial and gravitational masses, *all bodies inside $\mathcal{A}$ fall with the same acceleration* $\mathbf{g}$.

Comparing these two last examples, we see the an observer inside the spaceship cannot tell whether he is in case (iv), where the observed acceleration is due to a gravitational field and his frame of reference is inertial, or in case (iii) where his frame of reference is accelerated by the engines of the spacecraft with acceleration $\mathbf{a_R} = -\mathbf{g}$ with respect to an inertial frame. We conclude that: *It is not possible, through experiments performed in the interior of $\mathcal{A}$, to distinguish an inertial frame in the presence of a gravitational field from an accelerated system of reference.*

The previous discussion seems to lead to the conclusion that a perfect equivalence exists between the effects of a gravitational field as observed in an inertial frame of reference and those observed in an accelerated frame. This may seem very strange:

---

[3] The inertial motion inside a free falling system is a well known fact nowadays, think about the absence of weight of astronauts inside orbiting spacecrafts.

A gravitational field after all has its sources in the massive bodies where the field lines converge, and its intensity is a decreasing function of the distance from them, vanishing at infinity. The lines of force of the acceleration field $\mathbf{a}'$, on the contrary, are not converging and do not fall down to zero at infinity.

In fact, as we shall now show, a more accurate and quantitative discussion of the "Gedankenexperiment" examined above, shows that the assumed *equivalence between gravitational field and non-inertial frames, holds only if we restrict ourselves to events taking place in a small space region and during a small time interval, that is, mathematically, in an infinitesimal region of space–time.*

To clarify this point, let us examine the situations described in points (i) and (ii) in some more detail. It is not difficult to realize that the supposed equivalence between the free falling frame and the inertial system holds only in the limit where the acceleration $\mathbf{g}(\mathbf{r})$ can be regarded as uniform in the interior of $\mathcal{A}$, that is only if:

$$\mathbf{g}(\mathbf{r}) \simeq \mathbf{g}(\mathbf{r_0}), \tag{3.5}$$

where $\mathbf{r_0}$ is the barycenter of the spaceship.

Suppose indeed we have a system of particles of masses $m_1, m_2 \dots m_N$ in a gravitational field, $\mathbf{g}$, each obeying its own equation of motion; let us now rewrite the equation of motion of, say, the kth-particle (3.1), in an accelerated frame S' having a relative acceleration $\mathbf{a_R}$ with respect to an inertial frame S.[4] One has:

$$m_{G(k)}\mathbf{g}(\mathbf{r}_k) = m_{I(k)}\left(\mathbf{a}'_k + \mathbf{a}_R\right) \tag{3.6}$$

where $\mathbf{a}'_k$ is the acceleration of the particle in the frame S'. In particular, if S' is the free falling system, we have:

$$\mathbf{a}_R = \mathbf{g}(\mathbf{r_0}), \tag{3.7}$$

so that (3.6) becomes:

$$m_{G(k)}\mathbf{g}(\mathbf{r}_k) - m_{I(k)}\mathbf{g}(\mathbf{r_0}) = m_{I(k)}\mathbf{a}'_k. \tag{3.8}$$

The discussion made in points (i) and (ii) holds provided we use the approximation (3.5), $\mathbf{g}(\mathbf{r}_k) \simeq \mathbf{g}(\mathbf{r}_0)$, that is *we consider a sufficiently small neighborhood* of the center of mass of $\mathcal{A}$, such that the gravitational acceleration can be approximated by a constant vector and higher order effects in the distance $|\mathbf{r}_k - \mathbf{r}_0|$ can be neglected. In this case taking into account the principle of equivalence, $m_{G(k)} = m_{I(k)}$, from (3.8) it follows:

$$\mathbf{a}'_k \simeq 0. \tag{3.9}$$

This more accurate analysis implies that the equivalence between the free falling frame and the inertial frame described in the former two experiments only holds

---

[4] We recall that the relative acceleration $\mathbf{a}_R$ is given in general by the sum of three terms, the translation acceleration $\mathbf{a}'$, the centripetal acceleration $\mathbf{a}_{(centr)}$, and the Coriolis acceleration $\mathbf{a}_{(Cor)}$.

locally, that is in an infinitesimal neighborhood where, up to higher order terms, (3.5) is valid. The previous discussion can be made more general by assuming that, besides the interaction with the gravitational field, the particles are also subjected to reciprocal *non gravitational forces* $\mathbf{F}_{kl}$. In this case let us write the equation of motion of the kth particle in an inertial frame where a gravitational field $\mathbf{g}$ is present:

$$m_{Gk}\mathbf{g}(\mathbf{r}_k) + \sum_{l\neq k}\mathbf{F}_{kl}(|\mathbf{r}_k - \mathbf{r}_l|) = m_{Ik}\frac{d^2\mathbf{r}_k}{dt^2}. \tag{3.10}$$

We may write the corresponding equation in the free falling system through the coordinate transformation

$$\mathbf{r}' = \mathbf{r} - \frac{1}{2}\mathbf{g}t^2. \tag{3.11}$$

In the same hypotheses made before, namely assuming (3.5), which implies $\mathbf{g} = const.$ and (3.3), (3.10) takes the following form:

$$\sum_{l}\mathbf{F}_{kl}(|\mathbf{r}'_k - \mathbf{r}'_l|) = m_{Ik}\frac{d^2\mathbf{r}'_k}{dt^2}, \tag{3.12}$$

which is the equation of motion of classical mechanics in the absence of a gravitational field.

As far as the other two situations (iii) and (iv) are concerned, it is clear that also in this case the equivalence only holds if the approximation (3.5) is used, that is only *locally*, since the gravitational field would in general be a function of the point inside the spaceship, while the field of accelerations is, at each instant, exactly uniform.

Let us recall that our analysis so far has been made within the framework of classical Newtonian mechanics, without any reference to the implications of Einstein's special relativity. If we now assume that the statement of the *local equivalence* between an inertial frame of reference in a gravitational field and an accelerated one also holds in the framework of relativistic mechanics, described in Chap. 2, then we may reformulate the conclusions of points (i) and (ii), as follows:

In the presence of a gravitational field, locally, the physical laws observed in a free falling frame are those of special relativity in the absence of gravity. As explained above, *locally* means, mathematically, in an infinitesimal neighborhood or, more physically, in a sufficiently small neighborhood of a point such that, up to higher order terms, the approximation (3.5) holds.

The previous statement is referred to as the *equivalence principle in its strong form* or simply *strong equivalence principle*.

In particular we see that when gravitation is included in the description of physical systems, if the *strong equivalence principle* is assumed to hold, the special role played by *inertial frames* is lost, since frames of reference which are rigorously inertial only exist in infinitesimal regions of space–time. Moreover, since acceleration and gravitation are locally indistinguishable it is reasonable to assume that *the physical laws should take the same form also in non-inertial frames*, or, in other words, to require that *the principle of relativity be valid not only in inertial frames, but more generally, in every frame of reference, described by generic four-dimensional coordinate systems.* Recall indeed that we restricted ourselves, in the first chapter, to coordinate transformations which were linear, since we were only interested in inertial frames of references (endowed with three-dimensional Cartesian coordinate systems).[5] Anticipating concepts to be introduced in next chapter, this characterizes the four-dimensional coordinate system associated with inertial frames of reference to be Cartesian or *rectilinear*. Extending our analysis to non-inertial frames implies considering general (four-dimensional) coordinate systems, related to one another by non-linear transformations: Transformations to *arbitrary accelerated frames of reference* are described by *arbitrary transformations of the four coordinates labeling space–time.* It follows that in order to implement the principle of relativity on the laws of physics, in the presence of gravitation, we must require these to have the same form in *any frame of reference*, so that they be covariant under *general coordinate transformations*, i.e. arbitrary changes of coordinates with a non-vanishing, coordinate-dependent, Jacobian:

$$x^{\alpha\prime} = f^{\alpha}(x^0 \equiv ct, x^1, x^2, x^3). \tag{3.13}$$

Summarizing, while in the special theory of relativity, where the gravitational interaction is not taken into account, the physical laws were required to be covariant only under the linear Lorentz transformations, relating inertial frames, in the presence of gravity the implementation of the principle of relativity requires that:

The laws of the Physics be covariant under general coordinate transformations (3.13).

Note that *covariance under general coordinate transformations* means, as we discussed in the case of the Lorentz transformations, that the equations describing the physical laws have exactly the same form, albeit in the transformed variables, in every coordinate system.

In other words: A theory including a treatment of the gravitational field must be *generally covariant*.

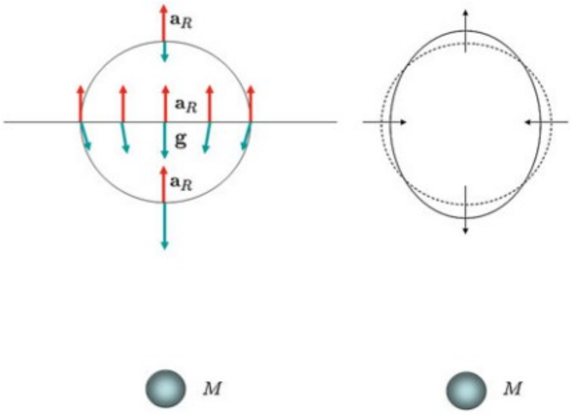
It is really amazing that this conclusion, assumed by Einstein as the starting point for a relativistic theory of gravitation, can be drawn simply from the principle of equivalence, that is the equality between inertial and gravitational masses.

Because of its general covariance the relativistic theory of gravitation is called *general theory of relativity.*

---

[5] Linearity was then a consequence of the requirement that the principle of inertia holds in both the old and the transformed frames: A motion which is uniform with respect to one of them cannot be seen as accelerated with respect to the other.

Fig. 3.1 Tidal forces



3.2 Tidal Forces

We have seen that it is always possible to *locally* eliminate the effects of a gravitational field by using a *free falling frame*. It is then extremely important to examine those effects of a gravitational field which cannot be eliminated in the free falling frame, that is which manifest themselves when we go beyond the crude equivalence implied by the approximate relation (3.5).

In the present section we shall work purely in the classical limit, that is with no reference to the corrections implied by special relativity, and show that what remains of a gravitational force in the free falling frame are the *tidal forces*, see Fig. 3.1.

Let us start indeed from equation (3.8) which, in the classical case, assuming $m_I = m_G$, contains no approximations:

$$\mathbf{g}(\mathbf{r}) - \mathbf{g}(\mathbf{r_0}) = \mathbf{a}', \tag{3.14}$$

the position vector $\mathbf{r}$ defining a generic point in a neighborhood of $\mathbf{r_0}$. We shall also denote by $\mathbf{h} = \mathbf{r} - \mathbf{r_0} = (h^i)$ the relative position vector between the two points, with components $h^k \equiv x^k - x_0^k$, where $k = 1, 2, 3$ and $(x^k) \equiv (x, y, z)$, $(x_0^k) \equiv (x_0, y_0, z_0)$ (see Fig. 3.2).

Let us compute, to the first order in h^k, the i-th component of the gravitational acceleration in the free falling frame. From (3.14) it follows:

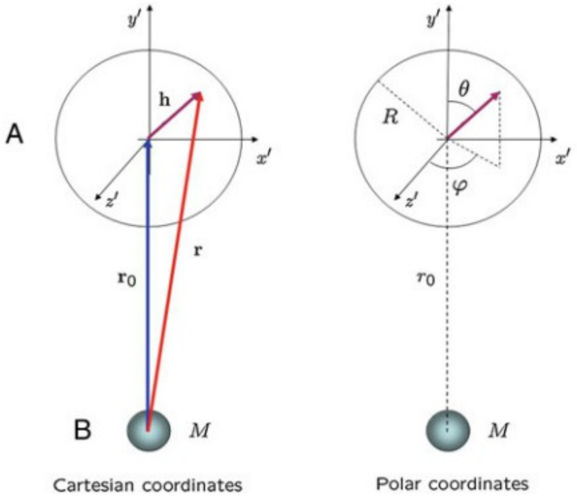
$$a^{i\prime} = \sum_{k=1}^{3} \left.\frac{\partial g^i}{\partial x^k}\right|_{h=0} h^k \equiv -\sum_{k=1}^{3} \left.\frac{\partial^2 \phi}{\partial x^k \partial x^i}\right|_{h=0} h^k + O(|\mathbf{h}|^2). \tag{3.15}$$

where $i = 1, 2, 3$ and ϕ denotes the gravitational potential.

Taking into account that

$$g^i = -\frac{\partial \phi}{\partial x^i} = -G\frac{M x^i}{r^3}, \tag{3.16}$$

Fig. 3.2 Coordinates



Cartesian coordinates

Polar coordinates

equation (3.15) becomes:

$$a^{i\prime} = -G\frac{M}{r_0^3}\sum_{k=1}^{3}\left(\delta^{ik} - 3\frac{x_0^i x_0^k}{r_0^2}\right)h^k. \tag{3.17}$$

The acceleration field $\mathbf{a}' \equiv (a^{i\prime})$, defined in (3.17), is *the remnant, to order* $O(|\mathbf{h}|)$, of the gravitational field in the free falling frame. We see that it is essentially given by the *gradient of the gravitational field* and is called the *tidal field*. Correspondingly, the force $\mathbf{f} = m\mathbf{a}'$ of the tidal field, acting on a given mass m, is the *tidal force*.

We stress that all these considerations have been obtained using the classical Newtonian formula for the gravitational field which is both *static and non-relativistic*.

In order to show what the effect of tidal forces on an extended body is, let us consider two bodies, say A and B, subject to their mutual gravitational interaction, and let us assume that A is free falling in the gravitational field of B, like for instance an orbiting satellite. We also assume, for the sake of simplicity, that the free falling body A is spherical. We call S' the frame of reference attached to A and S the one attached to B. Let the origin of S' coincide with the barycenter $\mathbf{r_0}$ of A, the z'-axis coincide with direction joining $\mathbf{r_0}$ to the center of mass of the attracting body B and the x' and y'-axes lie, as usual, in the plane orthogonal to the z'-axis (see Fig. 3.2).

With reference to this configuration we observe that $x_0^3 \equiv z_0 \equiv r_0$, so that (3.17) gives:

$$f^{z\prime} = 2G\frac{Mm}{r_0^3}h^{z\prime}, \tag{3.18}$$

$$f^{x\prime} = -G\frac{Mm}{r_0^3}h^{x\prime}, \tag{3.19}$$

$$f^{y'} = -G\frac{Mm}{r_0^3}h^{y'}, \tag{3.20}$$

that is, in matrix notation:

$$\begin{pmatrix} f^{x'} \\ f^{y'} \\ f^{z'} \end{pmatrix} = m \begin{pmatrix} -G\frac{M}{r_0^3} & 0 & 0 \\ 0 & -G\frac{M}{r_0^3} & 0 \\ 0 & 0 & 2G\frac{M}{r_0^3} \end{pmatrix} \begin{pmatrix} h^{x'} \\ h^{y'} \\ h^{z'} \end{pmatrix}, \tag{3.21}$$

where the entries of the matrix on the right hand side are $\partial g^i/\partial x^k$ computed in $\mathbf{r}_0$. From (3.18) it follows that $f^{z'}$ is attractive or repulsive according to the sign of $h^{z'}$; that is, referring to Fig. 3.1, it points downwards on the part of the body facing B $(z' > 0)$, and upwards on the opposite side $(z' < 0)$. The two horizontal components $f^{x'}$ e $f^{y'}$, instead, are always attractive, that is they are directed towards the origin of S'. The net result is an outward stress acting along the line joining A and B and an inward stress on the horizontal planes $z' = const$.

Tidal forces can be very strong in the astrophysical phenomena; for example the tidal forces exerted by the greatest planets of the solar system on their satellites induce a tidal heating due to the consequent internal friction; in the case of the Jupiter satellite Io this results in dramatic volcanic eruptions.[6]

In the case of a deformable body, tidal forces deform a spherical body to the shape of an ellipsoid, the major axis lying along the A-B direction. This is in fact what happens in the case of the earth where the corresponding phenomenon, induced by the moon, gives rise to the ordinary oceanic tides, whence the denomination *tidal forces* has its origin.

We may indeed think of the earth as the body A in free fall on the gravitational field of the moon, the body B. The "thin" layer represented by the oceans covering the earth's surface is indeed deformable. It follows that on the side facing the moon and on the opposite side tidal forces give rise to high tides, while in the directions perpendicular to the line earth-moon tidal forces produce low tides (Fig. 3.1). Because of the bipolar character of these bulges and compressions, the periodicity of tides is of 12 h. We may make a crude estimation of the tidal size on the earth.

First we observe that tidal forces are conservative. Indeed from equations (3.18), (3.19), (3.20) it follows that the associated tidal potential energy is:

$$\begin{aligned} \mathcal{E}_P &= -\frac{GM_L m_T}{r_0^3}\left(z'2 - \frac{1}{2}x'2 - \frac{1}{2}y'2\right) = -\frac{GM_L m_T}{r_0^3}\left(-\frac{1}{2}R^2 + \frac{3}{2}z'2\right) \\ &= -\frac{GM_L m_T}{r_0^3}R^2\left(\frac{3\cos^2\theta - 1}{2}\right), \end{aligned} \tag{3.22}$$

where we have introduced spherical coordinates with origin on the center of the earth (see Fig. 3.2), R being its radius, θ the latitude and we have denoted by $M_L,\ m_T,\ r_0$, the moon's mass, the earth's mass and the earth-moon distance, respectively.

---

[6] In the proximity of the event horizon of a black hole tidal forces are so strong as to completely disintegrate any body falling inside.

The total potential energy of a water particle is obtained as the sum $\mathcal{E}_P + mgh$, where *mgh* is the potential energy of the terrestrial attraction. At the equilibrium the form of the oceans' equipotential surface is determined by the condition:

$$E_P^{tot} = mgh - \frac{GM_L m_T}{r_0^3} R^2 \left(\frac{3\cos^2\theta - 1}{2} \right) = \text{cost}. \tag{3.23}$$

Equation 3.23 implies $h = h(\theta)$; the difference in height between high ($\theta = 0$) and low ($\theta = \frac{\pi}{2}$) tides turns out to be:

$$\Delta h \equiv h(0) - h(\pi/2) = \frac{3GM_l}{2gr_0^3} R^2 \simeq 53 \text{ cm}. \tag{3.24}$$

If the gravitational pull of the sun is also taken into account, one finds an additional contribution about half as large as the previous one.[7]

3.3 The Geometric Analogy

In this section we try to explain how the equivalence principle discussed in the previous section naturally leads to a modification of the space–time geometry, described in special relativity by the Minkowski space. To this end we need to anticipate part of the discussion of next chapter.

We begin by recalling that in Euclidean geometry the distance between two points P_1 e P_2, which is *invariant* under rotations and translations of the Cartesian coordinate system, can be written as[8]

$$\Delta\ell^2 = (\Delta\xi^1)^2 + (\Delta\xi^2)^2 + (\Delta\xi^3)^2 = \sum_{i,j} \delta_{ij} \Delta\xi^i \Delta\xi^j, \tag{3.25}$$

if and only if we are using Cartesian (rectangular) coordinates ξ^i. By Cartesian (rectangular) coordinates we mean rectangular (or rectilinear) coordinates, which, in studying Euclidean geometry, are defined throughout the space. This is possible only if the geometry is Euclidean, that is the properties of figures, the notion of parallelism and so on are those derived by Euclid's axioms.

In (3.25) we have adopted the following notation:

$$\begin{aligned} \delta_{ij} &= 1 \quad i = j, \\ \delta_{ij} &= 0 \quad i \neq j, \end{aligned} \tag{3.26}$$

---

[7] This crude estimate must be considered, together with the correction due to the sun, just a mean value. It does not take into account resonance phenomena due to the earth rotation and the shape of the oceanic depths which can locally alter in a sensible way the rough computation leading to (3.24).

[8] In this section only we denote by ξ^i the Cartesian coordinates, while the notation x^i is used for generic curvilinear coordinates.

that is, in matrix notation:

$$(\delta_{ij}) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{3.27}$$

The Kronecker symbol δ_{ij} defines the so called *metric tensor*

If we adopt the Einstein convention that repeated indices are summed over, then (3.25) can be written as follows:

$$\Delta\ell^2 = \sum_{i,j} \delta_{ij} \Delta\xi^i \Delta\xi^j \equiv \delta_{ij} \Delta\xi^i \Delta\xi^j, \tag{3.28}$$

or, if the two points are infinitesimally apart,

$$d\ell^2 = \delta_{ij} d\xi^i d\xi^j. \tag{3.29}$$

It is clear that the same considerations and formalism hold if the Euclidean space has a generic number D of dimensions; in this case the indices $i, j, \dots$ would run over D values instead of only three.

As we have already remarked in Sect. 1.5 of the first chapter, there is a close analogy between the *four-dimensional distance* in Minkowski space–time and the Euclidean distance (3.28) in $D = 4$ dimensions. Indeed the *four-dimensional distance* between two events[9] labeled by the four coordinates $\xi^0, \xi^1, \xi^2, \xi^3$ was written as[10]:

$$\begin{aligned} \Delta s^2 = c^2 \Delta\tau^2 = (\Delta\xi^0)^2 - (\Delta\xi^1)^2 - (\Delta\xi^2)^2 - (\Delta\xi^3)^2 = \sum_{\alpha,\beta} \eta_{\alpha\beta} \Delta\xi^\alpha \Delta\xi^\beta \\ \equiv \eta_{\alpha\beta} \Delta\xi^\alpha \Delta\xi^\beta \quad (\alpha, \beta = 0, 1, 2, 3) \end{aligned} \tag{3.30}$$

that is in a way which is strictly analogous to the four-dimensional Euclidean distance, the only difference being the replacement of the metric δ_{ij} with the Minkowski metric $\eta_{\alpha\beta}$:

$$\eta_{\alpha\beta} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \tag{3.31}$$

where the extra fourth coordinate is related to time, $\xi^0 = ct$. We stress that these simple expressions of distance in Euclidean space or proper distance in Minkowski case, are only valid if we use the three-dimensional Cartesian rectangular or the analogous four-dimensional Cartesian rectangular (also referred to as Minkowskian[11]) coordinates ξ^α, the latter being defined rectangular as the coordinates used to describe inertial frames in terms of the spatial Cartesian rectangular coordinates and the usual time coordinate t. In any other coordinate system, not related by a three-dimensional rotation or a Lorentz transformation, respectively, the Euclidean distance (3.28) or the Minkowski proper distance (3.30) would take a more complicated form.

---

[9] Recall that the space–time (four-dimensional) distance was conventionally defined as the *negative* of the *proper distance*, see (2.44).

[10] From now on, we use Greek indices to label four dimensional space-time coordinates and Latin ones for the coordinates in Euclidean space.

Suppose indeed that in the Euclidean case we want to use an arbitrary system of curvilinear coordinates $x^i, \; i = 1, 2, 3$ (an example would be the spherical polar coordinates); we would then have:

$$\xi^i = \xi^i(x^j). \tag{3.32}$$

In these new coordinates the infinitesimal distance (3.30) becomes:

$$d\ell^2 = \delta_{ij}\frac{\partial \xi^i}{\partial x^k}\frac{\partial \xi^j}{\partial x^\ell}dx^k dx^\ell \doteq g_{k\ell}dx^k dx^\ell, \tag{3.33}$$

where

$$g_{k\ell} = \delta_{ij}V^i_k V^j_\ell, \tag{3.34}$$

being:

$$V^i_k \doteq \frac{\partial \xi^i}{\partial x^k}. \tag{3.35}$$

The dimensionless quantity $g_{k\ell}(x)$, replacing δ_{ij} in the formula for the squared distance, is called *metric tensor* or, more simply, *metric*[12] in curvilinear coordinates.

It is obvious that all the geometric quantities of Euclidean geometry (lengths, angles, areas, etc) do not depend of the particular coordinates used for their description. However it is well known that in general it is much simpler to compute geometric quantities using Cartesian coordinates, rather than the curvilinear ones.[13]

The same considerations would of course apply to Minkowski space–time in special relativity, if we were to use arbitrary "curvilinear" four-dimensional coordinate frames. The physical interpretation in this case would be the following: Since an arbitrary change of coordinates would correspond to arbitrary functions of the original Minkowski coordinates $\xi_0 \equiv ct, \xi_1, \xi_2, \xi_3$, the new frame of reference cannot be inertial since the transformation is, in general, not linear as it is the case for Lorentz transformations. It then follows that the new coordinate system (x^μ) must correspond to an *accelerated frame of reference*. Moreover, as it happens in the Euclidean case, instead of a constant Minkowski metric $\eta_{\alpha\beta}$ we would end up with a metric tensor depending on the four coordinates $x^\mu = x^0, x^1, x^2, x^3$. This, of course, would not change the physical laws, but only describe them in a more general, albeit cumbersome, way.

---

[11] We shall call Minkowskian the Cartesian rectangular coordinates in the four-dimensional Minkowski space–time, with metric (3.31).

[12] Here and in the following of this chapter we use the word *tensor*, whose precise meaning will be given in Chap. 4, in a loose sense, that is as a quantity carrying indices and whose transformation properties are fixed in terms of the change of coordinates (or of reference frame). In this chapter the transformation of coordinates considered are either cartesian orthogonal, or Lorentzian or even arbitrary, as explained below.

[13] When dealing with problems which exhibit some degree of symmetry it may, however, be more useful to use curvilinear coordinates, like spherical, cylindrical, etc.

Given these preliminaries we now define a space, or a space–time as *flat* if there exists a *special class of coordinates* such that the metric assumes a constant value *in a finite or infinite domain of the space or space–time*. In Euclidean and Minkowski spaces this special class is given by the Cartesian coordinates (in particular the Minkowski coordinates of special relativity), any two elements of this class being related by a combination of rotations and translations in Euclidean space or of Lorentz transformations and translations in Minkowski space. Note that the computation in generic curvilinear coordinates of geometric quantities or of physical laws in Euclidean or Minkowskian flat space, respectively, would involve the use of the metric $g_{\mu\nu}(x^\rho)$, that is of a matrix whose elements are function of the coordinates. However, in the special class of frames, the corresponding metric is simply given by the constant matrices (3.27) or (3.31).

If, however, such a *special class of coordinates* cannot be found *in a large domain,*[14] we then say that the space or space–time is *curved*, that is it exhibits *curvature,* a concept which we dwell on in the next section.

3.4 Curvature

Suppose now we have a space (finite or infinite) which possesses a curvature, that is in which it is *not* possible to introduce in a large domain Cartesian (Minkowskian) coordinates. For the sake of simplicity, and to have a help from our intuition, we suppose for the moment that the space in consideration has two space dimensions, though it may not necessarily be the plane $\mathbb{R}^2$, but rather an arbitrary surface Σ. It is well known that on a generic surface it is not possible to introduce *in a finite domain* Cartesian coordinates, but only *curvilinear ones* $x^i,\ i = 1, 2$.

Restricting our attention to an *infinitesimal neighborhood* of a point *P*, however, we can approximate the surface by the tangent plane to Σ at *P*. We say that the *local geometry* of the surface at *P* is identified with that of the corresponding tangent plane, the local coordinates on Σ, in the close vicinity of *P*, coinciding with the Cartesian ones ξ^i, $(i = 1, 2)$ on the plane[15] (see Fig. 3.3):

In an infinitely small neighborhood of *P* we can then use (3.30) to compute the infinitesimal distance between two points, and thus we conclude that *locally the*

---

[14] By *large* domain we mean a domain whose extension is finite or infinite.

[15] Being the plane flat, we can describe it by Cartesian coordinates.

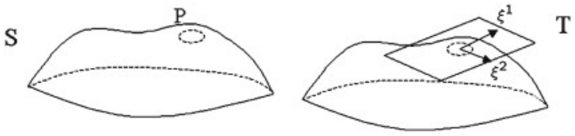


Fig. 3.3 Local geometry and tangent space

metric can be always reduced to the form δ_{ij}.[16] However to compute geometric quantities in a *finite domain* it is necessary to use general curvilinear coordinates by transforming the local coordinates through (3.32).[17] This means that the geometry in a large, possibly infinite, domain is determined by the metric tensor $g_{ij}(x^1, x^2)$, function of the curvilinear coordinates. For example, the length of a curve $\gamma = \gamma(\tau)$ can be computed as:

$$\ell = \int_\gamma d\ell = \int_\gamma \left(g_{ij}(x)dx^i dx^j\right)^{\frac{1}{2}} = \int_\gamma \left(g_{ij}(x)\frac{dx^i}{d\tau}\frac{dx^j}{d\tau}\right)^{\frac{1}{2}} d\tau, \tag{3.36}$$

τ being any parameter on the curve.

We conclude that on a surface with curvature *the metric cannot be reduced to the constant matrix* δ_{ij} *in a finite domain*; its geometry is therefore described by the metric tensor $g_{k\ell}(x)$ or, equivalently by the matrix V^i_k defined by (3.35).

Even if these considerations have been made in the special case of a two-dimensional surface, they can be straightforwardly extended to three-or N-dimensional curved spaces[18] that is to spaces where Cartesian coordinates cannot be introduced in large domains and, also, to spaces *where the local metric is not* δ_{ij}, *but* $\eta_{\alpha\beta}$, as it happens for the Minkowskian space–time of special relativity.

We can now give a precise geometric interpretation of the *strong equivalence principle* of the previous section: Saying that in a free falling frame the laws of the special relativity hold, means that the space–time geometry in such frame is *locally* the same as that of the four-dimensional (hyper)-plane tangent to space–time at the point in which the frame is located.

This (four-dimensional) tangent plane is of course the Minkowski space of special relativity. Indeed we have learned that in a free falling frame, *locally*, that is in an infinitesimal neighborhood of a point $P = (x^0, \mathbf{x})$ in its interior, up to higher order terms, gravitation is absent, so that the metric tensor reduces to the constant metric tensor $\eta_{\alpha\beta}$ of special relativity.[19] If instead we use a general frame of reference, which is not free falling, the metric tensor $g_{\mu\nu}(x)$ must describe the presence of the gravitational field.[20]

---

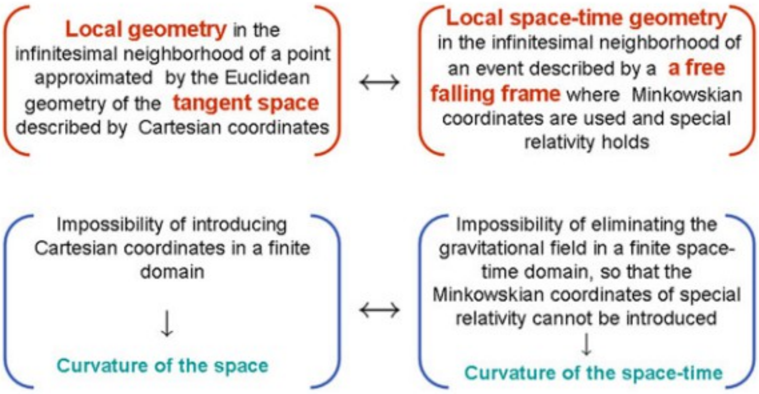
[16] Here and in the following by *locally* we mean that our statement is valid in an infinitesimal neighborhood of a point where higher order terms can be neglected.

[17] Alternatively one can use Cartesian coordinates at each point using the local tangent plane; in this case, however, one needs a quantity, called *connection*, which relates the local geometries associated with different tangent planes.

[18] A more precise definition of curvature will be given in the next section.

[19] Note that this implies that the free falling frames are the inertial frames described by special relativity. However, in the presence of a gravitational field, they can be only defined locally, since only locally the effects of gravity can be canceled.

We may thus establish the following correspondence between the presence of curvature in a four-dimensional space which is locally Euclidean (metric δ^i_j) and a space which is locally Minkowskian (metric $\eta_{\alpha\beta}$).



Local geometry in the infinitesimal neighborhood of a point approximated by the Euclidean geometry of the tangent space described by Cartesian coordinates
↔
Local space-time geometry in the infinitesimal neighborhood of an event described by a a free falling frame where Minkowskian coordinates are used and special relativity holds
Impossibility of introducing Cartesian coordinates in a finite domain
↓
Curvature of the space
↔
Impossibility of eliminating the gravitational field in a finite space-time domain, so that the Minkowskian coordinates of special relativity cannot be introduced
↓
Curvature of the space-time

Summarizing, the geometry of space–time is the geometry of a four-dimensional space with local Minkowski metric; this geometry cannot be flat in the presence of a gravitational field. Space–time geometry must then be described by a metric $g_{\mu\nu}(x)$ which depends on the presence of a gravitational field, each entry being a function of the space–time coordinates x^0, x^1, x^2, x^3. The metric can be reduced to the special relativity form $\eta_{\alpha\beta}$ only locally, that is in an infinitely small neighborhood of an event P, but not in a large region of space–time.

Generalizing equations (3.33) and (3.34) to a four dimensional space-time, where $\xi^\alpha (\alpha = 0, 1, 2, 3)$ are the local Minkowskian coordinates and $x^\mu (\mu = 0, 1, 2, 3)$ are the general coordinates parametrizing a large domain of the space, we have:

$$ds^2 = \eta_{\alpha\beta} V^\alpha_\mu V^\beta_\nu dx^\mu dx^\nu = g_{\mu\nu} dx^\mu dx^\nu, \tag{3.37}$$

where

$$V^\alpha_\mu \big|_P = \frac{\partial \xi^\alpha}{\partial x^\mu}\bigg|_P, \tag{3.38}$$

and ξ^α are the *local Minkowskian* (i.e., inertial) coordinates in an infinitesimal neighborhood of P.

---

[20] As we shall see in the sequel of this chapter the space–time metric $g_{\mu\nu}(x)$ is related to the gravitational *potential* rather than to the gravitational *field*.

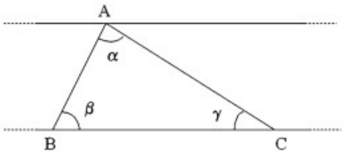


Fig. 3.4 Euclidean geometry

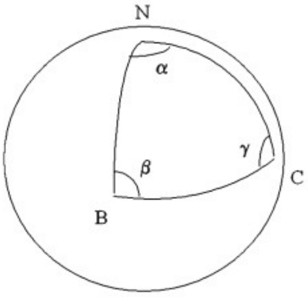

Fig. 3.5 Spherical geometry

3.4.1 An Elementary Approach to the Curvature

We recall that the Euclidean geometry is based on Euclid's eleventh postulate which states the uniqueness of the straight line passing through a given point P and parallel to a given straight line. This postulate, in particular, implies that the three interior angles of a triangle sum up to 180°, see Fig. 3.4:

$$\alpha + \beta + \gamma = \pi. \tag{3.39}$$

Let us take again, for the sake of simplicity and intuition, a two-dimensional space, more specifically a 2-sphere (see Fig. 3.5). Let us then consider a spherical triangle defined by joining along maximal circles three arbitrary points of the sphere.[21]

In spherical geometry one can show that the following relation holds:

$$\alpha + \beta + \gamma = \pi + \frac{A}{R^2}, \tag{3.40}$$

where A is the area of the spherical surface enclosed by the triangle and R is the radius of the sphere.

Let us define the *curvature* K of the sphere as:

$$K = \frac{1}{R^2}. \tag{3.41}$$

the meaning of K is to indicate how much the geometry of the sphere deviates from the Euclidean plane geometry where $K = 0$.

---

[21] A maximal circle is the shortest path joining two points on the sphere. It can be obtained by intersecting the spherical surface with a plane determined by the two points and the center of the sphere.

On the basis of its definition K seems to depend on the radius of the sphere considered as a two dimensional manifold embedded in the ambient Euclidean space $\mathbb{R}^3$. Equation (3.40) however tells us that the curvature K can be evaluated by just performing measures of angles and areas *on the two-dimensional surface of the sphere.* It follows that K has an intrinsic geometric meaning, that is independent of its embedding in the flat 3-dimensional space, since it can be computed by only using measures on the spherical surface. If we had considered a Lobacevskij surface, where K is constant, but negative, (3.40) is also valid.

Considering a *generic* surface Σ, K is of course no longer constant, but becomes a function of the point on the surface. Indeed we may characterize the value of K at P as the curvature of the sphere that best approximates the generic surface in a small neighborhood of P. In this case (3.40) can be generalized by writing:

$$\alpha + \beta + \gamma - \pi = \int_{\Delta} K(x^1, x^2) dA, \tag{3.42}$$

where dA is an infinitesimal element of the surface Σ and Δ is the integration domain.

$K(x^1, x^2)$ is called the *Gaussian curvature* of S at $P \equiv (x^1, x^2)$.

As it follows from the above discussion, K only depends on the intrinsic geometry of Σ, while it does not depend on its particular representation in $\mathbb{R}^3$, in terms of parametric equations of the form:

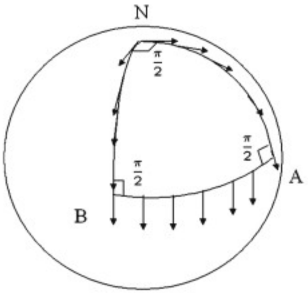
$$x = x(x^1, x^2), \quad y = y(x^1, x^2), \quad z = z(x^1, x^2), \tag{3.43}$$

where x^1, x^2, are curvilinear coordinates on Σ and x, y, z are Cartesian coordinates on $\mathbb{R}^3$. In fact one can show that K is invariant if S is flexed without stretching or tearing; for example, since K is zero on a plane, it will also be zero on a cone or a cylinder or in general on any surface which can be unfolded on a plane. If instead we are to map a portion of the terrestrial globe on a plane, stretching is necessary, since we have to change the value of K from a positive constant to zero. In this case the map can be considered a good approximation only if the area considered is much smaller than $\frac{1}{K} = R^2$.

3.4.2 Parallel Transport

There is an equivalent way of describing the curvature of a sphere. Consider a cannon at the north pole (which may metaphorically represent a tangent vector) and let us carry it along a meridian till it reaches the equator at a point A, displacing it in such a way as to always keep it *parallel to itself*, so that the angle it forms with the meridian remains constant (for example, in Fig. 3.6, the vector forms an angle zero with the arcs NA and BN and $\pi/2$ with the arc AB). This is what it is meant by *parallel transport*. Eventually, the same kind of *parallel transport* is performed along an arc AB of the equator whose length is $\frac{1}{4}$ the circumference, and finally we carry the cannon back to the north pole along the meridian BN, See Fig. 3.6.

Fig. 3.6 Parallel Transport



We easily realize that after this tour the cannon arrives back *rotated* by an angle of $\frac{\pi}{2}$, which is exactly the angular excess described by the curvature:

$$\Delta\theta = \alpha + \beta + \gamma - \pi = \frac{3}{2}\pi - \pi = \frac{\pi}{2} = kA. \tag{3.44}$$

Indeed the ratio between the angular excess $\Delta\theta$ and the area of the spherical octant, $\frac{\pi R^2}{2}$, gives exactly the value of the curvature, namely $\frac{1}{R^2} \equiv K$. Although this result was obtained in a very particular case, it can be shown to hold for a *parallel transport* along any closed path γ, not necessarily along geodesic triangles, enclosing an area Δ and on any surface. Indeed one can expect and actually show that in the general case the rotation angle is found by first applying (3.44) to an infinitesimal area *dA* and then integrating over the whole area Δ:

$$\Delta\theta = \int_{\Delta} K(x)dA. \tag{3.45}$$

where Δ is the area enclosed by the curve γ.

This alternative way of defining the curvature can be easily extended to manifolds with any number of dimensions. Since our goal is to define the curvature for the four-dimensional space–time with local Minkowski metric $\eta_{\alpha\beta}$, we consider the *parallel transport* of a vector v^{μ}, $(\mu = 0, 1, 2, 3)$ along a closed path γ in a four-dimensional manifold. After the trip, the vector will get back to the initial point "rotated" with respect to the original direction. However, as we have previously learned, such a "rotation" is a "four-dimensional rotation" in a space endowed with a metric which has the same signature as the Minkowski one $\eta_{\alpha\beta}$,[22] and therefore is a *Lorentz transformation*.

In particular, if the closed path γ is infinitesimal, we can obtain the analogous of the *Gaussian curvature* as in the case of a two-dimensional surface. However, while in two dimensions we just have one orientation for the infinitesimal area *dA*

---

[22] It can be shown that the signature of the metric, that is the number of positive and negative eigenvalues of the matrix $g_{\mu\nu}(x)$, is the same at each point of a manifold. Since at a given point the metric can be taken to coincide with $\eta_{\alpha\beta}$ this explains the meaning of the statement in the text.

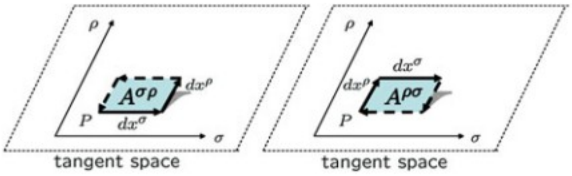


Fig. 3.7 Parallel transports along infinitesimal contours with opposite orientations

enclosed by the path γ, (that of the plane tangent to the surface), in four dimensions *dA* can have several different orientations. More specifically, if we represent γ as an infinitesimal parallelogram, we have $\binom{4}{2} = 6$ orientations, which we may label by the ordered couple of the two infinitesimal displacements dx^ρ, dx^σ defining the parallelogram *dA*: $(\rho, \sigma) = (01), (02), (03), (12), (13), (23)$. We can thus write:

$$dA \to dA^{\rho\sigma} = -dA^{\sigma\rho} \equiv dx^\rho \wedge dx^\sigma , \tag{3.46}$$

where the antisymmetry in the couple of indices $\rho\sigma$, denoted by the symbol $\wedge$, is due to the orientation of $dA^{\rho\sigma}$, which is related to the orientation of the curve γ (in other words the orientation of *dA* depends on whether the vector is transported along γ in one direction or in the other, namely if the displacement dx^ρ precedes or follows dx^σ, see Fig. 3.7).

In conclusion, performing a parallel transport of a Lorentz vector v^μ[23] along an infinitesimal path in space–time the vector undergo an (infinitesimal) Lorentz transformation given by:

$$\delta v^\mu = R^\mu{}_{\nu\rho\sigma} v^\nu dx^\rho \wedge dx^\sigma . \tag{3.47}$$

where Einstein convention of repeated indices is applied and we *define* $R^\mu{}_{\nu\rho\sigma}$ to be the *curvature* of the space–time manifold at a point *P*. We see that in four dimensions, the curvature is actually described by an object carrying four four-dimensional indices, called *Riemann curvature tensor*, or simply *Riemann tensor*, providing the natural generalization of the two-dimensional *Gaussian curvature*.

One can show that the number of *independent* components of $R^\alpha{}_{\beta\gamma\delta}$ is 20 (instead of 4^4).

3.4.3 Tidal Forces and Space–Time Curvature

From the discussion in the previous section on the geometric analogy and from the above geometric definition of the curvature, it follows that the *Riemann tensor* $R^\mu{}_{\nu\rho\sigma}$ describes the deviation of the actual space–time geometry from the *flat* Minkowski geometry, in an intrinsic, coordinate independent way. On the other hand, we have seen that, in the Newtonian approximation, tidal forces acting in the free falling frame, also describe the deviation from the Minkowskian geometry of special relativity. It is therefore obvious that there must be a close relation between curvature and tidal forces.

---

[23] Note that since the closed path is infinitesimal we are allowed to use the in the tangent hyper-plane the usual flat geometry of special relativity and therefore the reference to v^μ as a *Lorentz* vector is appropriate.

To establish this relation, we recall that (3.21) gives the tidal force in the *classical Newtonian approximation*, that is in the limit where the description of the gravitational field is static, non-relativistic and to the first order in the displacement vector **h**.

We also note that the matrix in (3.21), which is the explicit form of $\frac{\partial g^i}{\partial x^k}|_{\mathbf{r}=\mathbf{r}_0}$, has the physical dimensions of $[T^{-2}]$, while curvature has dimension $[L^{-2}]$. Thus if a relation between tidal forces and curvature exists, the two quantities must be related by a factor c^2. At first sight this could seem impossible, since $\frac{\partial g^i}{\partial x^k}$ is a 3×3 matrix with only spatial indices, $i, k = 1, 2, 3$, while the Riemann tensor has four four-dimensional indices, $\alpha, \beta, \dots = 0, 1, 2, 3$.

This different structure of indices, however, simply means that *only some components of the Riemann tensor survive when we take the non-relativistic, static limit of the full relativistic expression of the (gradient of the) gravitational field as given by the Riemann tensor in the general theory.* Indeed, from the exact formula of the Riemann tensor of the general theory of relativity, one can see that, in the non relativistic limit $c \to \infty$, denoting by Latin letters the space indices, to lowest order in *1/c* one obtains:

$$R^k{}_{0\ell 0} = -\frac{1}{2mc^2}\frac{\partial g^k}{\partial x^\ell}, \tag{3.48}$$

all the other components of the Riemann tensor being of higher order in *1/c*. We may therefore write:

$$f^k = -2mc^2 R^k{}_{0\ell 0} h^\ell \quad (k, \ell = 1, 2, 3). \tag{3.49}$$

Comparing (3.48) and (3.49) with (3.21) one obtains:

$$R^k{}_{0\ell 0} = -\frac{1}{2}\begin{pmatrix} 2\frac{GM}{r_0^3c^2} & 0 & 0 \\ 0 & -\frac{GM}{r_0^3c^2} & 0 \\ 0 & 0 & -\frac{GM}{r_0^3c^2} \end{pmatrix}, \tag{3.50}$$

We conclude that this matrix describes the curvature of space–time in the classical non-relativistic limit.

3.5 Motion of a Particle in Curved Space–Time

To determine the trajectory of a particle in space–time we take advantage of the principle of equivalence, by first writing the equation of motion in the free falling frame and then transforming to a general frame.

Locally, in the free falling frame attached to the particle, there is no gravitational field and the motion is purely *inertial* in the local special relativistic coordinates ξ^α $(\alpha = 0, 1, 2, 3)$. On the other hand, in Chap. 2, the special relativistic inertial motion was described by (2.74), namely[24]:

$$U^\alpha = \frac{d\xi^\alpha}{d\tau} = const. \longrightarrow \frac{d^2\xi^\alpha}{d\tau^2} = \frac{dU^\alpha}{d\tau} = 0, \tag{3.51}$$

We stress that this equation is valid in an infinitesimal (both space- and time-) neighborhood of the particle. Switching to the "laboratory" system where the general coordinates x^μ are used, and using the general relation between the two coordinates ξ^α and x^μ:

$$\xi^\alpha = \xi^\alpha(x^\mu), \tag{3.52}$$

we find

$$\frac{d\xi^\alpha}{d\tau} = \frac{\partial \xi^\alpha}{\partial x^\mu}\frac{dx^\mu}{d\tau} = V^\alpha_\mu \frac{dx^\mu}{d\tau}, \tag{3.53}$$

$$\frac{d^2\xi^\alpha}{d\tau^2} = \frac{d}{d\tau}\left(V^\alpha_\mu \frac{dx^\mu}{d\tau}\right) = V^\alpha_\mu \frac{d^2x^\mu}{d\tau^2} + \frac{\partial V^\alpha_\mu}{\partial x^\nu}\frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau} = 0. \tag{3.54}$$

We solve this equation with respect to the second derivatives, by multiplying both sides by the inverse matrix $(V^{-1})^\mu_\alpha$, that we denote by

$$V^\mu_\alpha \equiv (V^{-1})^\mu_\alpha; \quad V^\mu_\alpha V^\alpha_\nu = \delta^\mu_\nu. \tag{3.55}$$

Equation 3.54 takes then the following form:

$$\frac{d^2x^\mu}{d\tau^2} + \Gamma^\mu_{\nu\rho}\frac{dx^\nu}{d\tau}\frac{dx^\rho}{d\tau} = 0, \tag{3.56}$$

where we have set:

$$\Gamma^\mu_{\nu\rho} \equiv \frac{1}{2} V^\mu_\alpha \left(\frac{\partial V^\alpha_\nu}{\partial x^\rho} + \frac{\partial V^\alpha_\rho}{\partial x^\nu}\right). \tag{3.57}$$

---

[24] With respect to the notations used in Chap. 2, we have changed notation for the locally inertial coordinates from x^μ to ξ^α $(\alpha = 0, 1, 2, 3)$ since in the present setting the latter describe the locally inertial coordinates of special relativity, while the former describe a general frame, for example the coordinates used in the "laboratory" frame, where the gravitational field is present.

The number of independent components of $\Gamma^{\mu}_{\nu\rho}$, taking into account the symmetry in the two lower indices, is 40.

Note that the second term on the left hand side of (3.56) can be given the meaning of the *gravitational acceleration* impressed to the particle of coordinates x^{μ}; thus $\Gamma^{\mu}_{\nu\rho}$, called *affine connection*, represents the relativistic generalization of the gravitational field.

The solution to (3.56) for the spatial coordinates $x^i, (i = 1, 2, 3)$, gives the trajectory of the particle in the gravitational field while the solution for $x^0 = ct$ gives the relation between the local time t and the proper time τ.

One can show that $\Gamma^{\mu}_{\nu\rho}$ can be expressed in terms of the metric and its derivatives. The quickest way do so is to observe that (3.56), from the four-dimensional point of view, describes a *free inertial motion* in the curved space–time since the gravitational field has been expressed in terms of the affine connection which is a geometric property of space–time. From this point of view there is no force driving the particle; instead, the very presence of a non-trivial geometry, characterized by a non-vanishing Riemann tensor, implies that the free motion must be described by (3.56).

This interpretation is corroborated by the observation that a free motion in a *curved space–time* is the analogue of the inertial motion in flat space–time, given by a straight line. We must therefore expect that the solution to equation (3.56) must represent the analogue, in a curved space, of a straight line in flat space. Such curve is called a *geodesic* and is defined as the shortest line joining two points.

Let us consider two points A and B (events) in the four-dimensional space–time and let γ be a generic curve joining them. Its four-dimensional length $s(\gamma)$ is given by:

$$s(\gamma) = \int\limits_{\gamma[A\to B]} ds = \int\limits_{\gamma[A\to B]} (g_{\mu\nu} dx^{\mu} dx^{\nu})^{\frac{1}{2}}. \tag{3.58}$$

The analogue, in curved space, of the straight line in flat space can be obtained by requiring the curve γ to be such that its length $s(\gamma)$, as a functional of γ, be minimum, as it is the case for the straight line in flat space.

Solving the variational problem one precisely finds (3.56) with:

$$\Gamma^{\mu}_{\nu\rho} = \frac{1}{2} g^{\mu\delta} \left(-\frac{\partial}{\partial x^{\delta}} g_{\nu\rho} + \frac{\partial}{\partial x^{\rho}} g_{\nu\delta} + \frac{\partial}{\partial x^{\nu}} g_{\rho\delta} \right). \tag{3.59}$$

Note that since the relativistic gravitational field is given in terms of $\Gamma^{\mu}_{\nu\rho}$, which contains the first derivatives of the metric, the ten components of the metric $g_{\mu\nu}(x)$ are the relativistic generalization of the Newtonian gravitational potential.

To simplify formulas, in the rest of the book we shall often use the following short-hand notation for partial derivatives:

$$\partial_{\mu} \equiv \frac{\partial}{\partial x^{\mu}}; \quad \partial_i \equiv \frac{\partial}{\partial x^i}, \tag{3.60}$$

where $\mu = 0, 1, 2, 3$ and $i = 1, 2, 3$.

3.5.1 The Newtonian Limit

Since the geodesic (3.56) describes the trajectory of a particle in a gravitational field, it must reduce to the usual Newtonian formula in the non-relativistic limit. Recalling that the metric is related to the gravitational potential, we define the classical Newtonian limit as that in which, besides the non-relativistic condition $v \ll c$, we also require the gravitational field to be weak and static.

On the metric this implies:

$$g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu} + O(h^2), \tag{3.61}$$

$$\frac{\partial g_{\mu\nu}}{\partial t} = c\frac{\partial g_{\mu\nu}}{\partial x^0} = 0, \tag{3.62}$$

where $h_{\mu\nu}(x)$ is the first order deviation from the flat Minkowski space corresponding to the absence of gravitational field. In Appendix B we show that, in this case, the only non-vanishing component of the affine connection is:

$$\Gamma^i_{00} = \frac{1}{2}g^{i\mu}(-\partial_\mu g_{00}) \simeq -\frac{1}{2}\eta^{ij}\partial_j h_{00} = \frac{1}{2}\partial_i h_{00}, \tag{3.63}$$

where i is a three-dimensional space index and we have used $\eta^{ij} = -\delta^{ij}$.

With these approximations the geodesic equation for the index $\mu = 0$ gives $\frac{dt}{d\tau} \simeq 1$, while for the spatial index $\mu = i$ we have:

$$\frac{1}{c^2}\frac{d^2x^i}{dt^2} = -\frac{1}{2}\partial_i h_{00}. \tag{3.64}$$

Equation (3.64) then coincides with the Newton equation if we set:

$$\frac{\phi}{c^2} = \frac{1}{2}h_{00}. \tag{3.65}$$

where ϕ is the classical gravitational potential. With this identification, (3.64) becomes:

$$\frac{d^2x^i}{dt^2} = -\partial_i\phi. \tag{3.66}$$

In particular from (3.61) we find:

$$g_{00} = 1 + h_{00} = 1 + 2\frac{\phi}{c^2}. \tag{3.67}$$

3.5.2 Time Intervals in a Gravitational Field

Equation 3.67 allows us to evaluate how time intervals are affected by the presence of a gravitational field. Let us suppose that we are in a free falling frame, where the Minkowskian coordinates ξ^α can be used. According to the principe of equivalence, a clock at rest in such a system measures a time interval which coincides with the proper time in the absence of gravity:

$$d\tau^2 = \frac{1}{c^2}\eta_{\alpha\beta}d\xi^\alpha d\xi^\beta = \eta_{00}dt^2 = dt^2 \quad (\alpha, \beta = 0, 1, 2, 3), \tag{3.68}$$

since, for a clock at rest, $\frac{d\xi^i}{dt} = 0$.

In any other frame of reference with coordinates x^μ, like our laboratory, the gravitational field is present and the proper time interval will take the following form:

$$d\tau^2 = \frac{1}{c^2}g_{\mu\nu}dx^\mu dx^\nu. \tag{3.69}$$

If in this frame the clock has four-velocity $dx^\mu/dt = v^\mu$, then the time interval dt between two consecutive (infinitely close) ticks satisfies the relation:

$$\left(\frac{d\tau}{dt}\right)^2 = \frac{1}{c^2}g_{\mu\nu}\frac{dx^\mu}{dt}\frac{dx^\nu}{dt}. \tag{3.70}$$

In particular, if the clock is at rest in the laboratory frame, that is if $v^i = 0$, we obtain:

$$\frac{dt}{d\tau} = (g_{00})^{-\frac{1}{2}}. \tag{3.71}$$

The dilation factor on the right hand side of (3.71), however, cannot be observed, since the gravitational field affects in the same way the ticks of the standard clock and those of the clock being studied. However, the difference between dt_1 e dt_2 in two different points $\mathbf{x}_1,\ \mathbf{x}_2$ can be observed; indeed (3.71) implies:

$$dt_1 = d\tau(g_{00}(\mathbf{x}_1))^{-\frac{1}{2}}, \tag{3.72}$$

$$dt_2 = d\tau(g_{00}(\mathbf{x}_2))^{-\frac{1}{2}}, \tag{3.73}$$

so that:

$$\frac{dt_2}{dt_1} = \left[\frac{g_{00}(\mathbf{x}_1)}{g_{00}(\mathbf{x}_2)}\right]^{\frac{1}{2}}. \tag{3.74}$$

In particular, in the classical Newtonian limit, we may use (3.67) and, recalling (3.67), we obtain

$$\frac{dt_2}{dt_1} = \left[\frac{1+2\frac{\phi_1}{c^2}}{1+2\frac{\phi_2}{c^2}}\right]^{\frac{1}{2}} \approx \left(1+2\frac{\phi_1}{c^2}\right)^{\frac{1}{2}}\left(1-2\frac{\phi_2}{c^2}\right)^{\frac{1}{2}} \approx 1-\frac{\phi_2-\phi_1}{c^2} = 1-\frac{\Delta\phi}{c^2}, \tag{3.75}$$

where we have defined $\phi_1 = \phi(\mathbf{x}_1)$ and $\phi_2 = \phi(\mathbf{x}_2)$ and used that $\frac{\phi}{c^2}$ is very small in most situations.[25]

For example, if a clock is placed at the point $\mathbf{x}_1$ far away from other bodies, so that no gravitational field is present, we have $\phi(\mathbf{x}_1) = 0$, and therefore:

$$dt_1 = d\tau, \tag{3.76}$$

since $g_{00}(\mathbf{x}_1) = \eta_{00} = 1$. The same clock placed at a point $\mathbf{x}_2$, e.g., on the earth's surface, will tick time intervals dt_2 such that:

$$\frac{dt_2}{dt_1} = \frac{dt_2}{d\tau} \approx 1-\frac{\Delta\phi}{c^2} = 1-\frac{\phi_2}{c^2}. \tag{3.77}$$

Since $\phi_2 < 0$ we find $dt_2 > dt_1$, that is *time intervals are dilated in a gravitational field* by a factor $(1-\frac{\phi_2}{c^2})$. In the case of the terrestrial gravitational field we have:

$$dt_2 = \left(1+\frac{GM}{c^2 r}\right)d\tau. \tag{3.78}$$

where M is the earth's mass.

In particular a same clock will tick at a different rate, depending on whether it is placed at sea level or at height h. Indeed, since

$$\phi_1 = -\frac{GM}{R}; \quad \phi_2 = -\frac{GM}{R+h}, \tag{3.79}$$

we obtain:

$$dt_2 = \left(1-\frac{\phi_2-\phi_1}{c^2}\right)dt_1 = \left[1-\frac{GM}{c^2}\left(\frac{1}{R}-\frac{1}{R+h}\right)\right]dt_1. \tag{3.80}$$

In general we may say that the more negative the gravitational potential is, (or the greater its absolute value is), the more dilated time intervals are. Because of the factor $1/c^2$, these effects are generally small, however gravitational time dilation has been experimentally measured in various different situations.

The first verification by a experiment on earth was performed by Pound and Rebka combining the gravitational dilation with Doppler effect in the emission and absorption of photons in Fe^{57}. Further experimental evidence can be inferred from astrophysical observations (especially from the light spectra of white dwarfs). In this case we can safely set to zero the earth gravitational potential being much smaller in absolute value than the potential on the surface of a star. Thus, in this case, we have:

---

[25] As usual the value at infinity of ϕ is set equal to zero.

$$\frac{dt_2}{dt_1} = \frac{\nu_1}{\nu_2} > 1, \tag{3.81}$$

where ν denotes the light frequency and the suffix 1 and 2 are referred to the earth and to the star, respectively. The frequency of the emitted light is then higher than that observed on earth and we have a measurable shift towards the red.

In the eighties further confirmations were gained by experiments with time signals sent to and from Viking 1 Mars lander and from time measurements using atomic clocks on airplanes; the clocks that traveled aboard the airplanes, upon return, were slightly faster than those on the ground.

However, the most spectacular evidence of the gravitational red-shift is nowadays given by its technological application to GPS devices.

A GPS gives the absolute position on the surface of the earth to within 5–10 m of precision; this requires the clock ticks on the GPS satellite to be known with an accuracy of 20–30 ns. Such an accuracy cannot be reached if we neglected the special and general relativity effects on time intervals . To compute these effects we first observe that the transmitting clock is subject to the special relativistic time dilation due to the satellite orbital speed, compared to an identical clock on the earth.

From our discussion of time dilation in special relativity the clock on the satellite would run slower, compared to a clock on the earth, by the factor:

$$\sqrt{1 - \frac{v^2}{c^2}} \simeq 1 - \frac{v^2}{2c^2}, \tag{3.82}$$

at first order in $\frac{v^2}{c^2}$, since v, the satellite speed, is much smaller than c.

Suppose the satellite is orbiting at a distance from the center of the earth of about four times the earth's radius R. Using the classical result

$$\frac{v^2}{r} = \frac{GM}{r^2}, \tag{3.83}$$

with $r = 4R$, we obtain a time loss of about -7 µs/day.

We now compute the general relativistic effect. First we recall that a clock in a greater gravitational potential runs *faster* than one on earth. Then, calling Δt_E and Δt_s the time intervals on earth and on the satellite, respectively, we find:

$$1 - \frac{\Delta t_E}{\Delta t_s} = \frac{\Delta\phi}{c^2} = \frac{1}{c^2}\left[\frac{GM}{R+h} - \frac{GM}{R}\right] \tag{3.84}$$

and if $R + h \simeq 4R$ this gives a gain in time of $\simeq 45$ µs/day, six times larger than the special relativistic effect. Summing up the two effects we find that the clock on the satellite runs faster $\simeq 38$ µs/day $\equiv 38 \times 10^3$ ns/day. We see that neglecting the relativistic effects, would imply errors three order of magnitude higher than the necessary accuracy of 20–30 ns.[26]

3.5.3 The Einstein Equation

Until now we have been discussing some consequences of the principle of equivalence in relation to the motion of a particle in a given gravitational field. We have seen that the motion is essentially a *free motion* in a curved space–time, the generalized gravitational potential being described by the metric $g_{\mu\nu}(x)$ which was supposed to be a known function of the space–time coordinates.

The knowledge of the metric field is, however, not known *a priori*, and the description of the gravitational field requires the knowledge of the equation of motion of the metric field. To arrive to a rigorous determination of this equation the principle of equivalence is no more sufficient and we must address the full geometric formalism of general relativity. Nevertheless, in this section, with no ambition of being rigorous or complete, we shall try to develop some heuristic considerations to justify the actual form of the gravitational equations.

We recall that in the Newtonian non-relativistic theory the gravitational potential is static, that is, non-propagating, and, given a distribution of mass in space, it can be determined through the Poisson equation:

$$\nabla^2\phi = -4\pi G\rho(\mathbf{x}), \tag{3.85}$$

where ρ is the density of matter and, as usual, $\phi(\mathbf{x})$ the gravitational potential. On the basis of the discussions given in the previous sections, it is clear that the relativistic extension we are looking for must be *covariant under general coordinate transformations*. Furthermore the ten components of the metric field $g_{\mu\nu}(x)$ must describe a *propagating* field generalizing the single static component of the Newtonian gravitational potential ϕ. Indeed, we know that already at the level of special relativity, dependence on the spatial coordinates implies dependence on the time.

It then follows that the source term ρ must also be generalized, in a covariant setting,[27] in terms of ten quantities depending on the four space–time coordinates. As we will show in Chaps. 5 and 8, such relativistic extension is given in terms of the so-called *energy momentum tensor* $T_{\mu\nu}$, symmetric in $\mu\nu$, which describes the density of matter four-momentum and of its current and can be shown to reduce, to lowest order in *v/c*, to the single non-vanishing component $T_{00} = \rho c = \epsilon/c$, ϵ being the energy density. On the other hand, on the left hand side, the Laplace operator in the classical Poisson equation must be replaced by an expression satisfying the following requirements:

1. It must have the same index structure as $T_{\mu\nu}$;
2. It must be a second order differential expression on the metric field $g_{\mu\nu}(x)$;

---

[26] We also note that the given error increases day by day, since it is a *cumulative* effect.

[27] Here covariant means with respect to general coordinate transformations.

3. It must be covariant under general coordinate transformations;
4. It must reduce to the left hand side of Poisson equation in the non-relativistic limit.

Let us denote such unknown expression by $G_{\mu\nu}$. Then the equation we are looking for should have the form:

$$G_{\mu\nu} = \alpha T_{\mu\nu}. \tag{3.86}$$

where α is a constant. On the other hand our previous discussion on the geometric properties of space–time in the presence of gravitation tells us that the Riemann tensor $R^{\mu}{}_{\nu\rho\sigma}$, the relativistic extension of the tidal forces, determines the geometric properties of space–time associated with the presence of gravitation. Thus we expect that $G_{\mu\nu}$ must be related to the Riemann tensor. Actually one can show that, in Riemannian geometry, all the requirements enumerated before are satisfied if we set:

$$G_{\mu\nu} = R^{\alpha}{}_{\mu\alpha\nu} - \frac{1}{2} g_{\mu\nu} R^{\tau}{}_{\rho\tau\sigma} g^{\rho\sigma}, \tag{3.87}$$

and set the unknown constant α of (3.86) $\alpha = -8\pi G$ in order to reproduce in the non relativistic static weak-field limit the Poisson (3.85). Thus we see that the equation for the metric field, also known as Einstein's equation, is a second order differential equation whose source is $T_{\mu\nu}$, which, as we shall see later on, describes the distribution of energy and momentum in space–time. If such distribution is known and the initial Cauchy data are given, we can determine the solution for the metric field $g_{\mu\nu}$. In other words: *The energy-momentum distribution, that is the content of matter-energy and of its current, determines the geometry of space–time.*

It follows that

$$z = x + iy = \rho(\cos\varphi + i\sin\varphi).$$

If now z_1 and z_2 are two complex numbers,

$$z_1 = \rho_1(\cos\varphi_1 + i\sin\varphi_1),$$
$$z_2 = \rho_2(\cos\varphi_2 + i\sin\varphi_2),$$

their product $z_1z_2 = \rho_1\rho_2(\cos(\varphi_1+\varphi_2) + i\sin(\varphi_1+\varphi_2))$, as is easily seen by direct multiplication. Hence, to multiply two complex numbers, you multiply their moduli and add their arguments.

For division, let $z = z_1/z_2$, ($z_2 \neq 0$), so that

$$z_1 = zz_2.$$

Using the first rule, it follows that the quotient of two complex numbers has, for modulus, the quotient of their moduli, and, for argument, the difference of their arguments.

4. Circles as level curves

Let a, b, z be any three complex numbers. We denote by (zab) the ratio

$$\frac{z-a}{z-b} = (zab).$$

The modulus of this complex number is the quotient of the moduli of $z - a$ and $z - b$. It is therefore the quotient

az[†]$/bz$.

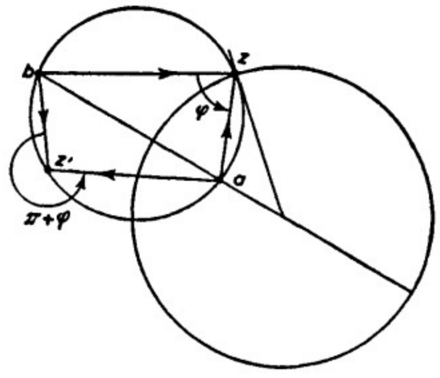

Fig. 49

[†] az denotes the distance between the points a and z in the Argand diagram.

As for its argument, by the above it is the angle through which the vector $z - b$ must be turned to give it the direction of the vector $z - a$. It is therefore the angle between the vectors $\overrightarrow{az}$ and $\overrightarrow{bz}$, oriented as in Fig. 49.

If we regard a and b as fixed, and z as variable, we may enquire into the nature of the curves along which mod (zab) and arg (zab) are respectively constant. These are the *level curves* of the respective functions. Both turn out to be circles.

If we have $az/bz =$ constant, the ratio of the powers of the point z with respect to the point circles a and b is constant. Therefore z moves on a circle of the coaxal system determined by the point circles a,b. This coaxal system has these point circles as limiting points.

If the angle between $\overrightarrow{az}$ and $\overrightarrow{bz}$ is constant, z moves on an arc of a certain circle passing through a and b. The other arc, the arc complementary to the first, corresponds to an argument $\varphi + \pi$. If φ takes all possible values, we obtain all circles of the coaxal system through a and b, including the radical axis ab, when $\varphi = \pi$ (this gives points between a and b) and when $\varphi = 0$ (this gives points outside ab).

For all values of the modulus and argument of (zab) we therefore obtain all circles of two conjugate coaxal systems as level curves.

5. The cross-ratio of four complex numbers

Let a, b, c, d be four complex numbers. By definition, the cross-ratio of the four numbers in the given order is the ratio $(acd)/(bcd)$. We write

$$\frac{(acd)}{(bcd)} = (ab,cd),$$

so that

$$(ab,cd) = \frac{(a-c)/(a-d)}{(b-c)/(b-d)}\,.$$

This is formally the same definition as that which occurs in projective geometry.

The *modulus* of the cross-ratio is equal to the quotient of the moduli of (acd) and (bcd). Hence, for this modulus to be equal to

1, it is necessary and sufficient for (acd) and (bcd) to have the same modulus. By what we have seen above, a and b must therefore lie on the same circle of the coaxal system which has c,d as limiting points.

The *argument* of the cross-ratio is equal to the difference of the arguments of (acd) and (bcd). The cross-ratio therefore has zero argument if (acd) and (bcd) have the same argument, which is the case if a and b are on the same arc of a circle bounded by c and d.

The argument of the cross-ratio is equal to π if the arguments of (acd) and (bcd) differ by π, which is the case if a and b are on complementary arcs of a circle through c and d.

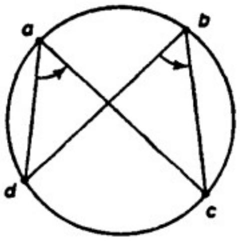

FIG. 50

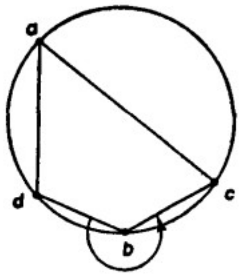

FIG. 51

Now, a number is real if its argument is 0 or π. Hence we have the theorem:

For the cross-ratio (ab,cd) *to be real, it is necessary and sufficient that the four points* a, b, c, d *should lie on a circle (or straight line).*

More generally, we find the locus of z such that the cross-ratio (za,bc) has (i) a constant modulus; and (ii) a constant argument.

Since $(za,bc) = (zbc)/(abc)$, the modulus and argument of (za,bc) will be constant if the respective modulus and argument of (zbc) are constant.

(i) The locus of points z such that mod (zbc) is constant is a circle of the coaxal system with limiting points b and c.

(ii) The locus of points z such that arg (zbc) is constant is an arc of a circle limited by b and c.

We deduce that if a, b, c are three distinct complex numbers, u any given complex number, then *there is a unique number* z *such that*

$$(za,bc) = u.$$

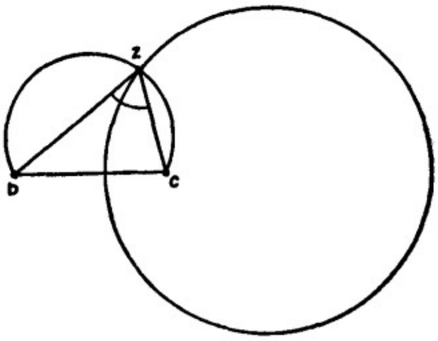

FIG. 52

For u has a definite modulus and argument, and z is given as the unique intersection of a circle and an arc of a circle, as shown in Fig. 52.

This important property is worth verifying algebraically. If $(za,bc) = u$, then we must have $(zbc) = (abc)u$. Write $(abc)u = k$. Then $(z - b)/(z - c) = k$, which gives

$$z = \frac{b - kc}{1 - k}.$$

We conclude this section by giving an interesting geometrical interpretation to the cross-ratio (ab,cd) of any four complex numbers. If ψ_1 is the argument of (acd), and ψ_2 that of (bcd), we know that the argument φ of (ab,cd) satisfies the equation

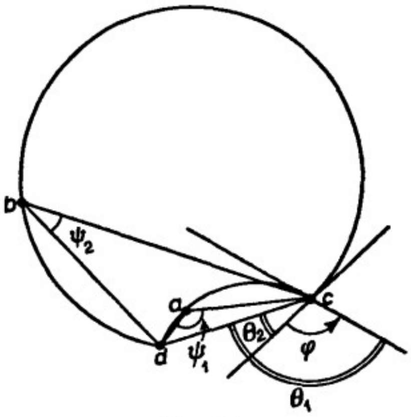

FIG. 53

$$\varphi = \psi_1 - \psi_2.$$

Draw the circles through a, c, d and b, c, d respectively, and let Θ_1, Θ_2 be the angles made by cd with the tangents at c to these circles. Then by the alternate segment theorem, $\psi_1 = \Theta_1$ and $\psi_2 = \Theta_2$, so that $\varphi = \Theta_1 - \Theta_2$. Hence φ is the angle between the two circles, and we have the theorem:

The argument of the cross-ratio (ab,cd) *is equal to the angle between the two circles passing through* a, c, d *and* b, c, d *respectively.*

6. Möbius transformations of the z-plane

These are transformations of the plane of the complex variable which map any point z on a point w according to the formula

$$w = \frac{Az + B}{Cz + D}, \tag{1}$$

where A, B, C, D are four complex constants, and $AD - BC \neq 0$.

We exclude the case $A/C = B/D$, because then $w = A/C$ for all values of z, and all points z transform into a single point w.

The reader is probably already familiar with transformations of type (1) in projective geometry, where they are called *bilinear* or *projective* transformations, and transform points of a line. The same algebra proves the theorem:

A Möbius transformation leaves cross-ratios invariant.

In other words, if a, b, c, d transform respectively into a', b', c', d', then $(ab,cd) = (a'b',c'd')$.

We make some important deductions from this theorem.

I. If $w = \dfrac{Az + B}{Cz + D}$, $(AD - BC \neq 0)$ is a Möbius transformation, and (a,a'), (b,b'), (c,c') are three pairs of corresponding points, then the equation of the transformation may be written in the form

$$(wa',b'c') = (za,bc). \tag{2}$$

This follows immediately from the theorem. If z is any point, and w the corresponding point under the Möbius transformation, then the pair (z,w) satisfy (2). On the other hand we know that, z having been given, there is a unique w which can make the cross-ratio $(wa',b'c') = (za,bc)$. Hence the equation (2) does, in fact, map z on the w given by the Möbius transformation.

II. Conversely, let a, b, c be three distinct complex numbers, and a', b', c' a second set of three distinct complex numbers. Then the equation

$$(wa',b'c') = (za,bc)$$

is the equation of a Möbius transformation which maps a on a', b on b' and c on c'.

This follows immediately by writing out both sides of the equation, and substituting $z = a, b, c$ in turn. We find that $w = a'$, b', c' in turn.

III. A Möbius transformation transforms circles into circles. (It is understood that straight lines come into the category of circles.)

We shall give two proofs of this important theorem.

In the first place let z be any point of the circle determined by the three points a, b, c. Then the cross-ratio

$$(za,bc) = \text{real number}.$$

Let z' be the transform of z. Then

$$(z'a',b'c') = (za,bc) = \text{real number},$$

and therefore z' lies on a circle through a', b', c'.

The second proof will be given in the next section. We conclude this section with:

IV. A Möbius *transformation* conserves the angle of intersection of two circles.

Let b and c be the points common to two circles $\mathscr{C}_1$ and $\mathscr{C}_2$, a_1 a third point on $\mathscr{C}_1$ and a_2 a third point on $\mathscr{C}_2$. We have seen (see page 50) that the angle between the two circles is given by the argument of the cross-ratio (a_1a_2,bc). But this argument is conserved, since the cross-ratio itself is conserved.

A second proof of this theorem will also be given later.

7. A Möbius transformation dissected

The reader may ask, at this stage, whether there is any connection between Möbius transformations and inversion. We show that there is.

We may write

$$w = \frac{Az + B}{Cz + D} = \frac{A}{C} + \frac{BC - AD}{C(Cz + D)},$$

by simple division, or

$$w = \frac{A}{C} + \frac{BC - AD}{C^2} \cdot \frac{1}{z + D/C}.$$

We now carry out the transformation on z in several stages:

(i) Let $$z_1 = z + \frac{D}{C};$$

(ii) Let $$z_2 = \frac{1}{z_1};$$

(iii) Let $$z_3 = \frac{BC - AD}{C^2} . z_2;$$

(iv) Then $$w = \frac{A}{C} + z_3.$$

Each stage can be interpreted geometrically, and this we proceed to do.

Stage (i) is equivalent to a *translation* of z in a definite direction and through a definite distance, given by the vector D/C.

Stage (ii) is equivalent to inversion in the unit circle, followed by reflection in the real axis. For with an obvious notation,

$$r_2(\cos \Theta_2 + i \sin \Theta_2) = \frac{1}{r_1(\cos \Theta_1 + i \sin \Theta_1)}$$
$$= \frac{1}{r_1} (\cos (-\Theta_1) + i \sin (-\Theta_1)),$$

and therefore $r_2 = 1/r_1$, so that $r_1 r_2 = 1$, and
$$\Theta_2 = -\Theta_1.$$

Stage (iii), *multiplication* by a fixed complex number is equivalent to a dilatation by a fixed amount from the origin, followed by a definite rotation about the origin. For if $(BC - AD)/C^2 = \rho(\cos \Theta + i \sin \Theta)$,

$$r_3 = \rho r_2,$$

and $$\Theta_3 = \Theta_2 + \Theta.$$

Stage (iv) is another translation.

We see that after each one of these sub-transformations circles are still circles (or straight lines), and that the angle of intersection of two circles is unchanged. Hence we have additional proofs of two of the theorems of the preceding section.

Another important deduction we can make from our dissection of a Möbius transformation is the following:

If a circle $\mathscr{C}$ is transformed into a circle $\mathscr{C}'$, the interior of $\mathscr{C}$ is mapped on the interior or the exterior of $\mathscr{C}'$.

We mean, of course, that every point inside $\mathscr{C}$ is mapped on points inside $\mathscr{C}'$, or every point inside $\mathscr{C}$ is mapped on points outside $\mathscr{C}'$.

The only transformation which can turn a circle inside-out is (ii), since this is an inversion followed by a reflection. The inverse of a circle with respect to a centre of inversion inside the circle turns the circle inside out. The other transformations which come into the dissection preserve insides and outsides.

If the circle $\mathscr{C}'$ is a straight line, the inside of $\mathscr{C}$ is mapped on one of the half-planes bounded by the line, the outside of $\mathscr{C}$ on the other.

8. The group property

The Möbius transformations of the z-plane form a group. Before we prove this, we give the definition of a *group of transformations*.

A set of transformations is said to form a group if it has the following properties:

(a) Every transformation T of the set possesses an inverse transformation which is also in the set. If this inverse transformation be denoted by T', the transformation effected by carrying out first T and then T' is the identical transformation, which leaves everything unchanged.

(b) If two transformations T_1, T_2 both belong to the set, the transformation obtained by carrying out first T_1 and then T_2 also belongs to the set.

That the Möbius transformations of the z plane form a group is a theorem easily proved by algebra. Alternatively we can proceed as follows:

The transformation inverse to

$$(za,bc) = (z'a',b'c'),$$

that is, the one which maps z' on z, is given by the equation

$$(z'a',b'c') = (za,bc).$$

Now let M_1 be a Möbius transformation which maps a on a', b on b', c on c'. It is determined by these three pairs of corresponding points. Let M_2 be a Möbius transformation which maps a' on a'', b' on b'' and c' on c''. It is also determined by these three pairs of corresponding points.

M_1 is given by the equation $(z'a',b'c') = (za,bc)$;

M_2 is given by the equation $(z''a'',b''c'') = (z'a',b'c')$.

The result of M_1 followed by M_2 is the transformation

$$(z''a'',b''c'') = (za,bc),$$

which is a Möbius transformation.

If a set of transformations, all of which belong to a group G of transformations, themselves form a group, we call this a *subgroup* of the group G. An important example of a group of transformations is afforded by the group of displacements in a Euclidean plane.

We imagine a fixed plane, and another like a large sheet of paper covering it. The paper is moved, with any possible figures on it, from one position over the plane to another. We consider only the initial and final positions of a motion or displacement. The path does not concern us. Suppose A, B, points of the plane in its first position, become A', B' in its final position. Join AA', BB', and let their perpendicular bisectors PX, PY meet in P. Evidently the triangles $PAB, PA'B'$ are congruent. Hence the displacement envisaged can be effected by a rotation round P.

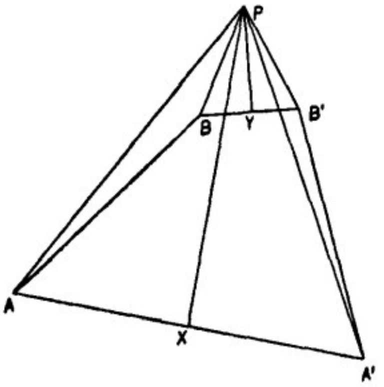

FIG. 54

If the right bisectors were parallel, then AA', BB' would be parallel, and the displacement would be a *translation*, every point of the plane moving through the same distance and in the same direction.

If we follow a given displacement by another, the result is a displacement, since only initial and final positions are considered. The inverse of a given displacement is merely that displacement which brings the moving plane back to its original position. Hence the displacements, or Euclidean motions of a plane, form a group.

The set of translations of the plane evidently form a subgroup of the group of displacements.

We may also regard the displacement of one plane over another as a *mapping* of the points of a Euclidean plane into itself which is one-to-one, transforms lines into lines, preserves angles, and also orientation. It is this notion which is the basis of *applicability* in Euclidean geometry. In the next section we investigate a group of transformations which, in our non-Euclidean geometry, corresponds to the group of Euclidean motions.

9. Special transformations

We are interested in a certain subgroup of the group of Möbius transformations, namely that subgroup which consists of all Möbius transformations which map the inside of a given circle on itself. Let us be more explicit.

We choose the circle with centre at the origin and radius $= 1$. We call the circumference ω, and the circular area bounded by ω we call Ω. The points of ω are not included in Ω.

There are Möbius transformations which transform Ω into itself. We shall call these M-transformations. For example:

the identical transformation $w = z$;
the transformation $w = (\cos\varphi + i\sin\varphi)z$;

this gives a rotation of the plane, through an angle φ, about the origin.

If an M-transformation maps Ω on itself, the dissection of §7 shows that the boundary ω is also mapped on itself. But the converse, as we know from the simple example $w = 1/z$, is not true.

It is easy to see that M-transformations form a group, which is a subgroup of the group of all Möbius transformations. For, if a transformation maps Ω on itself, this is also true for the inverse transformation; and if two transformations M_1, M_2 both map Ω on itself, this is also true for the transformation obtained by first carrying out M_1 and then M_2.

We shall now restrict ourselves to these M-transformations and to Ω, the interior of the unit circle, centre at the origin. We shall show that *Ω can be regarded as a non-Euclidean space, in which the M-transformations are the group of non-Euclidean motions.*

10. The fundamental theorem

We recall one of the characteristic properties of the group of displacements of a plane (over itself). Let A be any point in the plane, α a direction through it, X any other point in the plane and

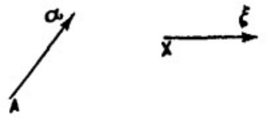

FIG. 55

ξ a direction through it. Then there is a unique displacement of the plane which maps A on X and α on ξ.

We show that the M-transformations have the same property in Ω. The theorem to be proved is:

Let X and A be any two points of Ω, *ξ and α directions through X and A respectively. Then there is a unique M-transformation which maps* (X,ξ) *on* (A,α).

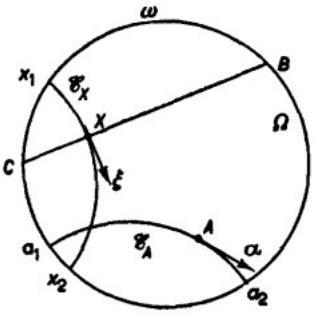

FIG. 56

We note in the first place that, through any point X, and touching any given line through the point, there passes exactly one circle orthogonal to ω. This is immediate by inversion, or may be proved as follows: draw the perpendicular at X to the given line, and let B, C be the points in which it cuts ω. Among the circles of the pencil through B and C, two are evidently orthogonal to the circle sought for: ω itself and the line BC. Hence the circle required is of the coaxal system conjugate to that defined by ω and the line BC. It therefore has B and C as limiting points, and is uniquely determined, since it passes through X.

If we care to regard it as an Apollonius circle, it is the locus of a point which moves so that the ratio of its distances from two fixed points B and C is always equal to XB/XC.

Call this circle $\mathscr{C}_X$, and let x_1 and x_2 be its intersections with ω. In the same way, there passes through A a unique circle $\mathscr{C}_A$ orthogonal to ω and tangent at A to the direction α. Let a_1, a_2 be its intersections with ω.

Now, since M-transformations map ω on itself, they necessarily map circles orthogonal to ω on to circles orthogonal to ω, being Möbius transformations.

Hence any M-transformation which maps (X,ξ) on (A,α) must necessarily map $\mathscr{C}_X$ on $\mathscr{C}_A$, since $\mathscr{C}_X$ will be mapped on a circle through A, with direction α, and orthogonal to ω, and there is only one such circle, namely $\mathscr{C}_A$.

Let us now suppose that the points of intersection of $\mathscr{C}_X$ and $\mathscr{C}_A$ with ω are so numbered that the direction ξ is that of x_1 towards x_2 in Ω, and the direction α is that of a_1 towards a_2 in Ω. The M-transformation we are looking for must map x_1 on a_1, x_2 on a_2 and X on A. These three pairs of corresponding points determine a unique Möbius transformation. Our proof will therefore be complete if we show it is an M-transformation, mapping Ω into itself. This is clear, since the unique Möbius transformation maps the circle through x_1 and x_2 orthogonal to $\mathscr{C}_X$, that is ω, on the circle through a_1 and a_2 orthogonal to $\mathscr{C}_A$, which is again ω. It therefore maps ω on ω. On the other hand it maps Ω on Ω, since it maps the interior point X of Ω on the point A of Ω. The unique Möbius transformation is therefore an M-transformation.

Corollary: Let a and b be two points of Ω, $\mathscr{C}_a$ a circle orthogonal to ω passing through a, $\mathscr{C}_b$ a circle orthogonal to ω passing through b. There exist precisely *two* M-transformations mapping a on b and $\mathscr{C}_a$ on $\mathscr{C}_b$. To a given orientation on $\mathscr{C}_a$ the one transformation maps one of the possible directions of motion on $\mathscr{C}_b$, and the second transformation maps the other.

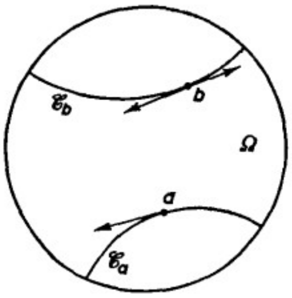

FIG. 57

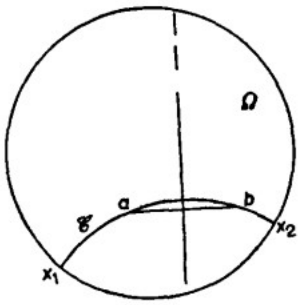

FIG. 58

In particular, let a, b be two points of Ω. There exists a unique M-transformation which permutes a and b (that is, which maps a on b and b on a).

To prove this, we note in the first instance that there exists a unique circle orthogonal to ω and passing through a and b. Call this circle $\mathscr{C}$. An M-transformation interchanging a and b must transform $\mathscr{C}$ into itself.

By the above, there are only two M-transformations which map a on b and $\mathscr{C}$ on itself. The one which conserves orientation on $\mathscr{C}$ cannot map b on a, since then the sense of a towards b in Ω would be transformed into the sense of b towards a in Ω.

Let M' therefore be the M-transformation which maps a on b and alters the orientation of $\mathscr{C}$. We show that M' maps b on a.

Let x_1 and x_2 be the intersections of $\mathscr{C}$ and ω, and a' the transform of b by M'. We want to prove that $a' = a$. Since M' changes the orientation of $\mathscr{C}$, x_1 is mapped on x_2, x_2 on x_1. Since a is also mapped on b, and b on a', the cross-ratio property gives

$$(x_1x_2,ab) = (x_2x_1,ba').$$

But, for any cross-ratio,

$$(x_1x_2,ab) = (x_2x_1,ba).$$

Hence

$$(x_2x_1,ba) = (x_2x_1,ba'),$$

and therefore

$$a' = a.$$

11. The Poincaré model

We can now discuss Poincaré's model of a hyperbolic non-Euclidean geometry. The term "non-Euclidean" refers to the fact that in this geometry Euclid's parallel axiom does not obtain.

Our space is *the interior Ω of the circle ω*. We shall call this the h-plane. A point of Ω is a point, or h-point, in our new geometry. But *our h-lines are the arcs of circles (or straight lines) inside Ω, limited by ω and orthogonal to ω*. These are the arcs considered in our previous theorems. If a point in Ω lies on one of these arcs, we shall say that the corresponding h-point lies on the corresponding h-line.

We see that the ordinary incidence theorems of Euclidean geometry hold in our h-geometry. Through two distinct points of Ω there passes a unique circle orthogonal to ω. Hence, *through two distinct h-points there passes a unique h-line.*

Two circles orthogonal to ω intersect in at most one point which is inside Ω. Hence, two h-lines intersect in at most one h-point. We shall consider the pairs of h-lines which do not intersect later.

Since arcs of circles inside Ω orthogonal to ω constantly recur, we call them ω-arcs.

The angle between two ω-arcs will be, by definition, the h-angle between the corresponding h-lines.

The relation of equality between the angles of ω-arcs will imply the relation of equality, or h-equality, between h-angles.

We now come to the more difficult notion of *h-equality* between h-segments. An *h-segment* is naturally the portion of an ω-arc bounded by two points of Ω.

In elementary geometry two segments are equal if one can be applied to the other. This involves a displacement, or motion, of the plane. Such a motion transforms lines into lines, and conserves angles. In our h-geometry the equivalent to this group of motions is the group of M-transformations, which transform h-lines into h-lines, and conserve angles. We therefore call an M-transformation of Ω *an h-displacement of the h-plane*, and say that two h-segments AB and CD are h-equal, written

$$AB \overset{h}{=} CD,$$

if there is an h-motion which transforms AB into CD. Since M-transformations form a group, the relation of h-equality satisfies the usual axioms of equivalence:

(i) $AB \overset{h}{=} AB$:

(ii) if $AB \overset{h}{=} CD$, then $CD \overset{h}{=} AB$:

(iii) if $AB \overset{h}{=} CD$, and $CD \overset{h}{=} EF$, then

$AB \overset{h}{=} EF$.

Again, since there is an M-transformation mapping the segment ab of an ω-arc on the segment ba, we also have

$$AB \overset{h}{=} BA.$$

The ordinary theorems on congruence in Euclidean geometry have an equivalent in our h-geometry. For example, let us prove the theorem:

In two h-triangles ABC and $A'B'C'$, the equalities $AB \overset{h}{=} A'B'$, $AC \overset{h}{=} A'C'$ and $\angle CAB \overset{h}{=} \angle C'A'B'$ imply the equality $\angle ABC \overset{h}{=} \angle A'B'C'$.

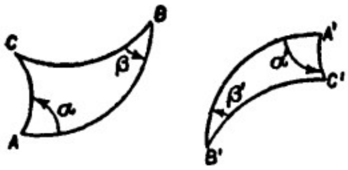

FIG. 59

To prove this we must show that if two triangles ABC, $A'B'C'$ (made up of ω-arcs) are such that $\alpha = \alpha'$ (Fig. 59), and there exists an M-transformation which maps AB on $A'B'$, and an M-transformation which maps AC on $A'C'$, then $\beta = \beta'$.

Suppose at first that the triangles ABC, $A'B'C'$ have the same orientation. The proof will consist in showing that there is an M-transformation which maps the ω-triangle ABC on the ω-triangle $A'B'C'$.

Since $AB \overset{h}{=} A'B'$, there exists a (unique) M-transformation which maps A on A' and B on B'. Since this transformation preserves angles in magnitude and orientation, it maps the ω-arc AC on the ω-arc $A'C'$ in the direction $A'C'$. This M-transformation is the only one which maps A on A' and the ω-arc AC in the direction AC on the ω-arc $A'C'$ in the direction $A'C'$. Hence, it is the one which maps A on A' and C on C', since we know such a transformation exists.

We have therefore found an M-transformation which maps the ω-triangle ABC on the ω-triangle $A'B'C'$. This transformation conserves angles, and therefore $\beta = \beta'$.

If the orientations of the ω-triangles ABC, $A'B'C'$ are different, we take *the geometrical image* of $A'B'C'$ in any diameter of Ω. Call the transformed triangle $A''B''C''$. Then the ω-triangles ABC, $A''B''C''$ have the same orientation, and the proof applies. Since the ω-triangle $A''B''C''$ arises from $A'B'C'$ by a reflection, the theorem follows.

12. The parallel axiom

So far we have shown that there is a complete equivalence between our h-geometry and that part of Euclidean geometry which is developed before the introduction of the parallel axiom. We now come to the parting of ways!

We could say that two ω-arcs which do not intersect shall be called *h-parallel h-lines*. Through a point A outside any ω-arc we can draw an infinity of ω-arcs which do not cut the given ω-arc. This would lead to there being an infinity of h-lines h-parallel to a given h-line through a given h-point outside the h-line.

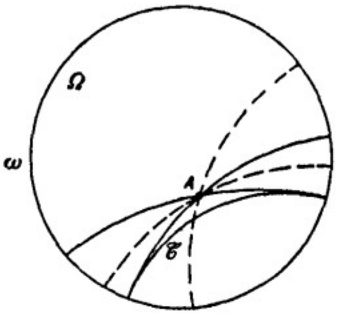

FIG. 60

We notice that there are two ω-arcs through A which *touch* the given ω-arc, the respective points of contact being on ω. These two ω-arcs separate the ω-arcs through A into two classes: those which cut the given ω-arc, and those which do not.

We prefer to reserve the term *h-parallel* for the two ω-arcs which touch the given ω-arc at a point of ω, and therefore now have, instead of Euclid's parallel axiom, the theorem:

Through any h-point A taken outside an h-line there pass precisely two h-parallels to the given h-line.

Hence, the term *non-Euclidean* geometry. The existence of a model for non-Euclidean geometry shows that the parallel axiom is *independent* of the other axioms, and *cannot be deduced from them.* Much fruitless effort has gone into attempts to *prove* the parallel axiom, and even today there exist organizations of people devoted to proving the axiom. Needless to say, these devotees are not shaken in their faith by mathematical arguments.

13. Non-Euclidean distance

We know how to compare two h-segments for equality. We now want to obtain a *distance-function* $D[ab]$ for any two h-points a, b which satisfies the conditions:

$$D[ba] = D[ab] \geqslant 0;$$
$$D[ab] = 0 \qquad \text{if and only if } b = a;$$
$$D[ab] + D[bc] \geqslant D[ac],$$

with equality if and only if b lies on the h-line ac between a and c.

We also want this distance function to be invariant under h-motions of the h-plane.

Let the h-line ab cut ω in the points α, β. Then

$$D[ab] = |\log(\alpha\beta, ab)|$$

is a suitable distance-function. It evidently satisfies the first two conditions, and also the condition that it be invariant under h-motions of the h-plane.

For $\quad D[ba] = |\log(\alpha\beta, ba)|$

$$= \left|\log\frac{1}{(\alpha\beta, ab)}\right| = |-\log(\alpha\beta, ab)|$$

$$= D[ab],$$

and, by definition, $D[ab] \geqslant 0$. It can only $= 0$ if $(\alpha\beta, ab) = 1$, when we must have $b = a$. Again, if any M-transformation of Ω maps the points α, β, a, b on α', β', a', b' respectively, we know that α', β' will be on ω, and that α', β', a', b' all lie on an h-line. Since also $(\alpha\beta, ab) = (\alpha'\beta', a'b')$,

$$D[ab] = D[a'b'].$$

If a, b, c are three points, in this order, on an h-line which cuts ω in α, β, we have, identically,

$$(\alpha\beta, ac) = (\alpha\beta, ab)\,.\,(\alpha\beta, bc).$$

As the points a, b, c are ordered as shown, the three logarithms $\log(\alpha\beta, ac)$, $\log(\alpha\beta, ab)$ and $\log(\alpha\beta, bc)$ all have the same sign. Therefore

$$D[ac] = D[ab] + D[bc].$$

To prove the full triangle inequality is more difficult, but we remark that since the parallel axiom is not used in Euclid's earlier theorems, we can apply the first twenty-eight propositions of Euclid's first book, without change, to our h-plane. We then obtain theorems concerning the congruence of triangles, as we have seen, the theorem that the greatest side of a triangle is opposite the greatest angle, and lastly, the triangle inequality:

$$D[ab] + D[bc] > D[ac],$$

if a, b, c are not, in this order, on an h-line.

It is possible to go much further into the study of non-Euclidean geometry, but we do not propose to do so in this book. The reader may find that his interest in the axioms of Euclidean geometry has been aroused, and he cannot do better than to study these afresh, and then see what are the essential differences between the non-Euclidean geometry we have been discussing and Euclidean geometry.

$a^2 + b^2 + c^2 = d^2$

2.1—The Pythagorean theorem is often pictured in two dimensions in terms of a right triangle with the sum of the lengths of the sides squared equaling the length of the hypotenuse squared: $a^2 + b^2 = c^2$. But, as shown here, the theorem also works in three dimensions $(a^2 + b^2 + c^2 = d^2)$ and higher.

3.7 Gaussian measures on Hilbert spaces and abstract Wiener spaces

Definition 3.11. A probability measure μ on $(\mathbb{R}, \mathcal{B}(\mathbb{R}))$ is said to be a *Gaussian measure* if its Fourier transform $\hat{\mu}$ has the following form

$$\hat{\mu}(x) = e^{imx} e^{-\frac{1}{2}\sigma^2 x^2} \qquad x \in \mathbb{R}\,, \tag{3.53}$$

for some constants $m, \sigma^2 \in \mathbb{R}$, $\sigma^2 \geq 0$. The constants m and σ^2 are called the *mean* and the *variance* of μ respectively.

In σ^2 is a strictly positive constant, then μ is absolutely continuous with respect to the Lebesgue measure on $(\mathbb{R}, \mathcal{B}(\mathbb{R}))$ with a Radon-Nicodym derivative $h : \mathbb{R} \to \mathbb{R}$ equal to

$$h(x) = \frac{e^{-\frac{1}{2\sigma^2}(x-m)^2}}{\sqrt{2\pi\sigma^2}} \qquad x \in \mathbb{R}\,,$$

while in the case $\sigma^2 = 0$, the measure μ is the δ_m point measure concentrated at $m \in \mathbb{R}$ (see Eq. (2.6)). In particular, the following identities hold

$$m = \int x \, d\mu(x) \qquad \sigma^2 = \int (x-m)^2 \, d\mu(x)\,. \tag{3.54}$$

Definition 3.12. A probability measure μ on the Borel σ-algebra of a real separable Banach space X is called *Gaussian measure* if for any $\theta \in X^*$ the image measure μ_θ of μ under the action of θ is a Gaussian measure on the real line.

By the change of variable formula (2.17), it turns out that the Fourier transform $\hat{\mu}$ of a Gaussian measure on X has the following form

$$\hat{\mu}(\theta) = e^{il(\theta)} e^{-\frac{1}{2}q(\theta)^2} \qquad \theta \in X^*\,, \tag{3.55}$$

where $l : X^* \to \mathbb{R}$ is the linear functional defined by

$$l(\theta) = \int_X \theta(x) \, d\mu(x)\,,$$

while $q : X^* \to \mathbb{R}$ is the quadratic form associated to the positive bilinear map $Q : X^* \times X^* \to \mathbb{R}$ defined as

$$Q(\theta, \eta) := \int_X (x - l(\theta))(x - l(\eta)) d\mu(x) \qquad \theta, \eta \in X^*\,.$$

Analogously to the finite-dimensional case, the bilinear map Q is called the *covariance* of the measure μ.

Conversely, if μ is a probability measure on $\mathcal{B}(X)$ such that its Fourier transform has the form (3.55) then μ is Gaussian since for any $\theta \in X^*$ the Fourier transform of the image measure μ_θ will have the form (3.53). It is important to point out that in an infinite dimensional setting not all positive bilinear map $Q : X^* \times X^* \to \mathbb{R}$ are the covariance of a Gaussian measure. In the particular case where X is a real separable Hilbert space $\mathcal{H}$, Theorem 3.12 allows to get a characterization of the bilinear maps $Q : X^* \times X^* \to \mathbb{R}$ which are the covariance of a Gaussian measure. In this setting it is convenient to exploit the natural isomorphism between $\mathcal{H}$ and $\mathcal{H}^*$ and identify them. In particular, by Riesz theorem it is possible to define a vector $m_\mu \in \mathcal{H}$ such that $l(x) = \langle m_\mu, x\rangle$, which is called the *mean vector* of the measure μ. Similarly we can uniquely associate to the positive bilinear map $Q : \mathcal{H} \times \mathcal{H} \to \mathbb{R}$ a bounded symmetric positive operator $S_\mu : \mathcal{H} \to \mathcal{H}$ such that

$$Q(x, y) = \langle x, S_\mu y\rangle \qquad x, y \in \mathcal{H}\,,$$

which is called the *covariance operator* of μ.

Theorem 3.13 (Prokhorov). *Let $\mathcal{H}$ be a real separable Hilbert space. A bounded symmetric positive operator $S : \mathcal{H} \to \mathcal{H}$ is the covariance operator of a Gaussian measure μ on $\mathcal{B}(\mathcal{H})$ if and only if S is nuclear.*

For additional details we refer to [69, 70, 38].

In particular, Prokhorov theorem shows that on an infinite dimensional Hilbert space the standard Gaussian measure (with mean $m = 0$ and covariance operator S equal to the identity $I : \mathcal{H} \to \mathcal{H}$) cannot exists since the identity I is not trace-class. This result can be also obtained as a consequence of Theorem 3.2. Indeed, if a Gaussian measure on $\mathcal{B}(\mathcal{H})$ with $m = 0$ and $S = I$ existed, then it would be invariant under isometries.

It turns out that a useful substitute for the standard Gaussian measure on $\mathcal{H}$ is a cylinder measure. By definition a *cylinder measure* on $\mathcal{H}$ is a positive and finitely-additive set function ν defined on the algebra $\mathcal{A}_\mathcal{H}$ of cylinder sets in $\mathcal{H}$. As remarked above, in a Hilbert space every cylinder set can be represented in the form

$$P^{-1}(C) = \{x \in \mathcal{H} \colon Px \in C\}\,,$$

where $P : \mathcal{H} \to \mathcal{H}$ is an orthogonal projection operator onto a finite dimensional subspace $P\mathcal{H} \subset \mathcal{H}$ and $C \subset P\mathcal{H}$ is a Borel set in $P\mathcal{H}$.

Let us consider the cylinder measure $\nu : \mathcal{A}_\mathcal{H} \to \mathbb{R}$ defined on a general cylinder set $P^{-1}(C)$ as

$$\nu\left(P^{-1}(C)\right) = (2\pi)^{-n/2} \int_C e^{-\frac{1}{2}\|Px\|^2}\, dx,$$

where n is the dimension of $P\mathcal{H}$ and dx denotes the Lebesgue measure on $P\mathcal{H}$. ν is called *standard Gaussian measure associated with* $\mathcal{H}$.

If $\mathcal{H}$ is infinite dimensional, by Prokhorov's theorem the standard Gaussian measure associated with $\mathcal{H}$ cannot be σ-additive on $\mathcal{A}_{\mathcal{H}}$, since in this case it could be extended to a σ-additive probability measure μ on $\mathcal{B}(\mathcal{H})$ invariant under isometries. Indeed, if such a μ existed, its Fourier transform would be given by

$$\hat{\mu}(x) = e^{-\frac{1}{2}\|x\|^2} \qquad x \in \mathcal{H}\,.$$

as it is easy to check since $\hat{\mu}$ is uniquely determined by the value of μ on the cylinder sets.

However, if $\mathcal{H}$ is embedded in a suitable Banach space $(X, |\ |)$, then ν can determine a unique Gaussian measure on $\mathcal{B}(X)$ [237, 169, 168] according to the procedure described below.

Definition 3.13. A norm $|\ |$ (or a semi-norm) on $\mathcal{H}$ is called *measurable* if for every $\epsilon > 0$ there exist a finite-dimensional projection $P_\epsilon : \mathcal{H} \to \mathcal{H}$, such that for all $P \perp P_\epsilon$ one has:

$$\nu(\{x \in \mathcal{H} |\ |P(x)| > \epsilon\}) < \epsilon,$$

where P and P_ϵ are called orthogonal ($P \perp P_\epsilon$) if their ranges are orthogonal in $(\mathcal{H}, \langle\ ,\ \rangle)$.

It turns out that $|\ |$ is weaker than $\|\ \|$. Indeed there exists a $c \in \mathbb{R}^+$ such that [237]

$$|x| \leq c\|x\|, \qquad \forall x \in \mathcal{H}. \tag{3.56}$$

In the following we shall denote X the Banach space constructed as the completion of $\mathcal{H}$ in the $|\ |$-norm and i the inclusion of $\mathcal{H}$ in X, which is continuous by (3.56). Analogously, the dual map $i^* : X^* \to \mathcal{H}^*$, which is given by restriction, i.e. $i^*(x) = x_{|\mathcal{H}}$, is continuous. Identifying $\mathcal{H} \equiv \mathcal{H}^*$ we have the following chain of densely embedded subspaces

$$X^* \subset \mathcal{H} \subset X.$$

The triple $(i, \mathcal{H}, X)$ is called an *abstract Wiener space.*

Given a cylinder set $C_{\theta_1,\ldots,\theta_n;H}$ in X, (with $\theta_1, \ldots, \theta_n \in X^*$ and $H \in \mathcal{B}(\mathbb{R}^n)$ (see Eq. (3.47)), the intersection $C_{\theta_1,\ldots,\theta_n;H} \cap \mathcal{H}$ is a cylinder set in $\mathcal{H}$. We can define the cylinder set measure μ_0 on the algebra $\mathcal{A}_X$ of cylinder sets in X as:

$$\mu_0\,(C_{\theta_1,\ldots,\theta_n;H}) := \nu\,(C_{\theta_1,\ldots,\theta_n;H} \cap \mathcal{H}),$$

A fundamental result of L. Gross is the following statement, which is actually a consequence of the Definition 3.13 of measurable norm [169].

Theorem 3.14. *μ_0 is σ-additive on $\mathcal{A}_X$. Hence it defines a unique probability measure μ on the Borel σ-algebra of X, in such a way that for any $\theta \in X^* \subset \mathcal{H}$:*

$$\int_X e^{i\theta(x)}\, d\mu(x) = e^{-\frac{1}{2}\|\theta\|^2}. \tag{3.57}$$

Example 3.5 (The classical Wiener space). *Let us consider the Sobolev space $\mathcal{H}^{1,2}([0,t],\mathbb{R}^d)$, i.e. the space of absolutely continuous functions $\gamma : [0,t] \to \mathbb{R}^d$ such that $\gamma(0) = 0$ and $\dot\gamma \in L^2([0,t])$, where $\dot\gamma$ denotes the distributional derivative of the function γ, endowed with the inner product*

$$\langle \gamma_1, \gamma_2 \rangle = \int_0^t \dot\gamma_1(s)\dot\gamma_2(s)ds.$$

Let $(C_0([0,t],\mathbb{R}^d), |\cdot|)$ be the Banach space of continuous functions $\omega : [0,t] \to \mathbb{R}^d$ such that $\omega(0) = 0$, endowed with the supremum norm:

$$|\omega| := \sup_{s\in[0,t]} |\omega(s)|.$$

It is possible to prove (see [237] for a additional details) that $\mathcal{H}^{1,2}([0,t],\mathbb{R}^d)$ is dense in $C_0([0,t],\mathbb{R}^d)$ with respect to the supremum norm $|\cdot|$.

Moreover, considered the standard Gaussian measure ν associated with $\mathcal{H}^{1,2}([0,t],\mathbb{R}^d)$, it is possible to prove that the supremum norm $|\cdot|$ is a ν-measurable norm on $\mathcal{H}^{1,2}([0,t],\mathbb{R}^d)$. This makes $(i, \mathcal{H}^{1,2}([0,t],\mathbb{R}^d), C_0([0,t],\mathbb{R}^d))$ an abstract Wiener space, which is called classical Wiener space *while μ is the* Wiener measure

In particular, it is possible to prove that the norm $\|i\|$ of the continuous embedding

$$i : \mathcal{H}^{1,2}([0,t],\mathbb{R}^d) \to C_0([0,t],\mathbb{R}^d)$$

is equal to $\|i\| = \sqrt{t}$.

By Theorem 3.14, each element $\theta \in \mathcal{B}^*$ can be regarded as a measurable function $n(\theta)$ on $(X, \mathcal{B}(X), \mu)$. By adopting the standard terminology of probability theory, $n(\theta)$ is a random variable on the probability space $(X, \mathcal{B}(X), \mu)$. Its distribution, i.e. the probability measure on $(\mathbb{R}, \mathcal{B}(\mathbb{R}))$ obtained as the image measure of μ under the action of $n(\theta)$, is a centered

Gaussian measure with covariance $\|\theta\|^2$. More generally, given $\theta_1, \theta_2 \in X^*$, one has

$$\int_X n(\theta_1)(x) n(\theta_2)(x)\, d\mu(x) = \langle \theta_1, \theta_2 \rangle. \tag{3.58}$$

Equation (3.58) and the density of X^* in $\mathcal{H}$ allow the extension of the map $n : X^* \to L^2(X, \mu)$ to a map $n : \mathcal{H} \to L^2(X, \mu)$ (with an abuse of notation we denote the map n on X^* and its extension to $\mathcal{H}$ with the same symbol)[169]. Moreover, given a complete orthonormal system $\{e_i\}$ in $\mathcal{H}$, for any $h \in \mathcal{H}$ the sequence of random variables

$$\sum_{i=1}^{n} h_i n(e_i), \qquad h_i = \langle e_i, h \rangle,$$

converges in $L^2(X, \mu)$ and by subsequences μ-almost everywhere to the random variable $n(h)$.

The family of measurable mappings $\{n(h)\}_{h \in \mathcal{H}}$ plays an important role in the study of transformation properties of the measure μ under translation. In particular, the following result shows that μ is quasi invariant under translations in the direction of vectors $h \in \mathcal{H}$.

Theorem 3.15. [169, 237] *Let $(i, \mathcal{H}, \mathcal{B})$ be an abstract Wiener space. For every vector $y \in \mathcal{H}$ and every function $f \in L^1(\mathcal{B}, \mu)$, the following holds*

$$\int_{\mathcal{B}} f(x) d\mu(x) = \int_{\mathcal{B}} f(x+y) \rho(y, x) d\mu(x),$$

where ρ is given by

$$\rho(y, x) = e^{-\frac{1}{2}\|y\|^2 - n(y)(x)}.$$

Given an orthogonal projection operator $P : \mathcal{H} \to \mathcal{H}$ with

$$P(h) = \sum_{i=1}^{n} \langle e_i, h \rangle e_i \qquad h \in \mathcal{H},$$

for some orthonormal $e_1, \ldots, e_n \in \mathcal{H}$, let us define the *stochastic extension* $\tilde{P} : X \to \mathcal{H}$ of P as the random variable

$$\tilde{P}(x) = \sum_{i=1}^{n} n(e_i)(x) e_i \qquad x \in X.$$

More generally, this procedure allows the extension of a larger class of mappings f from $\mathcal{H}$ to X. We present here the approach proposed in [278]. In the following $f : \mathcal{H} \to X_1$ will be a function with values in a real separable Banach space $(X_1, \| \, \|_{X_1})$.

Definition 3.14. A function $f : \mathcal{H} \to X_1$ is said to determine a random variable $\tilde{f} : X \to X_1$ if for any sequence $\{P_n\}$ of finite dimensional projection operators converging strongly to the identity on $\mathcal{H}$ the sequence of random variables $\{f \circ \tilde{P}_n\}$ converges in probability[6] on X. In this case the random variable $\tilde{f}$ will be called the *stochastic extension* of f.

The following important result holds [169]:

Theorem 3.16. *If $g : X \to X_1$ is continuous and $f := g|_{\mathcal{H}}$, then the stochastic extension of f is well defined and it is equal to g μ-almost everywhere.*

Other interesting classes of functions on $\mathcal{H}$ which admit a stochastic extension have been studied. For the application to the mathematical theory of Feynman path integrals a relevant role is played by the functions $f \in \mathcal{F}(\mathcal{H})$, i.e. by the mappings $f : \mathcal{H} \to \mathbb{C}$ of the form

$$f(h) = \int_{\mathcal{H}} e^{i\langle h,h'\rangle} d\mu(h') \qquad h \in \mathcal{H}\,, \tag{3.59}$$

for some complex Borel measure μ on $\mathcal{H}$. The following result shows that every function $f \in \mathcal{F}(\mathcal{H})$ admits a stochastic extension. We refer to [215] for the proof.

Theorem 3.17. *Let $f : \mathcal{H} \to \mathbb{C}$ be a function of the form (3.59). Then f admits a stochastic extensions $\tilde{f} : X \to \mathbb{C}$ equal to*

$$\tilde{f}(x) = \int_{\mathcal{H}} e^{in(h')(x)} d\mu(h') \qquad x \in X,.$$

Moreover $\tilde{f} \in L^1(X, \mu)$.

A similar result can be proved if we consider a quadratic form $q : \mathcal{H} \to \mathbb{R}$ on $\mathcal{H}$ associated to an Hilbert-Schmidt operator $K : \mathcal{H} \to \mathcal{H}$

$$q(h) := \langle h, Kh\rangle \qquad h \in \mathcal{H}\,. \tag{3.60}$$

Actually the mapping q can be extended to a random variable $\tilde{q}$ on X provided that suitable normalization counterterms are introduced.

---

[6] We recall that a sequence of random variables $\{g_n\}$ on a probability space $(\Omega, \mathcal{F}, \mu)$ is said to converge in probability to a random variable g on $(\Omega, \mathcal{F}, \mu)$ if the following holds

$$\forall \epsilon > 0 \quad \lim_{n\to\infty} \mu\left(\{\omega \in \Omega \colon |g_n(\omega) - g(\omega)| > \epsilon\}\right) = 0$$

Theorem 3.18. *Let $K : \mathcal{H} \to \mathcal{H}$ be an Hilbert Schmidt operator, $\{e_n\}$ an orthonormal basis in $\mathcal{H}$ and let $\{f_n\}$ be the sequence of random variables on X defined by*

$$f_n(x) := \sum_{j=1}^{n} \left(\widetilde{(e_i K)}(x) n(e_i)(x) - \langle e_j, Ke_j \rangle \right)$$

Then the sequence $\{f_n\}$ converges in $L^2(X, \mu)$ to a random variable $\tilde{f}$ which is independent of the choice of the basis $\{e_n\}_n$.

For the proof we refer to the original paper [278]. The random variable $\tilde{f}$ whose existence is given by Theorem 3.18 is denoted with the symbol $\tilde{f} = \langle x, Kx \rangle - \mathrm{Tr}K$. Clearly, if the operator K is not trace class, the sequence $\mathrm{Tr}P_n K = \sum_{j=1}^{n} \langle e_j, Ke_j \rangle$ doesn't converge.

In the case the operator $K : \mathcal{H} \to \mathcal{H}$ is trace class and self-adjoint, then it is possible to construct a stochastic extension $\tilde{q}$ of the quadratic form (3.60). Indeed, if $\{\lambda_j\}_j$ are the eigenvalues and $\{e_j\}_j$ the corresponding eigenvectors of K, then the mapping $\tilde{q} : X \to \mathbb{R}$ can be obtained as:

$$\tilde{q}(x) := \begin{cases} \lim_{n\to\infty} \sum_{j=1}^{n} \lambda_j \left(n(e_j)(x) \right)^2 & \text{if the limit exists} \\ 0 & \text{otherwise} \end{cases}$$

the mapping $\tilde{q}$ is also denoted with an abuse of notation in the following way

$$\tilde{q}(x) = \langle x, Kx \rangle \qquad x \in X \,.$$

Moreover the following holds:

Theorem 3.19. *Let $K : \mathcal{H} \to \mathcal{H}$ be a self-adjoint trace class operator and $\mu \in \mathcal{M}(\mathcal{H})$ a complex Borel measure on $\mathcal{H}$. The function $f : \mathcal{H} \to \mathbb{C}$*

$$f(h) = e^{\frac{i}{2} \langle h, Kh \rangle} \int_{\mathcal{H}} e^{i \langle h, h' \rangle} \, d\mu(h')$$

admits a stochastic extension $\tilde{f} : X \to \mathbb{C}$ equal to

$$\tilde{f}(x) = e^{\frac{i}{2} \langle x, Kx \rangle} \int_{\mathcal{H}} e^{i n(h')(x)} \, d\mu(h')$$

We end this section with a useful integrability result.

Theorem 3.20. *Let $K : \mathcal{H} \to \mathcal{H}$ be a self-adjoint trace class operator such that $(I - B)$ is strictly positive and let $y \in \mathcal{H}$. Then the random variable on $(\mathcal{B}, \mu)$ defined by*

$$g(x) = e^{n(y)(x)} e^{\frac{1}{2} \langle x, Kx \rangle}$$

is μ-summable and

$$\int_{\mathcal{B}} g \, d\mu = (\det(I-K))^{-1/2} e^{\frac{1}{2}\langle y,(I-B)^{-1}y\rangle},$$

where $\det(I-K)$ *denotes the Fredholm determinant of the operator* $I-K$.

For a proof of these results we refer to [237, 215].

Chapter 4

Projective systems of functionals and the Fourier transform approach

As explained in Section 3.5 it is impossible to construct a reasonable Feynman measure. In particular, the integrals appearing in the piecewise linear approximations of Feynman formula

$$\int_{\mathbb{R}^{dn}} \frac{e^{\frac{i}{\hbar}\sum_{j=1}^{n}\left(\frac{(x_j-x_{j-1})^2}{2(t/n)^2}-V(x_j)\right)\frac{t}{n}}}{(2\pi i\hbar t/n)^{nd/2}}\psi_0(x_0)dx_0\dots dx_{n-1}$$

cannot be interpreted as integrals of a cylinder function with respect to a complex measure μ_F on the space of paths $\Omega : \{\gamma : [0,+\infty) \to \mathbb{R}\}$ whose values on cylinder set is given by

$$\begin{aligned}&\mu_F\left(\{\gamma\in\Omega\colon \gamma(t_1)\in I_1,\dots,\gamma(t_n)\in I_n\}\right)\\&\quad=\int_{I_1\times\cdots\times I_n}\frac{e^{\frac{i}{2\hbar}\sum_{i=1}^{n}\frac{(x_i-x_{i-1})^2}{t_i-t_{i-1}}}}{(2\pi i\hbar)^{n/2}\sqrt{t_1(t_2-t_1)\cdots(t_n-t_{n-1})}}dx_1\dots dx_n \qquad (4.1)\end{aligned}$$

(where $n\in\mathbb{N}$, $0<t_1<\cdots<t_n<+\infty$ and $I_1,\dots,I_n\in\mathcal{B}(\mathbb{R})$).

At this point it is clear that the construction of Feynman integration theory requires to change point of view.

Let us recall that by Riesz-Markov Theorem 2.20, on locally compact Hausdorff topological spaces X there is a one-to-one correspondence between complex regular Borel measures μ and linear continuous functionals $L_\mu : C_0(X)\to\mathbb{C}$, given by the identity

$$L_\mu(f)=\int_X f(x)\,d\mu(x) \qquad f\in C_0(X)\,. \qquad (4.2)$$

On the other hand this result relies on the assumption of local compactness of the space X which is actually a rather strong condition which cannot be easily fulfilled in the case of infinite dimensional topological vector spaces. It cannot hold, for instance, in the case of Hilbert and Banach spaces.

In fact, in general the concept of linear functional on a suitable domain is wider than the concept of Lebesgue integral and can be used to give a mathematical meaning to Feynman formulas, in the spirit of Daniell's approach to integration (see [274]). This chapter presents a systematic implementation of infinite dimensional integration theory based on the concept of *projective system of functionals* instead of projective systems of measures [39]. Similarly to the construction proposed in Kolmogorov Theorem 3.7, the functional will be constructed out of its finite dimensional approximations. This point of view allows to provide a unified view of infinite dimensional integration which covers both the case of probabilistic and oscillatory integration. In particular, according to this approach the Feynman path integral will be constructed as a linear functional $L_F : D(L_F) \to \mathbb{C}$ defined on a suitable domain of "integrable functions" $f : \Gamma \to \mathbb{C}$ defined over a space of paths Γ. The property characterizing the functional as "Feynman integral" will be the following action over the cylinder functions $f \in D(L_F)$

$$L_F(f) = \int_{\mathbb{R}^n} \frac{g(x_1,\dots,x_n)e^{\frac{i}{2\hbar}\sum_{i=1}^{n}\frac{(x_i-x_{i-1})^2}{t_i-t_{i-1}}}}{(2\pi i\hbar)^{n/2}\sqrt{t_1(t_2-t_1)\cdots(t_n-t_{n-1})}}dx_1\dots dx_n$$

with $f(\gamma) = g(\gamma(t_1),\dots,\gamma(t_n))$, for some $n \geq 1$, $0 < t_1 < \cdots < t_n < +\infty$ and $g : \mathbb{R}^n \to \mathbb{C}$.

Sections 4.1 and 4.2 present the general theory of projective systems of functionals, while Section 4.3 focuses on those associated to projective systems of complex measures that do not admit a projective limit because of Theorem 3.8, also proposing some examples. Section 4.4 describes a particular construction of a functional associated to a projective systems of complex measures based on a Fourier transform approach. These results are the basis for the definition of *infinite dimensional Fresnel integrals*, which will be extensively described along with their applications to Feynman path integrals in Section 4.5. Eventually, Section 4.6 presents a generalization of infinite dimensional Fresnel integrals which allows to construct a class of Feynman-Kac type formulae for the representation of the solution of high-order heat-type equations.

4.1 Projective systems of functionals

Let $(\mathcal{I}, \leq)$ be a directed set and $\{S_J, \pi_J^K\}_{J,K\in\mathcal{I}}$ a projective family of sets. In the following we shall assume that $\{S_J, \pi_J^K\}_{J,K\in\mathcal{I}}$ is a perfect inverse system (in the sense of Definition 3.8). Let us denote with the symbol $\hat{S}_J$ the set of complex-valued functions $f_J : S_J \to \mathbb{C}$. For any pair $J, K \in \mathcal{I}$ such that $J \leq K$ let $\mathcal{E}_J^K : \hat{S}_J \to \hat{S}_K$ be the function which maps any element $f_J \in \hat{S}_J$ to its extension $\mathcal{E}_J^K(f_J)$ to $\hat{S}_K$, defined as

$$\mathcal{E}_J^K(f_J)(\omega_K) := f_J\big(\pi_J^K(\omega_K)\big), \qquad \omega_K \in S_K\,. \tag{4.3}$$

In particular, if $\{S_J, \pi_J^K\}_{J,K\in A}$ is a topological projective family and $f_J \in \hat{E}_J$ is a continuous function, then for any $K \in \mathcal{I}$ such that $J \leq K$, the extension $\mathcal{E}_J^K(f_J)$ is a continuous function on S_K.

We shall denote with the symbol $Map(\hat{S}_J)$ the family of linear maps $L_J : \hat{S}_J^0 \to \mathbb{C}$ from subspaces $\hat{S}_J^0 \subseteq \hat{S}_J$ to $\mathbb{C}$, called *functionals*. The set $\hat{S}_J^0$ is called the *domain of* L_J and it is required to be a linear space.

For $J, K \in \mathcal{I}$, such that $J \leq K$, let us define the map $\hat{\pi}_J^K : Map(\hat{S}_K) \to Map(\hat{S}_J)$ as the transport of functionals $L_K \in Map(\hat{S}_K)$ induced by the map $\mathcal{E}_J^K$ from $\hat{S}_J$ to $\hat{S}_K$, which is actually given by:

$$\hat{\pi}_J^K(L_K)(f_J) := L_K(\mathcal{E}_J^K(f_J)), \qquad L_K \in Map(\hat{S}_K), \tag{4.4}$$

where the domain of $\hat{\pi}_J^K(L_K)$ is given by

$$Dom(\hat{\pi}_J^K(L_K)) = \{f_J \in \hat{E}_J,\, |\mathcal{E}_J^K(f_J) \in \hat{S}_K^0\}.$$

Definition 4.1. A family of functionals $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$ labelled by the elements of the directed set $\mathcal{I}$ is called a *projective system of functionals* if for all $J, K \in \mathcal{I}$ with $J \leq K$ the projective (or coherence or compatibility) conditions hold

$$\mathcal{E}_J^K(f_J) \in \hat{S}_K^0, \qquad \forall f_J \in \hat{S}_J^0,$$
$$\hat{\pi}_J^K(L_K)(f_J) = L_J(f_J), \qquad \forall f_J \in \hat{S}_J^0. \tag{4.5}$$

Let $S_{\mathcal{I}} := \varprojlim S_J$ be the projective limit of the projective family of sets $\{S_J, \pi_J^K\}_{J,K\in\mathcal{I}}$ and let $\hat{S}_{\mathcal{I}}$ denote the set of complex-valued functions on $S_{\mathcal{I}}$. A function $f_J \in \hat{S}_J$, $J \in \mathcal{I}$, can be extended to a function $\mathcal{E}_J^{\mathcal{I}} f_J \in \hat{S}_{\mathcal{I}}$ defined by

$$\mathcal{E}_J^{\mathcal{I}} f_J(\omega) := f_J(\pi_J\omega), \qquad \omega \in S_{\mathcal{I}}\,.$$

By Eq. (3.40), the extension maps $\mathcal{E}_J^{\mathcal{I}} : \hat{S}_J \to \hat{S}_{\mathcal{I}}$ satisfy the following condition for any $J, K \in \mathcal{I}$, with $J \leq K$:

$$\mathcal{E}_J^{\mathcal{I}} = \mathcal{E}_K^{\mathcal{I}} \circ \mathcal{E}_J^K\,. \tag{4.6}$$

In particular, if $(S_J, \pi_J^K)_{J,K\in\mathcal{I}}$ is a topological projective family, then all the extensions $\mathcal{E}_J^K : \hat{S}^J \to \hat{S}_{\mathcal{I}}$ and $\mathcal{E}_J^{\mathcal{I}} : \hat{S}^J \to \hat{S}_{\mathcal{I}}$ map continuous functions into continuous functions.

In this context we shall call *cylindrical (or cylinder) functions* the mappings $f : S_{\mathcal{I}} \to \mathbb{C}$ of the form $\mathcal{E}_J^{\mathcal{I}} f_J$ for some $J \in \mathcal{I}$ and some $f_J \in \hat{S}_J$. The family of cylinder functions will be denoted with the symbol $\mathcal{C} = \cup_{J\in\mathcal{I}} \mathcal{E}_J^{\mathcal{I}}(\hat{S}_J)$.

Remark 4.1. If $\{S_J, \pi_J^K\}_{J,K\in A}$ is a perfect inverse system, then it is simple to prove the injectivity of the extension map $\mathcal{E}_J^{\mathcal{I}} : \hat{S}_J \to \hat{S}_{\mathcal{I}}$. Indeed for any $J \in \mathcal{I}$, $f, g \in \hat{S}_J$:

$$f = g \quad \Leftrightarrow \quad \mathcal{E}_J^{\mathcal{I}} f = \mathcal{E}_J^{\mathcal{I}} g.$$

Given a projective system of functionals $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$, we shall denote by $\mathcal{C}_0 \subset \mathcal{C}$ the set of those cylindrical functions obtained as extensions to $S_{\mathcal{I}}$ of functions belonging to the domain of L_J for some $J \in \mathcal{I}$, i.e.:

$$\mathcal{C}_0 := \cup_{J\in\mathcal{I}} \mathcal{E}_J^{\mathcal{I}}(\hat{S}_J^0) = \{f \in \mathcal{C} :\ f = \mathcal{E}_J^{\mathcal{I}} f_J, \text{ for some } J \in \mathcal{I}, f_J \in \hat{S}_J^0\}. \quad (4.7)$$

Definition 4.2. A *projective extension* $(L, D(L))$ of a projective system of functionals $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$ is a functional $L : D(L) \to \mathbb{C}$, with $D(L) \subset \hat{E}_{\mathcal{I}}$ such that

- $\mathcal{C}_0 \subseteq D(L)$,
- $L(\mathcal{E}_J^{\mathcal{I}} f_J) = L_J(f_J)$, for all $f_J \in \hat{S}_J^0$.

Theorem 4.1. *Let $\{S_J, \pi_J^K\}_{J,K\in\mathcal{I}}$ be a perfect inverse system and let $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$ be a projective system of functionals. Then the functional $(L, D(L))$ defined by:*

$$D(L) := \mathcal{C}_0 \quad (4.8)$$
$$L(f) := L_J(f_J), \qquad f = \mathcal{E}_J^{\mathcal{I}} f_J,\ f_J \in \hat{E}_J^0. \quad (4.9)$$

is a projective extension of $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$.

Proof. The functional L is unambiguously defined. Indeed let us consider function $f \in \mathcal{C}_0$ that can be obtained both as the extension of $f_J \in \hat{S}_J^0$ and of $f_K \in \hat{S}_K^0$, i.e., $f = \mathcal{E}_J^{\mathcal{I}} f_J = \mathcal{E}_K^{\mathcal{I}} f_K$, $J, K \in \mathcal{I}$. By the very definition of directed set, there exists an $H \in \mathcal{I}$ such that $J \leq H$ and $K \leq H$. If we define the two functions $f_H := \mathcal{E}_J^H f_J$ and $g_H := \mathcal{E}_K^H f_K$, it is easy to see that $\mathcal{E}_H^{\mathcal{I}} f_R = \mathcal{E}_H^{\mathcal{I}} g_R = f$. Thus, by Remark 4.1, $f_R = g_R$ and $L_R(f_R) = L_R(g_R)$. On the other hand, by the projectivity condition (4.5) it follows that:

$$L_J(f_J) = L_H(\mathcal{E}_J^H f_J) = L_H(f_H) = L_H(g_H) = L_H(\mathcal{E}_K^H f_K) = L_K(f_K).$$

Thus L is unambiguously defined by $L(f) = L_J(f_J) = L_k(f_K)$. $\square$

The functional $(L, D(L))$ defined by (4.8) and (4.9) is called the *minimal extension* of the projective system of $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$ since any other extension $(L', D(L'))$ of $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$ enjoys the following properties

$$D(L) \subseteq D(L') \tag{4.10}$$

$$L'(f) = L(f) \quad \forall f \in D(L) \,. \tag{4.11}$$

In the following the minimal extension will be denoted with the symbol $(L_{min}, D(L_{min}))$. We shall also write $L_{min} = \varprojlim L_J$.

An interesting characterisation of the domain of the minimal extension of a projective system of functionals $\{L_J, \hat{E}_J^0\}_{J\in A}$ relies on the concept of direct or inductive limit of a direct system. We recall here their definitions (see also [290]).

Definition 4.3. Let $(\mathcal{I}, \leq)$ be a directed set. A *direct system* on $\mathcal{I}$ is a collection $(S_J, F_{JK})_{J,K\in\mathcal{I}}$, where $\{S_J\}_{J\in\mathcal{I}}$ is a family of (non-empty) sets indexed by the elements of $\mathcal{I}$ and $\{F_{JK}\}_{J\leq K}$ a collection of mappings $F_{JK} : E_J \to E_K$ defined for all pairs $J, K \in \mathcal{I}$, $J \leq K$, and enjoying the following properties:

- for every $J \in \mathcal{I}$, F_{JJ} is the identity of E_J,
- $F_{KH} \circ F_{JK} = F_{JH}$ for all $J \leq K \leq H$.

Let us consider on the disjoint union $\cup_J E_J$ the equivalence relation $\sim$ as $\omega_J \sim \omega_K$, with $\omega_J \in E_J$ and $\omega_K \in E_K$, if there is some $H \in \mathcal{I}$ such that $J \leq H$, $K \leq H$, and $F_{JH}(\omega_J) = F_{KH}(\omega_K)$.

Definition 4.4. The *direct (or inductive) limit* $\varinjlim S_J$ of the direct system $(S_J, F_{JK})_{J,K\in\mathcal{I}}$ is the quotient set $\varinjlim E_J = \cup_J E_J / \sim$ of the equivalence relation $\sim$.

If the sets $(S_J)_{J\in\mathcal{I}}$ are topological spaces and the maps $(F_{JK})_{J,K\in\mathcal{I}}$ are continuous, the family $(S_J, F_{JK})_{J,K\in\mathcal{I}}$ is called a *topological direct system*. Its direct limit is the space $\varinjlim E_J$ endowed with the finest topology making all the maps $F_J : E_J \to \varinjlim E_J$ continuous.

Given a direct system $(S_J, F_{JK})_{J,K\in\mathcal{I}}$ and its direct limit $\varinjlim S_J$, let $F_J : S_J \to \varinjlim S_J$ be the function which maps each element of S_J into its equivalence class. It is easy to verify that the maps $\{F_J)_{J\in\mathcal{I}}$ and $\{F_{JK}\}_{J\leq K}$ enjoy the following composition property

$$F_J = F_K \circ F_{JK} \qquad J, K \in \mathcal{I}, J \leq K \,.$$

An application of the concept of Definitions 4.3 and 4.4 is found in considering a projective system of functionals $(L_J, \hat{S}^0_J)_{J\in\mathcal{I}}$. Indeed, the family of sets $\{\hat{S}^0_J\}_{J\in\mathcal{I}}$ and the collection $\{\mathcal{E}^K_J\}_{J\leq K}$ of extension maps

$$\mathcal{E}^K_J : \hat{S}^0_J \to \hat{S}^0_K, \qquad J \leq K, J, K \in A$$

form a direct system of sets. Its direct limit $\varinjlim \hat{S}^0_J$ is isomorphic to the set $\mathcal{C}_0$ of cylindrical functions defined in (4.7), as stated in the following theorem.

Theorem 4.2. *Let $\{S_J, \pi^K_J\}_{J,K\in\mathcal{I}}$ be a perfect inverse system, let $\{L_J, \hat{S}^0_J\}_{J\in\mathcal{I}}$ be a projective system of functionals and $(L_{min}, D(L_{min}))$ its minimal extension. Then $D(L_{min})$ is isomorphic to the direct limit $\varinjlim \hat{S}^J_0$ of the direct system $\{\hat{S}^0_J, \mathcal{E}^K_J\}_{J,K\in\mathcal{I}}$.*

Proof. We have to prove a one-to-one correspondence between $D(L_{min}) = \mathcal{C}_0$ and $\varinjlim \hat{S}^J_0$. Let us consider an arbitrary element $[f] \in \varinjlim \hat{E}^J_0$, i.e. an equivalence class of functions such that for any two elements f_J and f_K belonging to $[f]$ there is an $H \in \mathcal{I}$, with $J \leq H$ and $K \leq H$, such that $\mathcal{E}^H_J(f_J) = \mathcal{E}^H_K(f_K)$. In fact, all the elements belonging to this equivalence class $[f]$ define a unique cylindrical function. Indeed, given two points $f_J, f_K \in [f]$ and considering the associated cylindrical functions $\mathcal{E}^{\mathcal{I}}_J f_J$ and $\mathcal{E}^{\mathcal{I}}_K f_K$, it is simple to check that for any $\omega \in S_{\mathcal{I}}$ we have $\mathcal{E}^A_J f_J(\omega) = \mathcal{E}^A_K f_R(\omega)$. In order to show this equality it is sufficient to take an element $H \in \mathcal{I}$, with $J \leq H$ and $K \leq H$, such that $\mathcal{E}^H_J(f_J) = \mathcal{E}^H_K(f_K)$ (such an H exists as f_J and f_K belong to the same equivalence class g), and apply Eq. (4.6), which gives

$$\mathcal{E}^{\mathcal{I}}_J f_J(\omega) = \mathcal{E}^{\mathcal{I}}_H \circ \mathcal{E}^H_J f_J(\omega) = \mathcal{E}^{\mathcal{I}}_H \circ \mathcal{E}^H_K f_K(\omega) = \mathcal{E}^{\mathcal{I}}_K f_K(\omega)\,.$$

Conversely, under the assumption that $\{S_J, \pi^K_J\}_{J,K\in\mathcal{I}}$ is a perfect inverse system, to any cylindrical function belonging to $\mathcal{C}_0$ it is possible to associate a unique element of $\varinjlim \hat{E}^J_0$.

Indeed, let $f \in \mathcal{C}_0$ of the form $f = \mathcal{E}^{\mathcal{I}}_J f_J$, $J \in A$, $f_J \in \hat{S}^0_J$, and let $[f_J] \in \varinjlim \hat{E}^J_0$ be the equivalence class of f_J. If the cylindrical function f can be also be obtained as $f = \mathcal{E}^{\mathcal{I}}_K f_K$, for some $K \in \mathcal{I}$, $f_K \in \hat{S}^0_K$, then necessarily the following equality holds $[f_K] = [f_J]$, i.e., there exists an $H \in \mathcal{I}$, with $J \leq H$ and $K \leq H$ such that $\mathcal{E}^H_J f_J = \mathcal{E}^H_K f_K$. In order to prove this, it is sufficient to consider a set $H \in \mathcal{I}$ with $J \leq H$ and $K \leq H$ and the functions $f_H, f'_H \in \hat{S}^0_H$ of the form $f_H := \mathcal{E}^H_J f_J$ and $f'_H := \mathcal{E}^H_K f_K$. By Eq. (4.6) it follows that $\mathcal{E}^{\mathcal{I}}_H f_H = \mathcal{E}^A_H f'_H$, indeed $\mathcal{E}^{\mathcal{I}}_H f_H = \mathcal{E}^{\mathcal{I}}_H \mathcal{E}^H_J f_J = \mathcal{E}^{\mathcal{I}}_J f_J = f$ and analogously $\mathcal{E}^{\mathcal{I}}_H f'_R = \mathcal{E}^{\mathcal{I}}_H \mathcal{E}^H_K f_K = \mathcal{E}^{\mathcal{I}}_K f_K = f$, and by Remark 4.1 it follows that $f_R = f'_R$ (since we assumed that (E_J, π^K_J) is a perfect inverse system). □

Let $\mathcal{L} = \{(L, D(L))\}$ be the set of all possible projective extension of a projective system of functionals $\{L_J, \hat{S}^0_J\}_{J\in\mathcal{I}}$. Under the assumption that $(E_J, \pi^K_J)_{J,K\in A}$ is a perfect inverse system, the set $\mathcal{L}$ is not empty since in this case the minimal extension exists. In addition, it is possible to define a partial order relation $\leq$ on $\mathcal{L}$ as

$$L \leq L' \text{ if } D(L) \subset D(L') \text{ and } L(f) = L'(f)\ \forall f \in D(L)\,. \qquad (4.12)$$

Besides the study of the minimal extension, it is reasonable to investigate the existence of a *maximal extension* of a projective system of functionals $\{L_J, \hat{E}^0_J\}_{J\in A}$, i.e., a functional $(L_{max}, D(L_{max}))$ which cannot be further extended. More precisely, an extension $(L_{max}, D(L_{max})) \in \mathcal{L}$ is called maximal if the following holds

$$L_{max} \leq L \quad \Rightarrow L = L_{max}.$$

Similarly, we can define a *maximum extension* $(\bar{L}, D(\bar{L}))$, as the functional such that $L \leq \bar{L}$ for all $L \in \tilde{L}$. The latter problem is closely related to the uniqueness property of the extensions of a projective system. Indeed, if there existed two extensions $(L, D(L))$ and $(L', D(L'))$ such that $L(f) \neq L'(f)$ for some $f \in D(L) \cap D(L')$, then it would be impossible to construct $\bar{L}$, as it would be ambiguously defined on the element f. In fact, this property is also related to the existence of $(L_{max}, D(L_{max}))$, as is stated in the following theorem.

Theorem 4.3. *Let $\{L_J, \hat{E}^0_J\}_{J\in A}$ be a projective system of functionals, $\mathcal{L} = \{(L, D(L)\} \subset \mathcal{L}$ be the family of its projective extensions and let us consider the following statements:*

(1) Existence of a maximum extension: *there exists a functional $(\bar{L}, D(\bar{L})) \in \mathcal{L}$ such that $L \leq \bar{L}$ for all $L \in \mathcal{L}$.*

(2) Uniqueness property: *if $(L, D(L)), (L', D(L')) \in \tilde{\mathcal{L}}$ and $f \in D(L) \cap D(L')$, then $L(f) = L'(f)$.*

(3) Existence of a maximal extension: there exists a functional $(L_{max}, D(L_{max})) \in \mathcal{L}$ such that if $L \in \mathcal{L}$ and $L_{max} \leq L$ then $L = L_{max}$.

Then $1 \Rightarrow 2 \Rightarrow 3$.

Proof. The implication $1 \Rightarrow 2$ is trivial, as remarked above.
Concerning the implication $2 \Rightarrow 1$, it is sufficient to realise that $\mathcal{L}$ is a nonvoid partially ordered set, with partial order $\leq$ given by (4.12). Moreover any chain $\{L_\alpha, D(L_\alpha)\}_\alpha \subset \mathcal{L}$ has an upper bound $(\bar{L}; D(\bar{L}))$ given by

$$D(\bar{L})) = \cup_\alpha D(L_\alpha) \subset \hat{S}_{\mathcal{I}}, \qquad \bar{L}(f) = L_\alpha(f),\ f \in D(L_\alpha),$$

(the set inclusion being clear since all $D(L_\alpha)$ are in $\hat{S}_\mathcal{I}$). By Zorn's lemma we can deduce that $\mathcal{L}$ has a maximal element. □

Given two extensions $(L, D(L))$ and $(L', D(L'))$ of a projective system of functionals $\{L_J, \hat{E}^0_J\}_{J\in A}$, in general it is not always true that they coincide on the intersection of their domains, i.e., that for any $f : E_A \to \mathbb{C}$ such that $f \in D(L) \cap D(L')$, one has that $L(f) = L'(f)$. Indeed let us consider the following counterexample.

Example 4.1. Let us consider Example 3.3 in the particular case where $I = \mathbb{N}$, hence $\mathcal{I} = \mathcal{F}(\mathbb{N})$ is the totality of non-empty finite subsets of $\mathbb{N}$. Given an element $J \in \mathcal{I}$, let S_J be given by $S_J = \mathbb{R}^J$. We also identify $S_\mathcal{I}$ with the set $\mathbb{R}^\mathbb{N}$ of all real-valued sequences.
Let μ denote a probability measure on the Borel σ-algebra $\mathcal{B}(\mathbb{R})$ and let $(L_J, \hat{S}^0_J)$ be the family of functionals defined by

$$\begin{aligned}\hat{S}^0_J &= B_b(S_J)\\ L_J(f) &= \int_{S_J} f\, d\mu_J, \qquad f \in \hat{S}^0_J\end{aligned}$$

where $B_b(S_J)$ is the set of Borel bounded functions on S_J and $\mu_J = \times_{n\in J}\mu$ is the product measure of $|J| < \infty$ copies of μ ($|J|$ denoting the cardinality of $J \in \mathcal{I}$). By Kolmogorov's existence Theorem 3.4 there exists a probability measure $\mu_\mathcal{I}$ on the $\sigma-$algebra generated by the cylindrical sets in $S_\mathcal{I} = \mathbb{R}^\mathbb{N}$ obtained as the product $\times_{n\in\mathbb{N}}\mu$. In particular, if μ is the standard centered Gaussian measure on $\mathcal{B}(\mathbb{R})$, the subset $l_2 = \{\omega \in \mathbb{R}^\mathbb{N}, \mid \sum_n |\omega_n|^2 < \infty\}$ has zero $\mu_\mathcal{I}$-measure (see Example 3.2).

Let us consider the following two different extensions $(L, D(L))$ and $(L', D(L'))$ of the projective system of functionals $\{L_J, \hat{E}^J_0\}_{J\in A}$.
The functional L is defined by:

$$\begin{aligned}D(L) &= B_b(\mathbb{R}^\mathbb{N})\\ L(f) &= \int_{\mathbb{R}^\mathbb{N}} f(\omega)\, d\mu_\mathcal{I}(\omega), \quad f \in D(L)\end{aligned} \tag{4.13}$$

where $B_b(\mathbb{R}^\mathbb{N})$ denotes the Borel bounded functions over $\mathbb{R}^\mathbb{N}$.

Denote by $\pi_n : \mathbb{R}^\mathbb{N} \to \mathbb{R}^\mathbb{N}$ the projection of a sequence $\omega \in \mathbb{R}^\mathbb{N}$ to the sequence $\pi_n\omega$ given by

$$(\pi_n\omega)_m = \begin{cases}\omega_m & \text{if } m \le n\\ 0 & \text{otherwise.}\end{cases}$$

Let us consider the functional L' given by

$$D(L') = \{f : \mathbb{R}^{\mathbb{N}} \to \mathbb{C} \,|\, \exists \lim_{n\to\infty} \int f(\pi_n\omega)\, d\mu_{\mathcal{I}}(\omega)\},$$

$$L'_J(f) = \lim_{n\to\infty} \int f(\pi_n\omega) d\mu_{\mathcal{I}}(\omega). \tag{4.14}$$

Let us now consider the function $f : \mathbb{R}^{\mathbb{N}} \to \mathbb{C}$ defined as

$$f(\omega) = \begin{cases} 0 & \text{if } \omega \text{ has an infinite number of non-vanishing components} \\ 1 & \text{otherwise.} \end{cases}$$

In fact, f is the characteristic function of the set

$$B = \{\omega \in \mathbb{R}^{\mathbb{N}} \,|\omega \text{ has a finite number of non-vanishing components }\}. \tag{4.15}$$

One can easily verify that B is a measurable subset of $\mathbb{R}^{\mathbb{N}}$, indeed it belongs to the σ-algebra generated by the cylindrical sets, as:

$$B = \cup_{N\in\mathbb{N}} \cap_{n>N} B_n$$

where

$$B_n := \{\omega \in \mathbb{R}^{\mathbb{N}} \,|\, \omega_n = 0\}.$$

Then one has, for $\mu_{\mathcal{I}}$ the above Gaussian measure

$$\begin{aligned} L(f) &= \mu_{\mathcal{I}}(B) \\ &\leq \mu_{\mathcal{I}}(l_2) = 0 \end{aligned}$$

while

$$L'(f) = \lim_{n\to\infty} \int_{\mathbb{R}^n} f(\pi_n\omega)\, d\mu_{\mathcal{I}}(\omega) = \lim_{n\to\infty} 1 = 1.$$

4.2 Continuous extensions of projective systems of functionals

In the following we shall always assume, unless otherwise stated, that the projective family $(S_J, \pi_J^K)_{J,K\in\mathcal{I}}$ is a perfect inverse system, in such a way that, by Theorem 4.1, the minimal extension $(L_{min}, D(L_{min}))$ of a projective system of functionals $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$ is well-defined. We shall study its possible continuous extensions.

Let us consider the set of cylindrical functions $\mathcal{C}_0$ associated to a projective system of functionals $\{L_J, \hat{S}_J^0\}_{J\in\mathcal{I}}$ and let us endow the space $\hat{S}_{\mathcal{I}}$ of complex-valued functions on the projective limit $S_{\mathcal{I}}$ with a topology τ

Chapter 2

Axioms for the Plane

It is now time to insert a little geometry into our plane. The plane is intended to be an abstract model of the geometry of a flat surface such as a table or a piece of paper, with the difference that our plane will extend without end. So far we have points and some measures (with no details). We have also defined rigid motions, but except for the identity mapping, we have not yet claimed that any rigid motions actually exist. So there are things to do.

In this chapter, we state the six axioms for plane geometry that will be used in this book. The first four are closely related to the well-known Ruler and Compass axioms of G. D. Birkhoff [2], [3]:

- Incidence Axiom for points and lines
- Ruler Axiom concerning distance measure
- Protractor Axiom concerning angle measure
- Plane Separation Axiom concerning boundaries and orientation

We will explore consequences of these first four axioms in this chapter. From these axioms one can define some elementary but important geometrical concepts and prove a few key theorems.

At the end of the chapter, we complete the set of axioms by stating the remaining two axioms:

- Reflection Axiom
- Dilation Axiom

The Reflection Axiom will add rigid motions to our geometry. Significant geometrical connections between distance and angle measure will appear in Chapter 3 as consequences of the Reflection Axiom. This will lead to triangle congruence theorems in Chapter 4. In later chapters the importance of the Dilation Axiom will become evident.

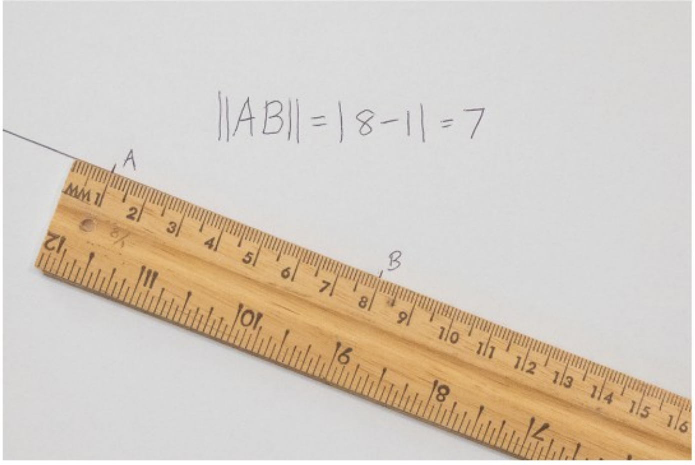

Figure 1. A Ruler Measuring Distance in the Plane

Incidence Axiom

The first axiom is very simple. The informal version is "two points determine a line".

Axiom 1 (Incidence). *The plane consists of a nonempty set of elements called points and a nonempty set of subsets called lines. For any two distinct points, there is exactly one line containing the two points; it will be denoted* $\overleftrightarrow{AB}$.

As a consequence of this, two distinct lines cannot intersect in more than one point. This already rules out our model looking like the sphere. We might think of this as the unmarked straightedge axiom: for any two points on a paper, we can draw a line with a straightedge through the two points.

Distance and the Ruler Axiom

The Ruler Axiom is an existence axiom for a distance measure and for "rulers" that provide distance measurement on a line by means of real numbers. Such a ruler is an abstraction of a marked straightedge.

Axiom 2 (Ruler). *The plane has a distance function.*

- *Distance is a function that maps any two points A and B in the plane to a nonnegative real number $\|AB\|$.*
- *Every line m in the plane has a ruler, a mapping of the real numbers $\mathbb{R}$ onto m so that distances are preserved.*

Another way of describing a ruler is that it is an isometry from $\mathbb{R}$ to m. Explicitly, if ρ is a ruler with $\rho(a) = A$ and $\rho(b) = B$, then the distance $\|AB\|$ equals the standard distance between two real numbers, the absolute value $|a - b|$.

Remark 2.1. This axiom implies a number of important properties of points, lines, and distance.

- For any A, $\|AA\| = 0$. This is true since, for A on a line m with ruler value $\rho(a) = A$, the distance $\|AA\| = |a - a| = 0$.
- A ruler is a one-to-one mapping, for if ρ is a ruler on a line m with $\rho(a) = \rho(b) = A$, then $|a - b| = \|AA\| = 0$, so $a = b$.
- For any two distinct points A and B, the distance $\|AB\| > 0$. For a ruler ρ on $\overline{AB}$, with $\rho(a) = A$ and $\rho(b) = B$ for distinct a and b, the distance $\|AB\| = |a - b| > 0$.
- There are an infinite number of points on each line, and the distances on the line are unbounded.
- If $\rho(x)$ is a ruler, then so is $\rho(x + k)$ or $\rho(-x + k)$ for any real k. Therefore, any point on the line can have coordinate 0.

The last item is true because, if we apply any distance-preserving transformation of the real numbers before mapping them by the ruler, this composition is still a ruler since the distance relations are still preserved. For example, if ρ is a ruler for m, let the function ρ_5 be defined as $\rho_5(x) = \rho(x + 5)$. Then ρ_5 is also a ruler for m, since for any real numbers a and b, $\|\rho_5(a)\rho_5(b)\| = \|\rho(a + 5)\rho(b + 5)\|$, and this equals $|(a + 5) - (b + 5)| = |a - b|$ since ρ is a ruler.

Exercise 1 explores these transformations of the real line.

The real numbers assigned to each point of m by the inverse map are the **coordinates defined by the ruler**. This inverse map will occasionally be designated as a function from points to numbers such as $a = x(A)$ and $b = x(B)$, but usually it will simply be stated that the real numbers a and b correspond to the points A and B in m.

These real numbers can be used to prove things about points on a line m.

For example, given a point A on m and any distance d, there are two points B and C on m at distance d, with $\|AB\| = \|AC\| = d$, since for any real number a, there are two numbers $b = a + d$ and $c = a - d$ with $|b - a| = |c - a| = d$.

Segments. From the Ruler Axiom, for distinct points A and B we can define AB, the **segment with endpoints** A **and** B. For the next few paragraphs, let the numbers a, b, c correspond to the points A, B, C on $\overline{AB}$.

Segment Definition by Ruler: The segment AB is the set of points C of $\overline{AB}$ such that the number c belongs to the interval with endpoints a and b: either $a \le c \le b$ or $b \le c \le a$. Equivalently, $|c - a| + |b - c| = |b - a|$.

Segment Definition by Distance: From the absolute value equation above, one sees that the segment AB is the set of points C of $\overline{AB}$ with $\|AC\| + \|BC\| = \|AB\|$.

Segment Interior Point: A point C is an **interior point** of AB, or is **between** A **and** B, if it is in AB but is not one of the endpoints.

Midpoint: The **midpoint** M of AB is the point on the segment equidistant from A and B. Hence, $2\|AM\| = \|AB\|$.

Convexity: A set S is **convex** if, for any points A and B in S, the segment AB is also contained in S.

Rays. For distinct points A and B, there is a **ray** $\overrightarrow{AB}$ with endpoint A in the direction of B. We continue with the assumption that the numbers a, b, c correspond to the points A, B, C on $\overline{AB}$.

Ray Definition: A point C on $\overline{AB}$ is in $\overrightarrow{AB}$ if A is not between B and C. In other words, $c \geq a$ if $b > a$ and $c \leq a$ if $b < a$.

Ray Interior Point: The set of all points except the endpoint is the set of **interior points** of the ray.

Opposite Ray: The opposite ray of $\overrightarrow{AB}$ is the ray consisting of endpoint A and the points C on $\overline{AB}$ not in $\overrightarrow{AB}$. In other words, $c \geq a$ if $b < a$ and $c \leq a$ if $b > a$.

Directed Line: A choice of ray determines a direction or orientation of the line containing it. Two rays in a line define the same direction if their intersection is a ray; this occurs if one ray is contained in the other, so a line has two possible directions.

Polygons. Now we can define polygons.

Definition 2.2. A **polygon** $P_1P_2\dots P_n$ is the figure consisting of n distinct points, the vertices P_i, and n sides, the segments $P_1P_2, P_2P_3, \dots, P_{n-1}P_n, P_nP_1$, such that (1) no interior point of a side is an intersection point of two sides and (2) any three consecutive vertices are noncollinear.

The sequences of three consecutive vertices include P_{n-1}, P_n, P_1 and P_n, P_1, P_2. This definition excludes self-intersecting polygonal figures and nonclosed polygonal paths, which can also be interesting but are not included as polygons.

The most familiar polygons have three sides (triangles), four sides (quadrilaterals), five sides (pentagons), and six sides (hexagons).

Protractor Axiom and Angles

Next, we will consider how to measure angles. Alas, even in informal geometry this is a bit more complicated than measuring along a line.

Definition 2.3. An **angle with vertex** A consists of two rays $\overrightarrow{AB}$ and $\overrightarrow{AC}$, denoted $\angle BAC$, where A, B, C are not collinear.

Two opposite rays $\overrightarrow{AB}$ and $\overrightarrow{AC}$ are said to form a **straight angle** and two equal rays $\overrightarrow{AB}$ and $\overrightarrow{AC}$ are said to form a **zero angle** even though these are not angles by the definition. This terminology is so well established that we will use it. But to be clear, if we say "angle" or refer to $\angle BAC$ without explictly including zero or straight angles, this means an angle by the definition and does not include zero or straight angles.

Axiom 3 (Protractor). *The plane has an* ***angle measure*** *that maps any two rays* $\overrightarrow{AB}$ *and* $\overrightarrow{AC}$ *with common endpoint to a real number* $m\angle BAC$.

Figure 2. A Wooden Protractor Measuring from 0 to 180

- *The angle measure maps any angle* $\angle BAC$ *to a positive number* $m\angle BAC$*, with* $0 < m\angle BAC < 180$.
- *In addition, when* $\overrightarrow{AB} = \overrightarrow{AC}$*, the angle measure of this zero angle is* $m\angle BAC = 0$. *If the rays* $\overrightarrow{AB}$ *and* $\overrightarrow{AC}$ *are opposite rays, the angle measure of this straight angle is* $m\angle BAC = 180$.
- *For any point* A*, there exists a* ***protractor*** *at* A*. This is a mapping* δ *from the real numbers onto the rays with endpoint* A*, such that* $\delta(t) = \delta(t + 360)$ *for every* t*, with the property that* $m\angle BAC = |b - c|$ *when* $\delta(b) = \overrightarrow{AB}$ *and* $\delta(c) = \overrightarrow{AC}$*, provided that* $|b - c| \le 180$.

Note. A protractor is also called a **polar angle parametrization** at A. The degree is the unit of angle measure used here, since this is more convenient for geometry than radians. However, the number 360 could be replaced by another positive number to provide a different choice of unit.

Example 2.4. Let's try to connect this angle measurement with our geometric intuition. Imagine that you are holding a compass (the magnetic directional kind, not the kind that draws circles). The directions on the compass face are numbered from 0 to 360, with the directions precisely at 0 and 360 being the same direction. Suppose this 0 direction points rightward (eastward).

If you are standing at point A, then the rays with endpoint A indicate the directions that you can be facing. Suppose direction $\overrightarrow{AB}$ is numbered 40, sort of a northeast direction, and a direction $\overrightarrow{AC}$ is numbered 250, sort of southwesterly. Then we could try to compute the angle measure of $\angle BAC$ by taking the difference between the numbers: $|250 - 40| = 210$. But this number is greater than 180, so it will not work as an angle measure. However, the number $250 - 360 = -110$ also corresponds to the ray $\overrightarrow{AC}$, so we can try again with this number: $|-110 - 40| = 150$. This is between 0 and 180, so 150 is the measure of $\angle BAC$.

Polar Angles. Using protractors directly is somewhat awkward; the inverse map from rays to real numbers is often more convenient. For a given protractor δ at A, we will say the point B (or the ray $\overrightarrow{AB}$) has **polar angle** t if t is one of the real numbers for which $\delta(t) = \overrightarrow{AB}$.

Two distinct rays never have the same polar angle. By Axiom 3, if the polar angles were the same, the angle measure of the rays would be zero and the rays would form a zero angle.

If two values of the polar angles of $\overrightarrow{AB}$ and $\overrightarrow{AC}$ satisfy $|\theta(\overrightarrow{AB}) - \theta(\overrightarrow{AC})| < 180$, we say the polar angles *measure* $\angle BAC$.

A choice of polar angle for $\overrightarrow{AB}$ will be denoted by $\theta(\overrightarrow{AB})$, even though the value of this angle is ambiguous without context, since adding 360 to this number produces another polar angle. To get around this problem in a given situation and to choose a polar angle unambiguously, we can restrict the protractor δ to a half-open segment in the real numbers of length 360.

For example, given the half-open interval $[0, 360)$, which is the set of real numbers t, with $0 \leq t < 360$, any protractor at A will define a one-to-one correspondence between this interval and the rays with endpoint A. Therefore, $\theta(\overrightarrow{AB})$ can be defined as the inverse of the restriction of δ to this interval, or in other words, $\theta(\overrightarrow{AB})$ will be the polar angle of B with $0 \leq \theta(\overrightarrow{AB}) < 360$.

Another choice of interval that is sometimes convenient is $(-180, +180]$, the real numbers $-180 < t \leq 180$. More generally, one can choose unambiguous polar angles θ either in the interval $a \leq \theta < a + 360$ or the interval $a - 180 \leq \theta < a + 180$, where a is any chosen real number.

If $\delta(t)$ is a protractor function at A, so are $\delta(t+k)$ and $\delta(-t+k)$, since these changes of real numbers do not affect the absolute value of the differences. This provides a convenience for computation: one may assign polar angle 0 to any convenient ray $\overrightarrow{AB}$.

Some Angle Terminology. There are a number of terms that specify a relationship between two angles or describe the size of an angle.

Supplementary Angles: Two angles are supplementary if the sum of their angle measures is 180. The vertices of the two angles do not have to be the same, but if $\overrightarrow{AB}$ and $\overrightarrow{AC}$ are opposite rays and D is a point not on $\overline{AB}$, then $\angle BAD$ and $\angle CAD$ are supplementary angles.

Vertical Angles: Two angles $\angle BAC$ and $\angle B'AC'$ are vertical angles if $\overrightarrow{AB'}$ is the opposite ray of $\overrightarrow{AB}$ and $\overrightarrow{AC'}$ is the opposite ray of $\overrightarrow{AC}$. These vertical angles have the same angle measure.

Right Angle: A right angle is an angle with measure 90. Two lines $\overline{AB}$ and $\overline{AC}$ are **perpendicular** if $\angle BAC$ is a right angle.

Acute Angle: An acute angle is an angle with measure less than 90, the measure of a right angle.

Obtuse Angle: An obtuse angle is an angle with measure greater than 90, the measure of a right angle.

Notice that a supplementary angle of a right angle is also a right angle. Therefore, two perpendicular lines form four right angles.

Definition 2.5. The **perpendicular bisector** of a segment AB is the line through the midpoint of AB perpendicular to $\overline{AB}$.

The perpendicular bisector of a segment always exists, since the midpoint M exists by the Ruler Axiom and a right angle $\angle DMA$ exists by the Protractor Axiom.

Plane Separation

There is one more axiom that is important for relationships of order and separation. It ensures that our model really acts like a two-sided two-dimensional space.

Axiom 4 (Plane Separation). *For any line m, any point not on the line belongs to one of two disjoint sets called the* ***half-planes of the line****.*

- *Points P and Q are in different half-planes when PQ intersects m. They are in the same half-plane if PQ does not intersect m.*
- *Let $m = \overline{AB}$. If a protractor is chosen so that $\theta(\overrightarrow{AB}) = 0$, the points P for which $0 < \theta(\overrightarrow{AP}) < 180$ lie in one half-plane, and the Q for which $-180 < \theta(\overrightarrow{AQ}) < 0$ are in the other half-plane.*

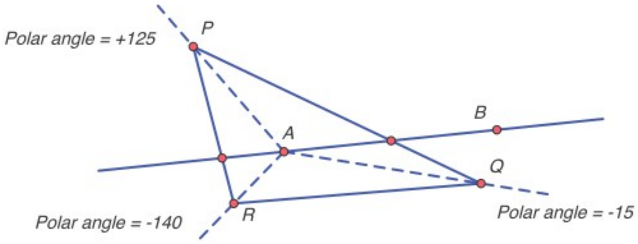

Figure 3. Point P in the Half-plane Opposite the Half-plane of Q and R

Note. We refer to the two half-planes as **opposite** one another. If two points are in different half-planes, we say they are on opposite sides of the line.

Definition 2.6. Given an angle $\angle BAC$, the **interior of the angle** is the intersection of the half-plane of $\overline{AC}$ containing B and the half-plane of $\overline{AB}$ containing C. For $\triangle BAC$, the **interior of the triangle** is the intersection of the interiors of the three angles $\angle BAC, \angle ACB, \angle CBA$.

Definition 2.7. A polygon $P_1P_2 \dots P_n$ is a **convex polygon** if, for every line $\overline{P_kP_{k+1}}$ that is a side extended, all the other vertices are in one half-plane of the line. The **interior of a convex polygon** is the intersection of all these half-planes

It follows that in a convex polygon, for any vertex angle, the interior of the polygon is contained in the interior of the angle. Since half-planes are convex, the interior of an angle or the interior of a triangle or other convex polygon is convex also.

The definition of the interior of a nonconvex polygon in general is surprisingly technical and will not be attempted here, since it would be an inappropriate digression in an introductory work. For a polygon with only a few sides, such as a quadrilateral, it is not hard to dissect the figure into triangles or other convex polygons and then take the interior of the convex polygons, plus common edges, to be the interior. But in general one must account for polygons with hundreds of thousands of sides. And this is not just some sort of "abstract mathematics" problem, for such triangles really appear in computer graphics and animation, and they can twist into amazingly complicated shapes. One algorithm for determining which points are inside a polygon is to intersect the polygon with a line passing through sides but not vertices. Then the points of intersection of sides with the line divide the line into alternating segments of outside points and inside points. But just to prove that the number of intersection points is even, so that this algorithm works, is complicated and to show that the interior is well-defined is even more so.

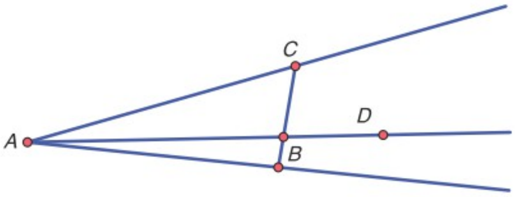

Figure 4. Intersection of CD with Ray Through Interior Point D

Theorem 2.8 (Addition of Angle Measure). *A point D is in the interior of $\angle BAC$ if and only if some polar angle of $\overrightarrow{AD}$ is between the polar angles of $\overrightarrow{AB}$ and $\overrightarrow{AC}$, provided those angles are chosen so that they measure $\angle BAC$. In this case, $m\angle BAD + m\angle DAC = m\angle BAC$.*

Proof. Let $\theta(\overrightarrow{AB}) = b$, $\theta(\overrightarrow{AC}) = c$, $\theta(\overrightarrow{AD}) = d$, with $|b - c| < 180$. Then we need to prove that D is an interior point if and only if some choice of d is between b and c.

Assume without loss of generality that b is the smaller of b and c, so $b < c < b+180$. D is in the half-plane of $\overline{AB}$ containing C when for some choice of d, $b < d < b + 180$. D is also in the half-plane of $\overline{AC}$ containing B when $d < c$. Thus, $b < d < c$ if and only if D is in the interior of the angle.

The angle measures are $m\angle BAD = d - b$, $m\angle DAC = c - d$, and $m\angle BAC = c - b$. This proves the final statement. □

If D is in the interior of $\angle BAC$, one also says $\overrightarrow{AD}$ is between $\overrightarrow{AB}$ and $\overrightarrow{AC}$. All the points of this ray have polar angle d, so they are interior to $\angle BAC$.

Definition 2.9. The **angle bisector** of $\angle BAC$ is the ray $\overrightarrow{AD}$ for which $m\angle BAD = m\angle DAC = (1/2)m\angle BAC$.

Using the notation from the proof of the theorem, the angle bisector exists and has polar angle $d = (b + c)/2$.

Theorem 2.10 (Crossbar). *Given any angle $\angle BAC$:*

(a) *The interior points of BC are interior to $\angle BAC$.*

(b) *For any point D interior to $\angle BAC$, the ray $\overrightarrow{AD}$ intersects the segment BC.*

Proof. Statement (a) is true since B is on $\overline{AB}$, so the interior points of $\overrightarrow{BC}$ are contained in the half-plane of $\overline{AB}$ containing C. Likewise, the interior points of $\overrightarrow{CB}$ are contained in the half-plane of $\overline{AC}$ containing B. The set of interior points of BC is the intersection of the interior points of these rays.

To show (b), continue to use the polar angles b, c, and d as above. Since $b < d < c$, we see that B and C are on opposite sides of $\overline{AD}$. Thus, BC intersects $\overline{AD}$ at a point in the interior of $\angle BAC$, therefore, at a point of $\overrightarrow{AD}$. □

Rigid Motions and Lines

We will now use our ruler and protractor axioms to prove some essential properties for doing geometry with rigid motions.

Theorem 2.11 (Line Images). *If T is a rigid motion, the T-image of a line, segment, or ray is, respectively, a line, segment, or ray.*

Proof. If A, B, C are distinct collinear points on line n, then $m\angle BAC = 0$ or $m\angle BAC = 180$. Then $m\angle T(B)T(A)T(C)$ also equals 0 or 180. This proves that the image of a line is a line.

Segments and rays are subsets of lines defined by distance relations. A point C on n is in segment AB if and only if $\|AC\| + \|BC\| = \|AB\|$. This equation still holds true for the image points, so $T(C)$ is in the segment $T(A)T(B)$. Similar reasoning for rays shows that the image of $\overrightarrow{AB}$ is $\overrightarrow{T(A)T(B)}$. □

Figure 5. A and B fixed — All Line Points Fixed

This next theorem will play a key role in classifying rigid motions.

Theorem 2.12 (Two Fixed Points). *If a rigid motion T fixes two distinct points A and B, then it fixes all points of $\overline{AB}$.*

Proof. To say T fixes a point A means that $T(A) = A$.

For a point C on $\overline{AB}$, let $D = T(C)$. If D is distinct from C, then $\|DA\| = \|T(C)T(A)\| = \|CA\|$, so A is the midpoint of CD. The same reasoning shows that B is also the midpoint of CD, so $A = B$, a contradiction. So D must be C. □

The Other Axioms

The last two axioms are stated here. What follows from assuming these axioms will be investigated in coming chapters.

The Reflection Axiom is an existence axiom for a very particular kind of rigid motion, not described in much detail in the axiom. The geometry of this rigid motion will be described in Chapter 3. Then by composing the transformations for different lines, in coming chapters we will prove many theorems of geometry and will generate familiar transformations such as rotations and translations. Already in Chapter 3 we will begin to see consequences for the geometry of triangles and other figures.

Axiom 5 (Reflection). *For any line m, there exists a rigid motion distinct from the identity transformation that fixes the points of m.*

We note by Theorem 2.12 that it is actually sufficient that this rigid motion fixes two points.

The last of the six axioms concerns the properties of dilations. These transformations are not rigid motions but are transformations that will be defined later as similitudes.

Definition 2.13. For point A and a real number $k > 0$, the **dilation** centered at A with dilation ratio k, denoted $\mathcal{D}_{A,k}$, is a transformation of the plane defined as follows: (a) $\mathcal{D}_{A,k}(A) = A$; (b) if $X \neq A$, $X' = \mathcal{D}_{A,k}(X)$ is the point on $\overrightarrow{AX}$ with $\|AX'\| = k\|AX\|$.

Axiom 6 (Dilation). *For every point A and every $k > 0$, the dilation $\mathcal{D}_{A,k}$ preserves angle measure and scales every distance by k: for all $P' = \mathcal{D}_{A,k}(P)$ and $Q' = \mathcal{D}_{A,k}(Q)$, $\|P'Q'\| = k\|PQ\|$.*

Note the difference in the nature of these two axioms. The Reflection Axiom is an existence axiom while the Dilation Axiom asserts properties of an existing transformation that is already defined.

We will see in Chapter 7 that the Dilation Axiom implies the famous Euclidean Parallel Postulate as a theorem. In contrast, everything proved using only the first five axioms is true not only in Euclidean geometry, but in hyperbolic non-Euclidean geometry as well. For many readers, this will not be important, but anyone thinking about proving theorems that are true in both Euclidean and non-Euclidean geometry will note that, except for a very few well-identified and isolated exceptions, only the first five axioms are used in proofs until the end of Chapter 6.

In Chapter 8, dilations will be central in the study of similarity. At that time, the definition of dilation will be extended to negative k.

Exercises and Explorations

1. (Rulers and Protractors). Let $\rho(x)$ be a ruler for a line m. It was claimed in Remark 2.1 that for a constant real number k, both $\rho(x+k)$ and $\rho(-x+k)$ are also rulers. Later it was similarly noted that if $\delta(t)$ is a protractor function at A, so are $\delta(t+k)$ and $\delta(-t+k)$.
   (a) Show that $\rho(x+k)$ satisfies the definition of a ruler. Next show that $\rho(-x)$ is a ruler. Combine the two results to prove the statement in the remark. You may wish to supplement words and symbols with drawings.
   (b) Show how almost identical reasoning justifies the statement about protractors.
2. (Midpoints). Let points A and B correspond by a ruler on line $\overline{AB}$ to a and b.
   (a) What real number m corresponds to the midpoint M of AB?
   (b) If D is a point corresponding to real number d and if B is the midpoint of AD, what number is d?
3. (Angle Bisectors). From Definition 2.9, an angle bisector is a ray that divides an angle into two angles of equal measure.
   (a) For a protractor at A, let the polar angles of B, C, and D be b, c, d. Assuming $|b-c| < 180$ and D is interior to $\angle BAC$, for what value of d will $\overrightarrow{AD}$ bisect this angle? In other words, for what D is $m\angle BAD = m\angle DAC$?
   (b) Two lines $\overline{AB}$ and $\overline{AC}$ form four angles at A. Explain how the four angle bisectors are related.
4. (Relationships on a Line). Let points A and B correspond by a ruler on line $\overline{AB}$ to a and b.
   (a) If $a = 3$ and $b = 5$, what number c corresponds to the point C on the line with $\|AC\| = 7$ and $\|BC\| = 9$?
   (b) If points A, B on line m correspond by a ruler to real numbers 3 and 5, what number c corresponds to the point $C = \mathcal{D}_{A,5}(B)$?
   (c) What is a general formula for c in terms of a and b if $C = \mathcal{D}_{A,k}(B)$?
5. (Fixed points on $\mathbb{R}$). Suppose that f is a map from the real numbers $\mathbb{R}$ to $\mathbb{R}$ that preserves distance.
   (a) If $f(3) = 3$, what are the possible values of $f(7)$?
   (b) If $f(3) = 3$, what are the possible values of $f(t)$, for any t?
   (c) If a point a is a fixed point of f (i.e., $a = f(a)$), what are the possible values of $f(t)$ for any other number t?
   (d) Based on your answers, if f has two fixed points, what can you say about $f(t)$?
6. (Plane Separation and Triangles). The plane separation axiom allows one to prove some facts that are basic and visually very believable but rather technical. One may choose to believe them without going through the proofs. However, they do provide good practice in reasoning with the Plane Separation Axiom.
   (a) In $\triangle ABC$, let D be an interior point of BC and let E be an interior point of CA. Prove that AD and BE intersect at a point G, an interior point of the triangle.

(b) (Pasch Axiom). There are other axioms of plane separation that are used in place of Axiom 4. One is called the Pasch Axiom: if a line m intersects side AB of $\triangle ABC$ at one point D, an interior point of side AB, then m also intersects either BC or CA. Prove this statement as a theorem using the axioms in this chapter.

(c) (Quadrilateral Shapes). Sketch a few quadrilaterals, convex and nonconvex. In your examples, is there always at least one diagonal that separates the other two vertices into opposite half-planes of the diagonal? If this is always true, how can one prove it from the axioms? If there are two such diagonals, what does this imply about the convexity or nonconvexity of the quadrilateral?

Suggestion: For each statement, begin by drawing possible cases and explain with informal reasoning what is possible before undertaking a more formal explanation.

Chapter 3

Existence and Properties of Reflections

In the previous chapters, we have been describing properties of rigid motions, but without the Reflection Axiom, there is nothing that tells us that any rigid motions actually exist (except for the identity)!

This axiom states the existence of some rigid motions that will turn out to be line reflections, with the usual geometric description. However, this description is not stated in the axiom. A bare minimum of existence is promised; in fact it is not even asserted that there is only one rigid motion whose existence is declared. But using the strong restrictions on behavior mandated by preservation of distance and angle measure, we will see that these vaguely described rigid motions must behave in exactly one way.

Recall the statement of the axiom:

Axiom 5 (Reflection)**.** *For any line m, there exists a rigid motion distinct from the identity transformation that fixes the points of m.*

Deducing the Properties of Reflections

At this point, we do not have a geometrical description of this rigid motion. The proof that this rigid motion is the usual reflection in a line with the usual geometrical description will come from the examination of a key figure.

Lemma 3.1 (Y Figure)**.** *Given a line $\overline{AB}$, take any point C not on the line. Then there is exactly one other point D in the plane so that $\|AC\| = \|AD\|$ and $m\angle BAC = m\angle BAD$. The points C and D are in opposite half-planes of $\overline{AB}$.*

Proof. Choose the protractor δ for rays with endpoint A so that the polar angle $\theta(\overrightarrow{AB}) = 0$. In the following, we choose polar angles in the interval $-180 < \theta < +180$.

Let $m\angle BAC = t$. Then the only rays $\overrightarrow{AE}$ for which $m\angle BAE = t$ have polar angle $+t$ or $-t$. There are only two such rays. One is $\overrightarrow{AC}$ itself. Call the other one $\overrightarrow{AF}$.

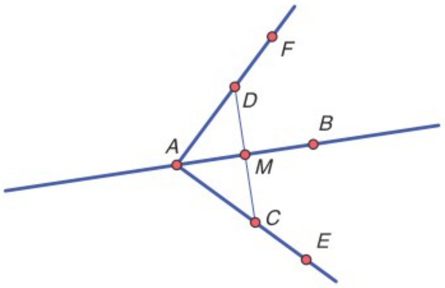

Figure 1. Only One Match to the Angle and Distance of C

Let $||AC|| = k$. There is exactly one point on each ray at distance k from A. One of these points is C. Let the point on $\overrightarrow{AF}$ be D.

Then $||AC|| = ||AD|| = k$, and $m\angle BAC = m\angle BAD = t$. From the Plane Separation Axiom, these points lie in opposite half-planes of $\overline{AB}$, so segment CD intersects $\overline{AB}$. $\square$

Lemma 3.2 (Reflection and Perpendicular Bisectors). *For any $\overline{AB}$, let T be a rigid motion that fixes the points of $\overline{AB}$. If C is not a fixed point of T, then C is not on $\overline{AB}$ and $T(C)$ is the point D constructed in the Y Figure Lemma. Moreover, the segment CD intersects $\overline{AB}$ at M, the midpoint of CD, and $\overline{AB}$ is the perpendicular bisector of CD.*

Proof. Let $D = T(C)$, a point distinct from C. T is a rigid motion that preserves angle measure and distance. Therefore, $m\angle BAC = m\angle BAD$ and $||AC||| = ||AD||$.

So from the Y Figure Lemma, D is uniquely determined and on the opposite side of $\overline{AB}$ from C.

Let M be the intersection of CD and $\overline{AB}$. (If $M = A$, interchange the roles of A and B in the proof.)

Since M is on $\overline{AB}$, $T(M) = M$. Since T is a rigid motion, $||CM|| = ||DM||$. Therefore M is the midpoint of CD.

In addition $m\angle CMA = m\angle DMA$ because T maps one angle to the other. Since the sum of these angle measures is 180, each of these angles is a right angle. This means that $\overline{AB}$ is the perpendicular bisector of CD. $\square$

Theorem 3.3 (Three Fixed Points). *If T is a rigid motion with three noncollinear fixed points, then T is the identify transformation. Furthermore, if S and T are two rigid motions that agree at three noncollinear points, then the transformations are the same: $S = T$.*

Proof. Let A, B, C be noncollinear fixed points of T. Suppose there is a point G that is not a fixed point, so that $T(G) = H$ is distinct from G.

Then by the Two Fixed Points Theorem, Theorem 2.12, for each of the three lines $\overline{AB}$, $\overline{BC}$, $\overline{CA}$, all the points are fixed. Then by Lemma 3.2, $\overline{AB}$ is the perpendicular bisector of GH and $\overline{AC}$ is also the perpendicular bisector of GH, as shown in Figure 2.

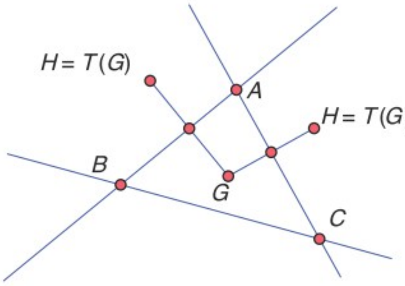

Figure 2. Impossible Images of G with A, B, C Fixed

Thus A, B, C are collinear with this assumption on G. Therefore, no such G exists and $G = T(G)$ for every G. In other words, T is the identity transformation I.

To prove the rest of the claim, let $S(A) = T(A)$, $S(B) = T(B)$, and $S(C) = T(C)$. Then $S^{-1}T$ has A, B, C as fixed points, so $S^{-1}T = I$. Multiplying on the left by S yields $T = (SS)^{-1}T = S(S^{-1}T) = SI = S$. ☐

This is a very powerful result. One can model it physically by tacking a piece of paper to a bulletin board. One tack allows a lot of swinging movement; two tacks allow no movement unless you remove the tacks, flip the paper over, and retack in the same holes. Three tacks allow no movement at all.

Next is the theorem that completes the geometric description of reflection for every point.

Theorem 3.4 (Line Reflection)**.** *Given any line m, there exists a unique rigid motion R distinct from the identity that fixes the points of line m. For any point E not on m, the image $E' = R(E)$ is the point such that m is the perpendicular bisector of EE'. We name this unique rigid motion* ***reflection in line*** *m, denoted $\mathcal{R}_m$. Reflection in $\overline{AB}$ is denoted $\mathcal{R}_{AB}$.*

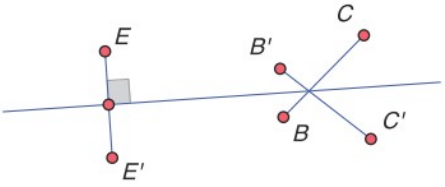

Figure 3. Reflection in the Perpendicular Bisector of EE'

Proof. By Theorem 3.3, an R given by the Reflection Axiom fixes the points of m but does not fix E (or else it would be the identity). Therefore by Lemma 3.2, this description of $R(E)$ is correct for every E not on m. ☐

Corollary. *If line p is perpendicular to line m, then $\mathcal{R}_m(p) = p$.*

Corollary. *For any line m, the inverse of* $\mathcal{R}_m$ *is* $\mathcal{R}_m$*.*

Proof. The perpendicular bisector of DC is the same as the perpendicular bisector of CD. ☐

The geometric description of line reflection also tells us some useful properties concerning intersection and half-planes.

Theorem 3.5 (Line Reflection and Half-Planes)**.** *Let m be a line.*

(1) *The reflection* $\mathcal{R}_m$ *maps each half-plane of m to the opposite one.*

(2) *If line n is perpendicular to m,* $\mathcal{R}_m$ *maps each half-plane of n to itself.*

Proof. By the Line Reflection Theorem, Theorem 3.4, any point A not on m is mapped to the opposite half-plane of m. This proves the first statement. For the second statement, let A be a point of m not on n and let B be a point in the same half-plane of n as A, so AB does not intersect n. Since $\mathcal{R}_m(n) = n$, the reflection image of the segment AB cannot intersect n, so $\mathcal{R}_m(A) = A$ and $\mathcal{R}_m(B)$ must be in the same half-plane. Since A did not move, B remains in its original half-plane of n also. ☐

Theorem 3.6 (Perpendicular Parallels)**.** *Let m be a line, and let p and q be distinct lines, each perpendicular to m. The lines p and q are parallel.*

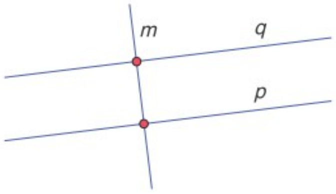

Figure 4. Perpendicular to Line m so Parallel

Proof. Suppose p and q intersect at a point A not on m. Reflection in m maps p to p and q to q. Therefore, $\mathcal{R}_m(A)$ is also a second, distinct intersection point of p and q in the opposite side of m from A. This means p and q have two points in common, so they must be the same line. This contradicts the assumption that p and q intersect m at distinct points. ☐

Theorem 3.7 (Dropping a Perpendicular)**.** *Let m be a line. If P is any point, there is a unique line p through P that is perpendicular to m.*

Proof. If P is on m, then there is a unique line through P that is perpendicular to m by the Protractor Axiom. If P is not on m, let $P' = \mathcal{R}_m(P)$. The line $\overline{PP'}$ is perpendicular to m by the Line Reflection Theorem. There is only one such line, for any two lines perpendicular to m are parallel so cannot both pass through P. ☐

The traditional name for construction of the perpendicular line to m through P is called **Dropping a Perpendicular from a Point**. Presumably one is dropping a vertical line like a plumb bob on a string to intersect a horizontal line. The intersection point of the perpendicular line with m is called the **foot of the perpendicular** from P to m.

Isosceles Triangles and Kites

With the properties of line reflection established, we can prove all the usual relationships in any isosceles triangle. Recall from Definition 2.2 that a **triangle** is a three-sided polygon. To spell this out: $\triangle ABC$ has three noncollinear vertices A, B, C and three sides AB, BC, and CA. The (interior) angles are the angles $\angle CAB$, $\angle ABC$, $\angle BCA$, often referred to as "angle A", etc.

Definition 3.8 (Isosceles Triangle)**.** An **isosceles triangle** is a triangle with two sides of equal length. If we label the two equal sides as AB and AC, then the side BC is called the base of the triangle. The angles at B and C are called base angles. The angle at A is called the apex angle.

A triangle with three equal sides is called an **equilateral triangle**.

This theorem points out a lot of congruent parts in an isosceles triangle. The theorem is labeled as a theorem about symmetry, since it shows that an isosceles triangle has a **line of symmetry**, which means that reflection in the line maps the figure onto itself.

Theorem 3.9 (Isosceles Triangle Symmetry)**.** *Given an isosceles triangle ABC with $\|AB\| = \|AC\|$, the perpendicular bisector of the base BC passes through A and bisects $\angle BAC$. Also, the base angles $\angle BCA$ and $\angle CBA$ are congruent.*

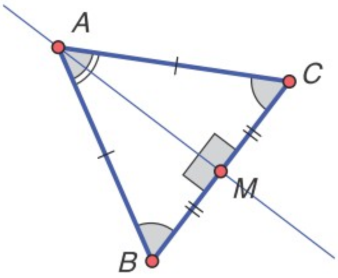

Figure 5. Symmetry and Many Congruences in an Isosceles Triangle

Proof. Construct $\overrightarrow{AP}$ as the angle bisector of $\angle BAC$. Then the Y Figure Lemma, Lemma 3.1, applies, and B and C are the mirror points in the lemma with respect to $\overline{AP}$. This means C is the reflection of B in $\overline{AP}$ and $\overline{AP}$ intersects BC at the midpoint M. Therefore the line $\overline{AP} = \overline{AM}$ is the perpendicular bisector of the base BC. The base angles are congruent since $\mathcal{R}_{AM}$ maps one to the other. $\square$

The traditional word for a set of points satisfying a geometrical condition is **locus**. This next theorem says that the locus of points equidistant from A and B is the perpendicular bisector of AB.

Theorem 3.10 (Perpendicular Bisector as Locus). *For any distinct points B and C, the perpendicular bisector of BC is the set of points P for which $\|PB\| = \|PC\|$.*

Proof. To prove set equality, one must prove containment in two directions.

If $\|PB\| = \|PC\|$, then the isosceles theorem proves that P is on m, the perpendicular bisector of BC, except in the case when $\angle BPC$ is a straight angle. But in this case, P is the midpoint of BC, so it is on m. For the converse, let Q be any point on m. Then $\mathcal{R}_m(B) = C$ and $\mathcal{R}_m(Q) = Q$, so $\|QB\| = \|QC\|$ since $\mathcal{R}_m$ is a rigid motion. □

A **quadrilateral** was defined in Definition 2.2 as a polygon with four vertices. A quadrilateral $ABCD$ has four vertex points A, B, C, D, no three of which are collinear, and four sides AB, BC, CD, DA, with no sides intersecting at interior points.

A **kite** is a quadrilateral with two pairs of equal adjacent sides, e.g., $\|AB\| = \|AD\|$ and $\|CB\| = \|CD\|$.

Theorem 3.11 (Kite Symmetry). *If $ABCD$ is a kite with $\|AB\| = \|AD\|$ and $\|CB\| = \|CD\|$, the diagonal $\overline{AC}$ is the perpendicular bisector of the segment BD.*

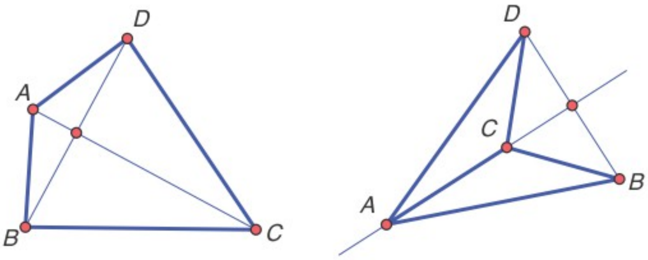

Figure 6. Line Symmetry of Kites

Proof. Let M be the midpoint of BD. Apply the Isosceles Triangle Symmetry Theorem, Theorem 3.9, to $\triangle ABD$ and $\triangle CDB$. In $\triangle ABD$, the perpendicular bisector of the base BD contains the point A and bisects $\angle BAD$. Likewise, in $\triangle CDB$ the same perpendicular bisector of BD contains C and bisects $\angle DCB$. This says that the line $\overline{AC}$ is the perpendicular bisector of BD. This line also bisects the angles at A and C. □

Notice that one of these kites in Figure 6 is not convex, but $\overline{AC}$ still is the perpendicular bisector of BD.

The proof of this theorem about equal base angles is left to Exercise 1.

Theorem 3.12 (Equal Base Angles). *For a triangle $\triangle ABC$, if $m\angle ABC = m\angle BCA$, the triangle is isosceles.*

Circles and Lines

A circle with center P was defined in Definition 1.6 as the set of points at distance r from P, for some positive radius r. This means that if A and B are two points on the circle, either P is the midpoint of AB or $\triangle PAB$ is isosceles with base AB. Combining this observation with what we have learned about isosceles triangles can tell us about a number of other properties of circles.

Some terminology will be used for a circle with center P:

- A segment PA from the center to a point on the circle is called a **radius segment**, or just a radius if the meaning is clear.
- A segment AB with A and B on the circle and with P as midpoint is a **diameter**; both PA and PB are radius segments. A line through P is a **diameter line**.

Reflection in any line through P maps the circle into itself, and for any reflection that maps the circle into itself, the reflection line passes through the center P. (The proof has been left as a problem in the exercises.)

The intersections of a circle with a line can be characterized using what we know.

Theorem 3.13 (Line-Circle Intersection)**.** *Let c be a circle with center P and radius r. If m is a line, there are four ways in which the line can meet the circle.*

- *The line and the circle may not intersect.*
- *The line and the circle may intersect at one point A. Segment PA is perpendicular to m.*
- *The line and the circle may intersect at two points A and B, as a diameter line or not. Center P is on the perpendicular bisector of AB; it will be the midpoint if AB is a diameter.*
- *The line cannot intersect the circle in more than two points.*

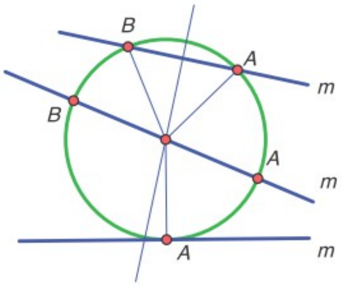

Figure 7. Circle and Possible Line Intersections

Proof. If A and B are two distinct points of intersection of circle c and line m, then by the Perpendicular Bisector as Locus Theorem, Theorem 3.10, the center P is on the perpendicular bisector of AB. This is the unique line n through P perpendicular to m.

If A, B, and C are three distinct points of intersection of c and m, then n must be the perpendicular bisector of both AB and AC, which is impossible since this would mean $B = \mathcal{R}_n(A) = C$.

To prove the third case and then the second case, suppose A is a point of intersection of c and m. Then $\mathcal{R}_n$ must map A to a point of intersection, since a reflection in a line through P maps c to itself and reflection in a perpendicular line maps m to itself. If $B = \mathcal{R}_n(A)$ is distinct from A, then the third case holds. If $B = A$, then A must be on n, so $n = \overline{PA}$. In this case $B = A$ is the only point of intersection. If there were another intersection point C, then $D = \mathcal{R}_n(C)$ would be a third point of intersection, a case that has been ruled out above. Thus, in this case the second statement holds.

Finally without trying to describe when this would happen, the first disjoint case may happen as well. □

The intersection of a circle and a line will be related to the distance of the line from the circle center in Theorem 6.8.

Light, Angles, and Reflections

When speaking of the physics of reflection of light rays, one hears the statement "angle of incidence equals angle of reflection". But when you look in a mirror, there is a copy of your face and your surroundings apparently just on the other side of the mirror, which seems to be a window into that scene.

Some of this can be seen in our plane geometry of reflections if one views a line as a plane mirror from above. In Figure 8, points A and B are on one side of the mirror line and the line reflection B' is on the other side. The observer at A sees a reflection of B in the mirror by looking in the direction of $\overrightarrow{AB'}$, a ray that intersects the mirror at C.

There are congruent vertical angles in this figure and also an isosceles triangle BCB', with congruent angles at the apex C. So the angle of incidence does equal the angle of reflection.

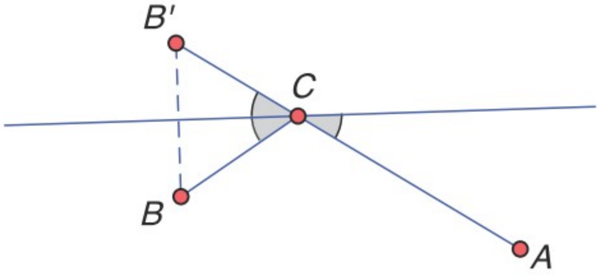

Figure 8. Line Reflection and Congruent Angles

Paper Folding and Tools for Construction

The proof of the geometric description of line reflection from the Reflection Axiom suggests why a paper fold through two points produces a nice, sharp straight line. The distance and angles on the paper are preserved by folding, so the destinations of all the points of the paper are determined, especially those of the points on the fold line.

This connection offers many ways to experiment with line reflections by folding. Some of these are identified as experiments in the exercises at the end of the chapter. In addition to revealing mathematical relations, a paper fold and some scissors can produce all kinds of figures with line symmetry, from paper dolls to abstract shapes.

Folding thin or translucent paper (such as patty paper) can also produce interesting traceable geometric figures, including ones that will appear in the next chapter.

Actual glass or plastic mirrors are also tools for experimentation, though it is hard to actually draw the reflection behind a mirror. For this reason, semitransparent red plastic mirrors have been offered for classroom experiments since they allow one to see both the figure behind the mirror and the reflection of the figure in front of the mirror at the same time.

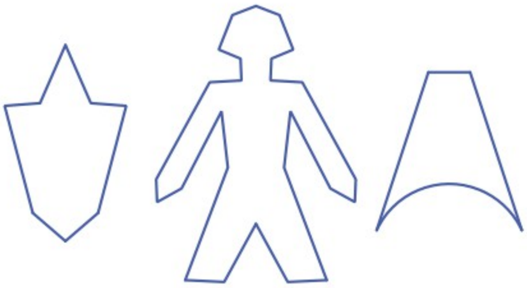

Figure 9. Line Symmetry from Folding and Cutting

The most versatile tool is dynamic geometry software that allows an abundance of examples with movable figures for experimentation.

Compasses and Constructions. Euclid's axioms for geometry were abstractions of drawing with an unmarked straightedge and a compass, so it was natural to use those tools when carrying out geometric constructions. The axioms in this book are abstractions of marked straightedges and protractors, so it may seem reasonable to use a marked ruler to measure distances when constructing geometric figures. However, compasses still are a more accurate way of constructing or copying lengths than using a physical ruler.

The main problem with a physical marked ruler is that there are only a finite number of marks, so most distances have to be approximated. A second reason is the process of making a pencil mark at a point on the ruler depends on more hand and eye coordination than making a mark with a compass. Therefore, a physical marked ruler is not really a good model for the ruler functions in the Ruler Axiom. A better model is a line drawn on a computer screen with software, since the software will plot (as accurately as the screen allows) any distance on the line.

In the exercises in the chapter, there are some directions for straightedge and compass constructions. These have the virtue of accuracy, but they also illustrate geometrical relationships between circles, lines, isosceles triangles and other figures. These methods complement the aforementioned paper folding, which is also a very accurate method for constructing certain lines.

Note about High School Texts. While transformations do not play a central role in most high school geometry textbooks, one exception is *Geometry* [6] from the University of Chicago School Mathematics Study Group. This book introduces line reflections early and uses them to prove such results as the symmetry properties of isosceles triangles. The set of axioms in that book assumes the parallel postulate before introducing line reflections and then assumes the basic properties of line reflections as postulates instead of proving them as theorems based on a general concept of rigid motion as is done here.

Exercises and Explorations

1. (Congruent Base Angles). Prove Theorem 3.12. Namely, prove for $\triangle ABC$ that if $m\angle ABC = m\angle ACB$, then $\|AB\| = \|AC\|$, so the triangle is isosceles.
2. (Rhombus Question). A **rhombus** is a quadrilateral $ABCD$ with all four sides the same length. How are the diagonals of a rhombus related? Construct a rhombus by paper folding.
3. (Ruler Reflection on $\mathbb{R}$). Let n be a line perpendicular to line m at A. Reflection in n maps m to itself. Identifying line m with $\mathbb{R}$ by using a ruler; this defines a mapping of the real number line $\mathbb{R}$ into itself. If the real number a corresponds to A and x corresponds to a point X on m, what number corresponds to $\mathcal{R}_n(X)$?
4. (Reflection of a Circle). Show that $\mathcal{R}_m$ maps a circle c with center O into itself, if and only if O is on m. Notice that this implies that all lines through the center (the diameter lines) are lines of symmetry for c.
5. (Segment Image Experiment). Try this experiment either with geometry software or paper. Draw a segment and a line not intersecting the segment, preferably at no special angle with respect to the segment. Then construct the reflection of the segment (paper folding and tracing is a good option if you are working on paper). You now have four endpoints. Draw all the segments connecting the endpoints. Do the diagonals intersect on the fold line? Why? What happens if you repeat the experiment with a segment and a fold through the segment? What happens with special cases such as a segment parallel to or perpendicular to the fold line?

6. (X Symmetry Experiment).
   (a) Draw an X shape made of two lines (or as much as will fit on the paper) as in Figure 10. They need not be segments of equal length. Fold the paper so that the shape is folded onto itself. This fold is a line of symmetry of the figure consisting of two lines. Fold another line of symmetry. How are these lines related to the angles defined by the lines? How are they related to each other?
   (b) Fold a piece of paper; then fold it again so that the original fold is folded onto itself. What angle results? How is this related to the previous experiment?

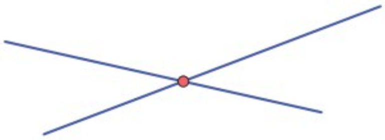

Figure 10. Folds Are Symmetry Lines for This X

7. (Free Folds). Fold a piece of paper and then cut a shape; unfold and see what shape with line symmetry you have produced. It could be a geometric shape or a tree or a face or something else you design.

8. (Billiards). Draw your own example of a figure that shows where to look to see a figure in a mirror (or in what direction to aim a billiard ball off a cushion). This idea can be extended to reflections in two mirrors in a corner, as illustrated in Figure 11. Make your own mirror lines, place points A and B, and find the billiard double cushion (or light double reflection) path between them.

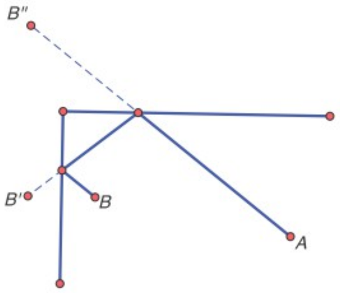

Figure 11. Double Mirror Reflection Path from A to B

9. (Symmetry Line Experiment). Find all the lines of symmetry for some familiar polygons: squares, rectangles, parallelograms, pentagons, hexagons (regular and otherwise). (Note: Some of these figures will not be "officially" defined until later chapters. This is informal experimentation at this stage.)

10. (Perpendicular Bisector Construction). Draw a segment AB on a piece of paper.
    (a) Folding construction: Construct the perpendicular bisector of AB by folding the paper. How did you fold?
    (b) Compass and straightedge construction: Construct the perpendicular bisector by drawing two intersecting circles of the same radius, one centered at A and the other at B. If there is one point of intersection not on line $\overline{AB}$, there will be two points of intersection. (Why?) Draw the line through the two points of intersection. Explain why this is the perpendicular bisector based on what was proved in this chapter.
11. (Angle Bisector Construction). Draw an angle $\angle BAC$ on a piece of paper.
    (a) Folding construction: Construct the angle bisector of AB by folding the paper.
    (b) Compass and straightedge construction: Using the compass, construct points D on $\overrightarrow{AB}$ and E on $\overrightarrow{AC}$ equidistant from A. Then construct F as in the previous problem to be an intersection point of two circles of the same radius with centers at D and E. What shape is $ADFE$ and what about its symmetry gives a reason why the ray $\overrightarrow{AF}$ is the angle bisector?

Chapter 7

Parallel Lines and Translations

This chapter marks an important point in the development of the geometry of the Euclidean plane. With the exception of a limited use of Triangle Angle Sum, proved by the Dilation Axiom, almost everything proved so far has used only the first five of our axioms. These axioms are also valid for the non-Euclidean plane geometry discovered by Lobachevsky and others in the nineteenth century, so theorems proved only with those axioms are true in both geometries. From now on, with the extensive use of the Euclidean Parallel Property, our text will be hewing exclusively to the Euclidean path.

The Euclidean Parallel Postulate

While we have defined parallel lines as lines that do not intersect, we have proved very little about parallel lines so far. This is because we need something additional to make our geometry conform to the intuition we have about rectangles, about lined notebook paper, and many other flat things. The key to making our geometry Euclidean is an axiom that is equivalent to the Euclidean Parallel Postulate.

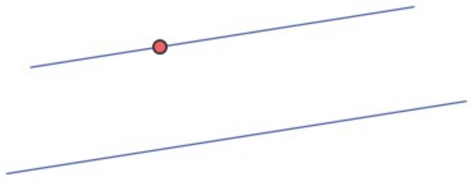

Figure 1. Playfair's Version of the Parallel Postulate

There have been many statements equivalent to the Parallel Postulate proposed as axioms over the centuries. The axiom that we have chosen in this book is Axiom 6, the Dilation Axiom. This axiom will be used to prove a theorem about parallel lines that is equivalent to Euclid's statement of the Parallel Postulate. The one we state and prove below is called the axiom of Playfair, named for its originator, the Scottish mathematician John Playfair.

Euclid stated the Parallel Postulate as an axiom, but since we are assuming an equivalent axiom, the Dilation Axiom, it will be proved here as a theorem using dilation.

Theorem 7.1 (Euclidean Parallel Postulate (EPP))**.** *Let m be a line. For any point P not on m, there is only one line through P parallel to m.*

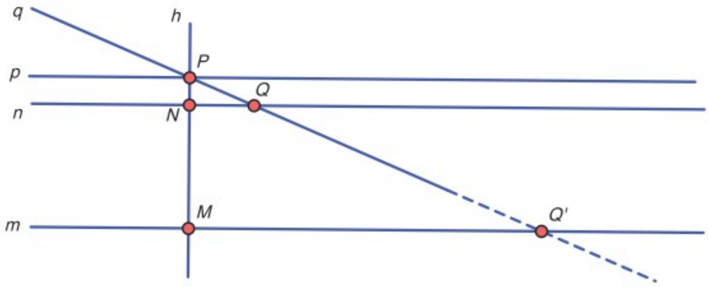

Figure 2. Dilation Proof of Parallel Postulate

Proof. Let h be the line through P perpendicular to m and let p be the line through P perpendicular to h. Let M be the intersection of h and m. Since both m and p are perpendicular to h, p is a line through P parallel to m by Theorem 3.6.

Now suppose that q is another line through P distinct from p. Since this line is not perpendicular to h, there is a point Q on the line with $m\angle MPQ < 90$.

Construct the line n through Q perpendicular to h, with N as the intersection of n and h. (All these perpendiculars can be constructed by line reflection.) These lines and points are shown in Figure 2.

Now we have a triangle $\triangle PNQ$, with a right angle $\angle PNQ$. The strategy is to dilate this triangle so that the image of Q is the intersection of q and m. Let $D_{P,k}$ be the dilation with center P that maps N to M. The value of k is $\|PM\|/\|PN\|$.

Since this dilation maps lines through P to themselves, the images of lines q and h are q and h. By the Dilation Axiom, which says angle measure is preserved by dilation, the right angle $\angle PNQ$ maps to a right angle $\angle PMQ'$. But $\overline{MQ'} = m$, since both are lines through M perpendicular to h.

This means that Q' is on both q and m. So these lines intersect, and q is not parallel to m. ☐

As an example of how one can use the EPP, here is a second proof of the Angle Sum Theorem, Theorem 4.12. If the EPP had been assumed as an axiom, this is the proof that would have come first. It shares some ideas with the proof in Chapter 4 but does not use dilation explicitly.

Theorem 7.2 (Angle Sum)**.** *For any triangle $\triangle ABC$, the images of $\triangle ABC$ by half-turns centered at the midpoints of the sides form a triangle $\triangle A'B'C'$, with $\triangle ABC$ as the midpoints. Therefore, the sum of the measures of the angles of $\triangle ABC$ is* 180 *degrees.*

Proof. Denote by F and E the midpoints of AB and AC, respectively.

If we apply $\mathcal{H}_F$ to $\triangle ABC$, $\mathcal{H}_F(A) = B$, $\mathcal{H}_F(B) = A$, and $\mathcal{H}_F(C) = C'$. The half-turn is a rigid motion, so $\angle BAC' \cong \angle ABC$. Since by Theorem 6.1 half-turns map any line to a line parallel to it, line $\overline{AC'}$ is parallel to $\overline{BC}$.

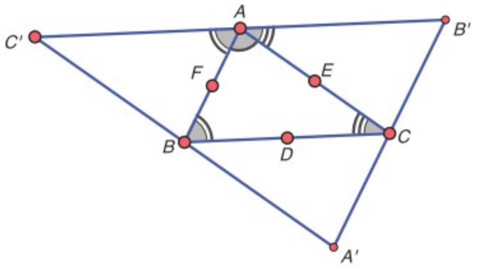

Figure 3. Angle Sum

Now apply $\mathcal{H}_E$ to $\triangle ABC$ and get the image $\triangle CB'A$. Again we see $\overline{AB'}$ is parallel to $\overline{BC}$, and $\angle CAB' \cong \angle ACB$.

But since lines $\overline{AC'}$ and $\overline{AB'}$ are lines through A parallel to BC, they must be the same line, so B', A, and C' are collinear. And A is the midpoint of $B'C'$. The same reasoning applies to the midpoints of the other two sides of $\triangle A'B'C'$.

This means that the sum of the measures of the three angles $\angle BAC'$, $\angle BAC$, and $\angle CAB'$ must be 180 degrees. Since these angles are congruent to the angles of $\triangle ABC$, this proves the result. □

Corollary. *The measure of an exterior angle of a triangle is equal to the sum of the measures of the interior angles at the other two vertices.*

Transversals and Parallel Lines

Definition 7.3. A line that intersects each of a pair of lines at two distinct points is called a **transversal** of the lines.

The Parallel Postulate says something important about transversals:

Theorem 7.4 (Transversal of Parallels)**.** *Suppose m and n are parallel lines. If p is a line distinct from m that intersects m, then p also intersects n, so p is a transversal.*

Proof. If p intersects m at M and does not intersect n, then p and m are two lines through M that are parallel to n. By the Parallel Postulate, the lines cannot be distinct. Therefore, p must intersect n. □

In the next theorem, a half-turn is used to establish important properties of transversals.

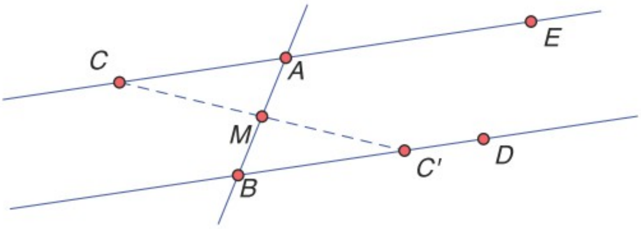

Figure 4. Transversal with Half-turn at Midpoint

Theorem 7.5 (Transversal Theorem). *Suppose* $\overline{AB}$ *is a transversal of* c *and* d*, with* A *on* c *and* B *on* d*. Let* $\mathcal{H}_M$ *be the half-turn with center* M*, the midpoint of* AB*.*

(1) *The line* $d = \mathcal{H}_M(c)$ *if and only if* c *and* d *are parallel.*

(2) *If* C *is not on* $\overline{AB}$*, let* $C' = \mathcal{H}_M(C)$*. Then* $\mathcal{H}_M(\overrightarrow{AC}) = \overrightarrow{BC'}$ *is a parallel ray on the opposite side of* $\overline{AB}$*. Also* $\overline{CB}$ *is parallel to* $\overline{C'A}$*.*

(3) *If* C *and* D *are on opposite sides of* $\overline{AB}$*, then* $m\angle BAC = m\angle ABD$ *if and only if* $\overline{CA}$ *is parallel to* $\overline{BD}$*.*

Proof. The line $\mathcal{H}_M(c)$ is parallel to c by Theorem 6.1. The Parallel Postulate says that if d is also a line through B parallel to c, then it must be the same line. This proves the first statement.

If $C' = \mathcal{H}_M(C)$, then CC' intersects $\overline{AB}$ at M. So if C is not on $\overline{AB}$, then C and C' are in opposite half-planes. Since $AC' = \mathcal{H}_M(BC)$, the lines $\overline{CB}$ and $\overline{C'A}$ are parallel. Also, since $\mathcal{H}_M$ is a rigid motion, $m\angle BAC = m\angle ABC'$.

If $m\angle BAC = m\angle ABC' = m\angle ABD$, with C and D on opposite sides of $\overline{AB}$, then $\overrightarrow{BD} = \overrightarrow{BC'}$. Therefore $\overline{CA}$ is parallel to $\overline{BD} = \overline{BC'}$. Conversely, if the lines are parallel and D is on the opposite side of $\overline{AB}$, then $\overrightarrow{BD} = \overrightarrow{BC'}$ since both are on the unique parallel to $\overline{CA}$ through B. □

This theorem can be used to prove the version of the Parallel Postulate stated in Euclid's *Elements*. It tells more about the location of the intersection of two nonparallel lines.

Theorem 7.6 (Euclid's Version of the Parallel Postulate). *Given two points* F *and* D *on the same side of* $\overline{AB}$*, if* $m\angle FAB + m\angle DBA < 180$*, then the rays* $\overrightarrow{AF}$ *and* $\overrightarrow{BD}$ *intersect at a point* G*.*

Proof. Let E be a point on the same side of $\overline{AB}$ as D, with $\overline{AE}$ parallel to $\overline{BD}$ and $\overrightarrow{AC}$ the opposite ray of $\overrightarrow{AE}$, as pictured in Figure 4. Let $d = m\angle ABD$ and $f = m\angle BAF$. Then $m\angle BAC = d$ and $m\angle BAE = 180 - d > f$, by Theorem 7.5. Therefore, $\overline{AF}$ is not the unique parallel to $\overline{BD}$ through A, so it intersects $\overline{BD}$ at a point G.

What remains to be proved is that G is on the rays $\overrightarrow{AF}$ and $\overrightarrow{BD}$. To see this, we prove the points F and D are in the interior of $\angle BAE$.

From the Addition of Angle Measure Theorem, Theorem 2.8, the interior points of $\overrightarrow{AF}$ are in the interior of $\angle EAB$. To show D is also in the interior we must show it is on the same side of $\overline{AB}$ as E (true by assumption) and on the same side of $\overline{AE}$ as B (true since the entire parallel line $\overline{BD}$ is on that side).

Now G cannot be on the opposite ray of $\overrightarrow{AF}$ because that ray is on the opposite side of $\overline{AE}$ from $\overline{BD}$, so the intersection point must be on $\overrightarrow{AF}$ and so must be in the interior of $\angle EAB$. But this means that G is on the same side of $\overline{AB}$ as D and E, so it must be on $\overrightarrow{BD}$ rather than its opposite ray. □

The angles $\angle BAC$ and $\angle ABD$ are called the **alternate interior angles** defined by the transversal. As illustrated in Figure 5, two lines are parallel if and only if the alternate interior angles of a transversal are congruent. This includes the Important special case of a right angle, when the transversal is perpendicular to both lines.

Theorem 7.7 (Perpendiculars to Intersecting Lines)**.** *Let m and n be distinct intersecting lines. If line m' is perpendicular to m and line n' is perpendicular to n, then m' and n' are distinct intersecting lines as well.*

Proof. The lines m' and n' cannot be parallel, for if they were, both m and n would be perpendicular transversals of m' and n' and so would be parallel or equal. And m' and n' cannot be the same line for again m and n would be perpendicular to m' and so parallel or equal. □

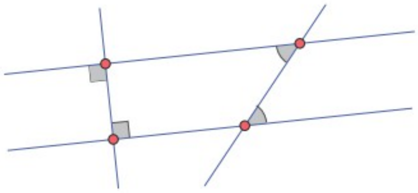

Figure 5. Transversals of Parallel Lines with Alternate Interior Angles

This theorem has a number of applications. It was already needed in Exercise 4 of Chapter 6 to prove that two bisectors of adjacent exterior angles of a triangle always intersect, because they are each perpendicular to an internal angle bisector. Another application is the next theorem, which concerns circumscribing a circle about any triangle.

Theorem 7.8 (Triangle Circumcircle)**.** *For any $\triangle ABC$, there is a unique circle that passes through the points A, B, and C. The center O of the circle is the point of concurrence of the perpendicular bisectors of the sides of the triangle.*

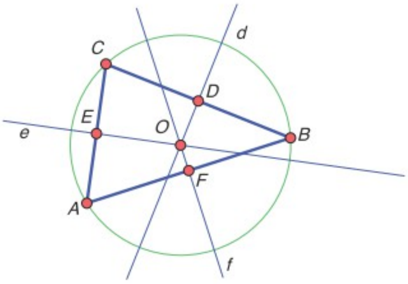

Figure 6. Circumcircle and Circumcenter of $\triangle ABC$

This circle is called the **circumcircle** of the triangle, and the point of concurrence O is called the **circumcenter** of the triangle.

Proof. Consider the bisectors of two of the sides, say the lines e and f that are the perpendicular bisectors of sides AC and AB, as shown in Figure 6. By Theorem 7.7 these two lines intersect at a point O, since they are each perpendicular to a side of the triangle, and these sides are not collinear. Since the perpendicular bisector of a segment is the locus of points equidistant from the endpoints by Theorem 3.10, the points of e are equidistant from A and C and the points of f are equidistant from A and C. Together this says that O satisfies $\|OC\| = \|OA\| = \|OB\|$. If we call this common distance r, the circle with radius r and center O passes through all three vertex points of $\triangle ABC$.

For the final part of the proof, since $\|OC\| = \|OB\|$, the point O is equidistant from B and C and so is on d, the perpendicular bisector of BC. Thus, O is on all three perpendicular bisectors. □

Parallelograms

The study of parallel lines leads to parallelograms.

Note. We will say that two segments or rays are parallel if the lines they belong to are parallel.

Definition 7.9. A quadrilateral $ABCD$ is a **parallelogram** if its opposite sides are parallel, i.e., AB is parallel to CD and DA is parallel to BC.

Theorem 7.10 (Parallelogram Symmetry)**.** *For a parallelogram ABCD, the opposite sides are congruent and the opposite angles are congruent. Also, the two diagonals AC and BD intersect at a point M that is the midpoint of each diagonal. The half-turn* $\mathcal{H}_M$ *is a symmetry of the parallelogram.*

Proof. Let M be the midpoint of the diagonal AC. Then $\mathcal{H}_M(A) = C$ and $\mathcal{H}_M(C) = A$.

The line $\overline{AC}$ is a transversal of both pairs of opposite sides. Therefore, by the Transversal Theorem, Theorem 7.5, $\mathcal{H}_M(\overline{AB}) = \overline{CD}$ and $\mathcal{H}_M(\overline{AD}) = \overline{CB}$.

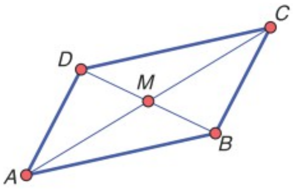

Figure 7. Parallelogram with Diagonals

Point B is the intersection of $\overline{AB}$ and $\overline{CB}$, so its image is the intersection of the image lines $\overline{CD}$ and $\overline{DA}$, namely D. So $\mathcal{H}_M(D) = B$. Therefore, since $\mathcal{H}_M(B) = D$ also, $\mathcal{H}_M$ is a symmetry of the parallelogram.

This means that $\mathcal{H}_M$ maps AB to CD and BC to DA, so the opposite sides are congruent.

The half-turn with center M also maps each angle of $ABCD$ to its opposite angle, so the opposite angles are congruent.

Finally, the midpoint of BD is also M, since $\mathcal{H}_M(B) = D$. ☐

Corollary. *A quadrilateral is a parallelogram if and only if it has point symmetry.*

Proof. The theorem has been proved in one direction. If $ABCD$ has a half-turn $\mathcal{H}_M$ that is a symmetry, then $\mathcal{H}_M(AB) = CD$ and $\mathcal{H}_M(BC) = DA$, so the opposite sides are parallel, by the properties of half-turns. ☐

Earlier, the meaning of "direction" was defined for two rays or two segments on the same line. With these properties of parallels proven, it is possible to extend this definition to parallel rays and segments.

Definition 7.11. Two rays on parallel lines, $\overrightarrow{AB}$ and $\overrightarrow{CD}$, have the **same direction** if both B and D are on the same side of $\overline{AC}$. They have opposite direction if B and D are on opposite sides. The same definition applies for the same direction of segments AB and CD on parallel lines. Two directed lines that are parallel either have directing rays in the the same direction or the opposite direction.

There are several properties of a quadrilateral $ABCD$ that ensure it is a parallelogram.

Theorem 7.12 (Equal Parallels). *If two segments AB and CD are parallel and $||AB|| = ||CD||$, then either*

- *AB and CD have opposite direction and $ABCD$ is a parallelogram with AC and BD as diagonals or*
- *AB and CD have the same direction and $ABDC$ is a parallelogram with AD and BC as diagonals.*

Therefore, if $ABCD$ is a quadrilateral with two opposite sides parallel and congruent, then $ABCD$ is a parallelogram.

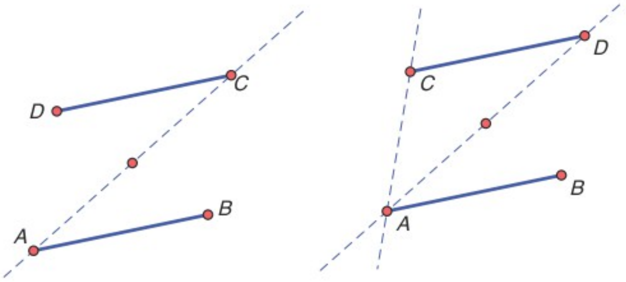

Figure 8. Congruent Parallel Segments

Proof. If B and D are on opposite sides of $\overline{AC}$, then $ABCD$ is a parallelogram. Let M be the midpoint of AC. Then by the Transversal Theorem, Theorem 7.5, $\overline{AD}$ is parallel to $\overline{CB}$. Therefore $ABCD$ is a parallelogram. Since AC and BD are diagonals that intersect at their common midpoint, $ABDC$ is not a quadrilateral.

As illustrated in Figure 8, if B and D are on the same side of $\overline{AC}$, then D is an interior point of $\angle BAC$. First, B and D are in the same half-plane of $\overline{AC}$. Second, D and C are on the same side of $\overline{AB}$ because DC is parallel to AB. Putting these together, D is interior to $\angle BAC$.

The Crossbar Theorem, Theorem 2.10, implies that C and B are on opposite sides of $\overline{AD}$. Then by the same reasoning as before $ABDC$ is a parallelogram and AD and BC are diagonals that intersect at their common midpoint, so $ABCD$ is not a quadrilateral. This implies that the last statement is true. □

A corollary of this theorem is that the midpoints of a parallelogram define more parallelograms and parallel lines.

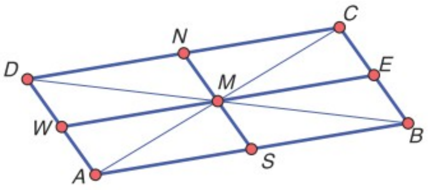

Figure 9. Midpoints and Midsegments in a Parallelogram

Theorem 7.13 (Parallelogram Midsegments)**.** *If $ABCD$ is a parallelogram, a segment EW connecting the midpoints of two opposite sides is parallel to the other two sides and forms a parallelogram with either of those sides. The two such segments intersect at M, the intersection point of the diagonals.*

Proof. Let the midpoints be labeled as in Figure 9. Then E and W are the midpoints of the opposite sides BC and DA. The quadrilateral $BEWA$ has two sides BE and WA, parallel and of the same length, so it is a parallelogram by Theorem 7.12. Therefore,

EW is parallel and congruent to AB. By the same reasoning, NS, the other segment connecting midpoints of opposite sides, is parallel to DA.

Since the symmetry $\mathcal{H}_M$ maps each midpoint of a side of $ABCD$ to the midpoint on the opposite side, M is the midpoint of both segments EW and NS. ☐

By symmetry $ENWS$ is a parallelogram with the segments EW and NS as diagonals.

Here is a second criterion for a quadrilateral to be a parallelogram.

Theorem 7.14 (Congruent Opposite Sides). *A quadrilateral ABCD with opposite sides of equal length is a parallelogram.*

Proof. By assumption $\|AB\| = \|CD\|$ and $\|BC\| = \|DA\|$. The diagonal AC is thus the common side of two triangles $\triangle ABC$ and $\triangle CDA$ that are congruent by SSS. Let T be the rigid motion of the congruence defined by SSS.

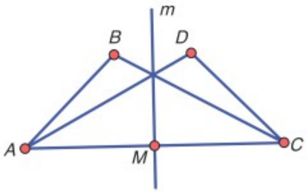

Figure 10. SSS Rigid Motion from $\triangle ABC$ to $\triangle CDA$

This rigid motion T maps AC to CA, so the midpoint M of AC is a fixed point. Therefore, T is either the half-turn $\mathcal{H}_M$ or the reflection $\mathcal{R}_m$, where m is the perpendicular bisector of AC.

If $T = \mathcal{H}_M$, the quadrilateral has a point symmetry and $ABCD$ is a parallelogram. So what remains is to rule out the other case.

Since $T(B) = D$, if $T = \mathcal{R}_m$, then B and D must be on the same side of $\overline{CA}$, since the reflection maps each half-plane of $\overline{CA}$ into itself. It cannot be the case that B is on m, for then $B = D$ and $ABCD$ is not a quadrilateral.

Therefore, B is in the m-half-plane of either A or C. Suppose it is in the half-plane of A, as in Figure 10. The segment CB intersects m at a point P, since B and C are in opposite half-planes. Applying $\mathcal{R}_m$ to CB, the image AD also intersects m at P. But this means that the sides CB and AD intersect at P, so $ABCD$ is not a quadrilateral. ☐

This is an example of how having a rigid motion included in a triangle congruence test like SSS can help in a proof.

Rectangles

Now we define a very familiar polygon that is a special parallelogram.

Definition 7.15. A **rectangle** is a quadrilateral $ABCD$ with each vertex angle a right angle.

Theorem 7.16 (Rectangle Symmetry). *If ABCD is a rectangle, then it is a parallelogram with the lines through the midpoints of opposite sides as lines of symmetry.*

Proof. Lines $\overline{AB}$ and $\overline{CD}$ are perpendicular to $\overline{AD}$, so they must be parallel. Likewise, $\overline{BC}$ and $\overline{AD}$ are parallel. This proves $ABCD$ is a parallelogram. Let the midpoints be labeled as in Figure 11. It was proved in Theorem 7.13 that the midpoint segment EW is parallel to AB and DC. So in a rectangle, EW is perpendicular to the transversals DA and BC. Thus, the reflection $\mathcal{R}_{EW}$ maps AB to DC. The other midpoint line is also a line of symmetry. □

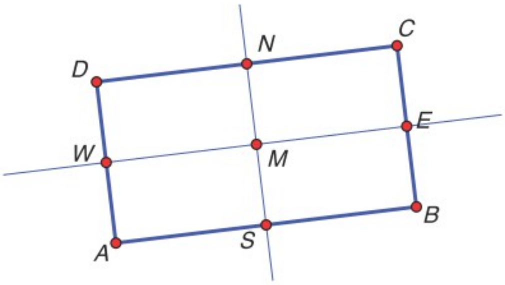

Figure 11. Rectangle with Lines of Symmetry

Note. Because of the line symmetry, the two diagonals of a rectangle are congruent, since a line reflection maps one to the other. The converse of this statement is also true. In addition, if one angle of a parallelogram is a right angle, then all are right angles and the figure is a rectangle. The proofs are problems in Exercise 12.

Every parallelogram, including rectangles, has a point symmetry. The product of the reflections in the two perpendicular midlines of a rectangle is a 180-degree rotation centered at the point of intersection. This is the half-turn $\mathcal{H}_M$ that defines the point symmetry. Thus, in general, parallelograms have two rotational symmetries, the identity and $\mathcal{H}_M$, but rectangles also have, in addition, two line symmetries. This is consistent with the discussion of dihedral symmetry in Chapter 5.

This agrees with a visual sense that rectangles are more symmetric than a general parallelogram. A square is a special rectangle that is yet more symmetric. It is a regular 4-gon and has four rotations and four reflections as symmetries.

Distance Between Parallel Lines. One can use rectangles to define the distance between two parallel lines and also to define the unique parallel line of symmetry of a figure consisting of two parallel lines.

Theorem 7.17 (Midline Theorem). *Let p and q be parallel lines.*

(1) *Every segment PQ perpendicular to p at P and to q at Q has the same length.*

(2) *The perpendicular bisector of every such perpendicular PQ is the same line m.*

(3) *This line m is parallel to p and q and is a line of symmetry for p and q, i.e.,* $\mathcal{R}_m(p) = q$.

(4) *If a transversal intersects p and q at A and B, the midpoint of AB is on m.*

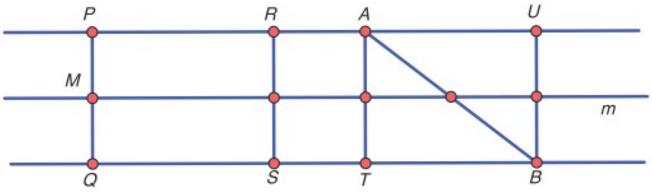

Figure 12. Midline with Transversals

Proof. Most of these statements are immediate consequences of properties of rectangles. If P and R are on p and Q and S are on q, then if PQ and RS are perpendicular to p and q, then $PQSR$ is a rectangle and the opposite sides PQ and RS have the same length.

Also the perpendicular bisector m of either PQ or RS is the unique line of symmetry of the rectangle $PQSR$ parallel to p and q, so it is a well-defined line m with $\mathcal{R}_m(p) = q$.

If AB is a segment with A on p and B on q with midpoint C, then $\mathcal{H}_C(p) = q$ by Theorem 7.5. Therefore, $\mathcal{H}_C(m) = m$ and C is on m. Another way to see this is to construct perpendicular segments AT and UB to form a rectangle as in Figure 12. ☐

Definition 7.18. For two parallel lines p and q, the **distance between** p **and** q is the length of any segment PQ perpendicular to p at P and to q at Q. The **midline of the two parallel lines** is the perpendicular bisector of any such PQ.

This distance and this line are well-defined, according to the theorem.

Consider the symmetries of a pair of parallel lines p and q. By the Transversal Theorem, Theorem 7.5, and the Midline Theorem, every point M on the midline is the center of a point symmetry $\mathcal{H}_M$. Also, the midline is a line of symmetry, the only one parallel to p and q. But every perpendicular transversal c is a line of symmetry, for $\mathcal{R}_c$ will map p to p and q to q (and also the midline to itself as well). It is also true that the products of these symmetries are also symmetries. We will see some of these products later in the chapter.

Midpoint Figures

For any triangle $\triangle ABC$, we encountered in Theorem 4.12 the triangle $\triangle DEF$ formed by the midpoints of the sides. More recently, in the proof of Theorem 7.2, we have seen that the images of $\triangle ABC$ by the half-turns centered at these midpoints create a triangle $\triangle A'B'C'$ that has the original $\triangle ABC$ as its midpoint triangle. All these triangles are shown in Figure 13. By Theorem 7.17, a midpoint line such as $\overline{DE}$ is the midline of the parallel lines $\overline{AB}$ and $\overline{A'B'}$.

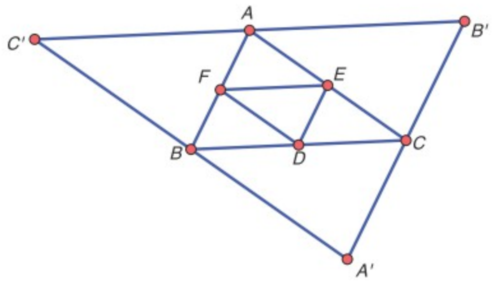

Figure 13. Midpoint Triangles

Such structures of triangles within triangles can be built up to create arbitrarily large triangles tiled with congruent triangles, such as the one in Figure 14 with eight triangles to a side. Within $\triangle ABC$ in this figure, if one takes a subtriangle such as $\triangle ADE$, one can see that the ratio of the length of DE to the length of BC is the same as AD/AB and AE/AC. Also one sees parallel lines and congruent angles such as $\angle ADE \cong \angle ABC$ in these triangles.

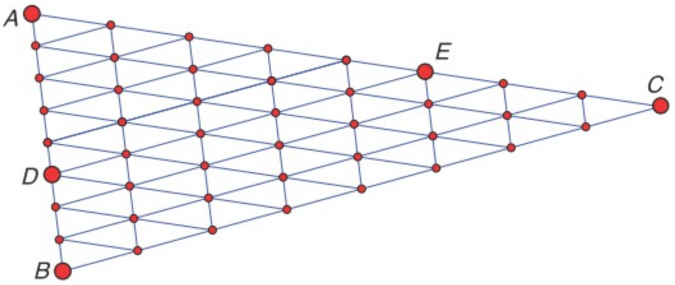

Figure 14. Triangle Tiled with Congruent Triangles

This suggests how, if one assumed the Euclidean Parallel Postulate as an axiom instead of our Axiom 6 , one could prove the Dilation Axiom as a theorem for rational ratios and then extend to real ratios using a limit argument similar to that used in the proof of Theorem 6.8 about the intersection of a line with a circle.

There are many other interesting features in this figure: parallelograms of different shapes and rigid motions that are products of half-turns. These rigid motions will be taken up in a few pages from now.

Midpoint Quadrilaterals. A quadrilateral $ABCD$ also has a midpoint figure $JKLM$. Unlike the case of triangles, this figure is not similar to the original quadrilateral. Instead, it is always a parallelogram.

Theorem 7.19 (Midpoint Parallelogram)**.** *For any quadrilateral ABCD, the midpoints of the sides are the vertices of a parallelogram.*

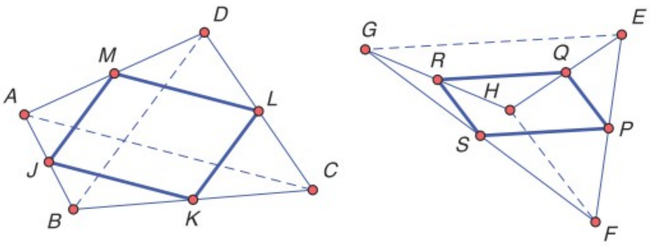

Figure 15. Midpoint Quadrilaterals

Proof. Assume that B and D are on opposite sides of $\overline{AC}$. Using the labels in Figure 15 for the midpoints, the segments JK and ML are segments parallel to and in the same direction as the diagonal AC. The lengths of these segments are both equal to $\|AC\|/2$.

Therefore, these segments are the opposite sides of a parallelogram if they are not collinear, but they cannot be collinear if B and D are on opposite sides of the diagonal. Thus, it only remains to check that for at least one of the diagonals, the other vertices are on opposite sides.

Given quadrilateral $ABCD$, if B and D are one the same side of $\overline{AC}$, then since the sides of the quadrilateral do not intersect, either D is in the interior of $\triangle ABC$ or B is in the interior of $\triangle ADC$. (This is to be proved in Exercise 7.) In either case, A and C are on opposite sides of $\overline{BD}$ so we should choose BD as the diagonal in the proof. $\square$

For some cases, the midpoint quadrilateral is a special kind of parallelogram. There is a question about this in the exercises. Also, in the exercises is a method for proving the concurrence of medians of a triangle using midpoint quadrilaterals.

Circumcircles of Right Triangles. Right triangles provide an interesting special case of midpoint triangles, as illustrated in Figure 16. Two of the midlines, $\overline{DF}$ and $\overline{EF}$, are perpendicular bisectors of legs. The parallelogram $CEFD$ is a rectangle.

From Theorem 7.8 we know the F, the intersection of these perpendicular bisectors, is the circumcenter of the triangle and is equidistant from the three vertices. This means that the segment AB is a diameter of the circumcircle.

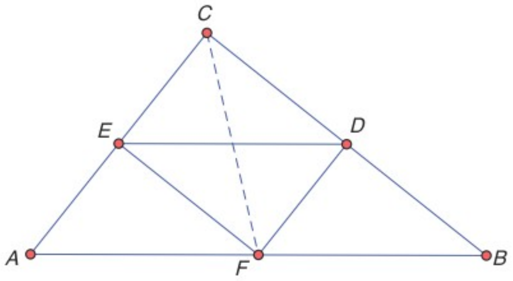

Figure 16. Midpoint Right Triangle

This leads to an important relationship between circles and right angles.

Theorem 7.20 (Right Angle Locus). *If $\triangle ABC$ has a right angle at C, then the midpoint F of AB is equidistant from all three vertices of the triangle. Therefore, C is a point on the circle with diameter AB.*

Conversely, if a segment AB is the diameter of a circle c, then for any point C on c distinct from A and B, $\angle ACB$ is a right angle.

In addition, $m\angle BFC = 2m\angle BAC$, where F is the midpoint of AB and the center of the circle.

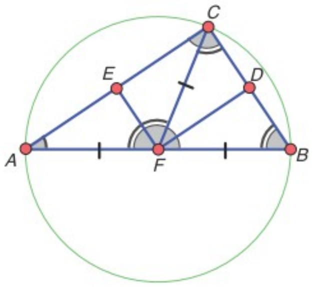

Figure 17. Congruent Angles in an Inscribed Right Triangle

Proof. We continue to use the same names for the points as in Figures 16 and 17.

The first statement was already proved in the comments above, using properties of rectangles.

To prove the second part of the theorem, take a triangle $\triangle ABC$ inscribed in a circle with diameter AB. This triangle is divided by CF into two isosceles triangles, which in turn can be divided into two right triangles. In Figure 17, congruent angles are marked.

Since the triangles $\triangle AFC$ and $\triangle CFB$ are isosceles, in each triangle the base angles are congruent. Let $a = m\angle FAC = m\angle FCA$ and $b = m\angle FBC = m\angle FCB$ be the measures of these base angles.

In $\triangle ABC$, the measure of the angle at C is the sum of two base angles, so $m\angle ACB = a + b$. But $m\angle BAC = a$ and $m\angle ABC = b$, so the sum of the angle measures of $\triangle ABC$ is $a + b + (a + b) = 2a + 2b = 180$, so that $90 = a + b = m\angle ACB$. Therefore, the angle at C is a right angle.

To prove the final equation of angles, $\angle CAB$ has measure a. The base angles in $\triangle BFC$ have measure b, so the central angle $\angle BFC$ has measure $180 - 2b = 2a$. □

Generalizing Parallelograms

One might ask if there is an "SSSS" test for parallelograms analogous to the SSS test for triangles. As many a do-it-yourselfer can attest, the answer is no. If one starts a bookcase by nailing four boards together to form a rectangle, it will be prone to collapse, for there are an infinite number of parallelograms with the same pair of side lengths. One needs some kind of cross-brace, such as a diagonal, to hold the shape.

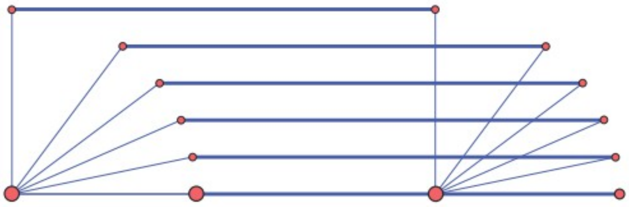

Figure 18. Collapsing Parallelograms with the Same Side Lengths

This can also be seen with delivery boxes. If one breaks out the bottom, the four sides form a parallelogram that collapses flat.

When we study translations in the next section, we will need such flattened parallelograms as well as ordinary parallelograms. So we extend our parallelogram definition with this additional one.

Definition 7.21. A **linear parallelogram** *ABCD* consists of four collinear points A, B, C, D with the midpoint M of AC being also the midpoint of BD. In other words, the figure has a point symmetry, with M as the center.

Theorem 7.22 (Linear Parallelogram)**.** *Let four collinear points A, B, C, D correspond to real numbers a, b, c, d, m by a ruler. Then $ABCD$ is a linear parallelogram if $a+c = b+d$, or equivalently if AB and DC have the same direction and length, meaning $b-a = c-d$. In that case, AD and BC also have the same direction and length, since $d - a = c - b$.*

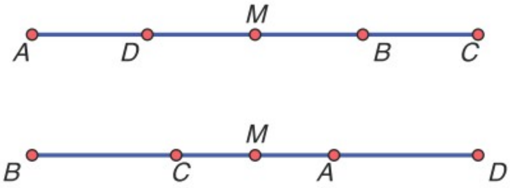

Figure 19. Two Linear Parallelograms *ABCD*

Proof. Working on the real line m using a ruler, the midpoint of AC corresponds to $(a + c)/2$ and the midpoint of BD corresponds to $(b + d)/2$. If these midpoints are the same point, then $a + c = b + d$, which implies the other equations. □

Such linear parallelograms can arise as limiting cases of well-known figures. For example, for a self-intersecting four-sided figure such at the ones in Figure 20, the midpoint figure may be a parallelogram or it may be a linear parallelogram. Some hints for a proof are in Exercise 8.

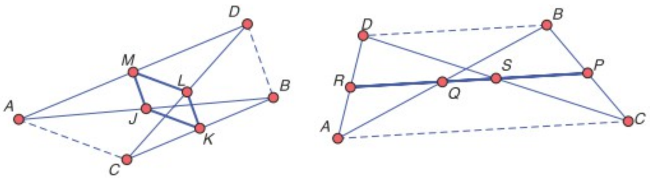

Figure 20. Midpoint Quadrilaterals for More General *ABCD*

The next theorem combines a uniqueness property of parallelograms with a test for congruence.

Theorem 7.23 (Fourth Parallelogram Point)**.** *Given three noncollinear points A, B, C, there is a unique point D so that $ABCD$ is a parallelogram. If A, B, C are collinear, there is a unique point D so that $ABCD$ is a linear parallelogram.*

Proof. Let M be the midpoint of AC and construct $D = \mathcal{H}_M(B)$. In the noncollinear case, this is a parallelogram since $\mathcal{H}_M$ is a symmetry. It is unique because for any parallelogram $ABCD$, it is true that $D = \mathcal{H}_M(B)$. The same reasoning applies to the collinear case. In this case, using a ruler and real numbers, the formula for $\mathcal{H}_M(B)$ is $2(a + c)/2 - b = a + c - b$. ☐

Corollary. *Two parallelograms $ABCD$ and $EFGH$ are congruent if two pairs of adjacent sides and one pair of included angles are congruent; e.g., $AB \cong EF$, $BC \cong FG$, and $\angle ABC \cong \angle EFG$. This applies to linear parallelograms as well.*

Proof. By SAS for triangles, there is a unique rigid motion T that maps $\triangle ABC$ to $\triangle EFG$. Let D be the unique point so that $ABCD$ is a parallelogram. Then the T-image of $ABCD$ is a parallelogram $EFGT(D)$. But H is the unique point so that $EFGH$ is a parallelogram, so $T(D) = H$. For linear parallelograms, the angle will be either a zero angle or a straight angle. ☐

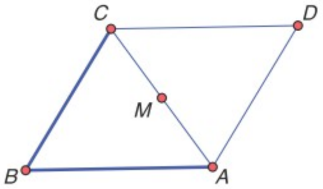

Figure 21. Constructing a Parallelogram from Two Sides and an Angle

Translations as Half-turn Products

In the study of parallels, we have used half-turns extensively to map one parallel segment to another. This was very efficient and effective for these purposes, but now we will use half-turns to expand our repertoire by defining the last well-known rigid motion, the translation.

Definition 7.24. A **translation** is a rigid motion that is the product of two half-turns.

An example of such a translation can be found in the parallelogram with midpoints in Figure 9. The rigid motion $T = \mathcal{H}_M\mathcal{H}_S$ maps AB to DC, since $\mathcal{H}_M\mathcal{H}_S(A) = \mathcal{H}_M(B) = D$ and $\mathcal{H}_M\mathcal{H}_S(B) = \mathcal{H}_M(A) = C$. In addition the rigid motions $\mathcal{H}_C\mathcal{H}_E$ and $\mathcal{H}_N\mathcal{H}_M$ also map AB to DC. We will see that these are all the same translation.

To get a general idea of how such a product of half-turns will behave, let A and B be distinct points and let P be any point. Then let $P' = \mathcal{H}_A(P)$ and $P'' = \mathcal{H}_B(P')$.

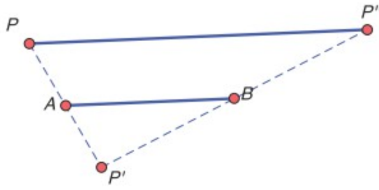

Figure 22. Translation of a Point as the Product of Half-turns

It is clear in Figure 22 that in $\triangle PP'P''$, the segment AB is a midsegment parallel to PP'', in the same direction and half its length. This shows that translations have a property not shared by rotations and reflections: the distance from any point to its image is always the same.

Before proceeding further, there is one observation about this translation that is already apparent. The line $\overleftrightarrow{AB}$ and all lines parallel to it are **invariant lines of the translation** $\mathcal{H}_B\mathcal{H}_A$. These are not lines of fixed points, but each point of such a line is mapped to another point of the same line. As we will see below, any other line is mapped into a line distinct from it but parallel.

Now consider the relationship between the images of P and those of another point Q. For now, assume a general case when no three of the points A, B, P, Q are collinear and PQ is not parallel to AB. These special cases will be addressed afterwards.

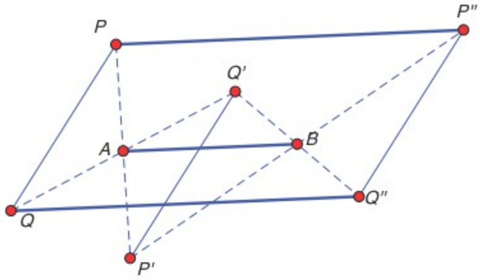

Figure 23. Translations of Two Points as the Product of Half-turns

Again, we observe that the segments PP'' and QQ'' are parallel and have the same length. Also, since half-turns map segments to parallel segments, the segments PQ, $P'Q'$, and $P''Q''$ are parallel, so $PP''Q''Q$ is a parallelogram.

It seems reasonable to expect that the special cases also result in a parallelogram or a linear parallelogram, and this is so. It can be checked using our definition of a translation as a product of half-turns, but instead we can use an important alternative definition of a translation as a product of line reflections.

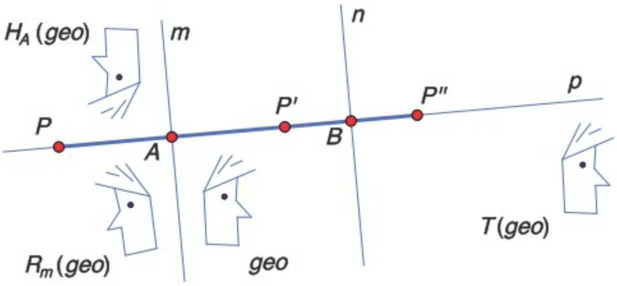

Figure 24. Translations of a Figure Named "geo" in Two Ways

Theorem 7.25 (Translations as Double Line Reflections). *For distinct points A and B, the translation $\mathcal{H}_B\mathcal{H}_A = \mathcal{R}_b\mathcal{R}_a$, where a and b are the lines perpendicular to $\overline{AB}$ at points A and B.*

Proof. The half-turn at A is the product of reflections in any two perpendicular lines at A, so one choice is $\mathcal{H}_A = \mathcal{R}_{AB}\mathcal{R}_a$. And at B, $\mathcal{H}_B = \mathcal{R}_b\mathcal{R}_{AB}$. Then $\mathcal{H}_B\mathcal{H}_A = \mathcal{R}_b\mathcal{R}_{AB}\mathcal{R}_{AB}\mathcal{R}_a = \mathcal{R}_b\mathcal{R}_a$. ☐

This gives a new perspective on the behavior of translations and a new tool. For any pair of parallel lines, the product $\mathcal{R}_b\mathcal{R}_a$ is a translation whose invariant lines are the perpendicular transversals of the parallel lines a and b.

Figure 24 shows the translation of a figure both by a product of half-turns and by the corresponding line reflections. They both terminate at the image of T, but the intermediate steps are quite different.

In addition, in this figure there are the same points P, P', and P'' as before, but this time on the line $\overline{AB}$. One can see how the lengths add up to $\|PP''\| = 2\|AB\|$.

With this definition it is not difficult to take care of the missing pieces.

Theorem 7.26 (Translation of a Segment). *If T is a translation distinct from I, then for any points P and Q, PQ and T(P)T(Q) are opposite sides of a parallelogram or linear parallelogram.*

Proof. Let $T = \mathcal{H}_B\mathcal{H}_A$. When needed, T can also be written as $T = \mathcal{H}_D\mathcal{H}_C$, where $ABDC$ is a rectangle, since $T = \mathcal{R}_{BD}\mathcal{R}_{AC}$.

We continue to use the notation in Figure 23: $P'' = T(P)$ and $Q'' = T(Q)$.

First, assume that PQ is not parallel to or collinear with AB. If neither P nor Q is on $\overline{AB}$, then from the discussion of Figure 23, it follows that $P''Q''$ is parallel to PQ, so $PQQ''P''$ is a parallelogram. In case either P or Q is on $\overline{AB}$, the proof can be carried out by a computation with rulers, but a simpler method is to use $T = \mathcal{H}_D\mathcal{H}_C$, where neither P nor Q is on $\overline{CD}$ and $ABDC$ is a rectangle.

In the case when PQ is parallel to or collinear with AB, let a and b be lines perpendicular to AB so that $T = \mathcal{R}_b\mathcal{R}_a$. Then each line reflection reverses direction on $\overline{PQ}$ and the segment $P''Q''$ is collinear with PQ and has the same direction and length. Therefore, by Theorem 7.22, $PQQ''P''$ is a linear parallelogram. □

This theorem has a very powerful corollary.

Corollary (One Point Determines Translation). *If T is a translation and if E and $F = T(E)$ are given, then T is completely determined. For any other point G, $T(G)$ is the unique point such that $GEFT(G)$ is a parallelogram or linear parallelogram.*

Notation. The unique translation that maps A to B will be denoted $\mathcal{T}_{AB}$. The AB in this notation is far from uniquely determined since for any point P and its translation image $Q = T(P)$, the translation is $\mathcal{T}_{PQ}$.

Products of Translations

This section is devoted to two properties of the products of translations: closure and commutativity.

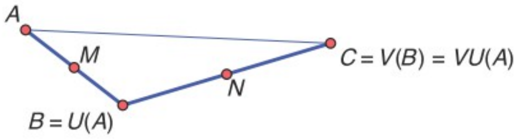

Figure 25. Translation UV

Theorem 7.27 (Closure). *The product of two translations is a translation. The product of a translation and a half-turn is a half-turn.*

In other words, the set of all translations of the plane is closed under composition. Also, the set of all half-turns and translations together is also closed under composition. Each of these sets has the group property. This fact will play a role in the symmetric patterns studied in Chapter 10.

Proof. Let U and V be translations. The task is to prove VU is also a translation.

Choose any point A. Then $U = \mathcal{T}_{AB}$ for $B = U(A)$ and $V = \mathcal{T}_{BC}$ for $C = V(B)$.

Let M be the midpoint of AB and let N be the midpoint of BC. Then $U = \mathcal{H}_B\mathcal{H}_M$ since $\mathcal{H}_B\mathcal{H}_M$ is a translation with $\mathcal{H}_B\mathcal{H}_M(A) = \mathcal{H}_B(B) = B$, so $\mathcal{H}_B\mathcal{H}_M = \mathcal{T}_{AB}$.

By similar reasoning $V = \mathcal{H}_N\mathcal{H}_B$, since $\mathcal{H}_N\mathcal{H}_B(B) = C$.

Multiplying these translations, $VU = \mathcal{H}_N\mathcal{H}_B\mathcal{H}_B\mathcal{H}_M = \mathcal{H}_N\mathcal{H}_M$. This is a translation that maps A to C, so $UV = \mathcal{T}_{AC}$.

To prove that the product of a translation and a half-turn is a translation, one uses the same ideas. Let the half-turn be $\mathcal{H}_B$ and the translation be $\mathcal{T}_{AB}$. Then continuing with the notation above, $\mathcal{H}_B\mathcal{T}_{AB} = \mathcal{H}_B\mathcal{H}_B\mathcal{H}_M = \mathcal{H}_M$. Likewise, $\mathcal{T}_{BC}\mathcal{H}_B = \mathcal{H}_N\mathcal{H}_B\mathcal{H}_B = \mathcal{H}_N$. □

The second theorem is a product property quite different from that for line reflections and most other products of rigid motions.

Theorem 7.28 (Commutativity). *Products of translations are commutative. For any translations S and T, $ST = TS$.*

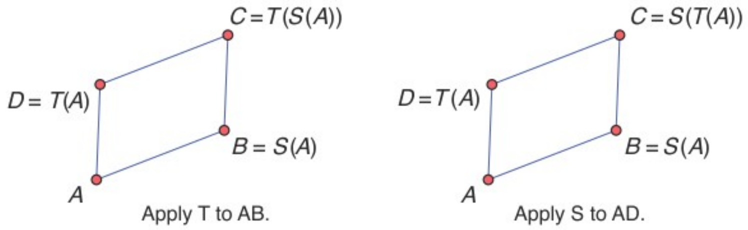

Figure 26. Commutative S and T

Proof. If either S or T is the identity, the theorem is immediate. For the rest of the proof, we assume neither translation is the identity. This proof works for linear parallelograms also. Take any point A and let $B = S(A)$ and $D = T(A)$.

Apply T to AB to get image $DT(B)$. Since $DT(B)$ is the image of AB by translation T, $DABT(B)$ is a parallelogram (or linear parallelogram), by Theorem 7.26. This is illustrated on the left side of Figure 26.

Now compare with a second construction of a parallelogram. Beginning with A and D, apply S to AD with image $BS(D)$. Then we have $DABS(D)$ is a parallelogram or linear parallelogram. This is illustrated on the right side of Figure 26.

Now we have two parallelograms with three points in common. So the fourth points $T(B)$ and $S(D)$ must be the same point C by Theorem 7.23. Therefore, $C = T(B) = TS(A)$ and $C = T(D) = ST(A)$. So $ST = \mathcal{T}_{AC} = TS$. □

Direction from Translation

Now that the theory of translations is well developed, one can use translations to rephrase or reframe some earlier ideas in a simpler and more flexible form.

Previously, the concept of same direction for two parallel rays $\overrightarrow{AB}$ and $\overrightarrow{CD}$ was defined in Definition 7.11 as the rays being on the same side of $\overline{AC}$. For collinear rays, the definition on page 14 was that one ray was contained in the other. In either case, for endpoint C there is a unique ray $\overrightarrow{CD}$ in the same direction as $\overrightarrow{AB}$. These definitions can be combined into one case using translations. With this definition, some equivalence properties of the direction relation for rays become clear.

Theorem 7.29 (Direction by Translation). *The rays $\overrightarrow{AB}$ and $\overrightarrow{CD}$ have the same direction if and only if $\mathcal{T}_{AC}$ maps $\overrightarrow{AB}$ to $\overrightarrow{CD}$. They have opposite direction if the half-turn $\mathcal{H}_M$ maps $\overrightarrow{AB}$ to $\overrightarrow{CD}$, where M is the midpoint of AC.*

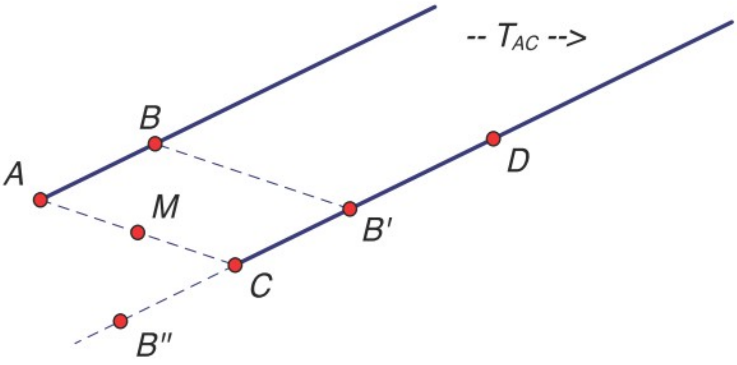

Figure 27. Rays with the Same Direction Related by Translation

Proof. Let M be the midpoint of AC. Then $\mathcal{T}_{AC} = \mathcal{H}_C\mathcal{H}_M$. Let $B' = \mathcal{T}_{AC}(B)$.

Consider when A, B, C are not collinear. The image $\mathcal{T}_{AC}(\overrightarrow{AB})$ is a ray with endpoint C parallel to $\overrightarrow{AB}$. Since $ACB'B$ is a parallelogram, B and B' are on the same side of $\overline{AC}$. Therefore, $\overrightarrow{CB'}$ is the unique ray with endpoint C in the same direction as $\overrightarrow{AB}$.

The ray opposite $\overrightarrow{CB'}$ is $\overrightarrow{CB''} = \mathcal{H}_C(\overrightarrow{CB'}) = \mathcal{H}_M(\overrightarrow{AB})$, where $B'' = \mathcal{H}_M(B)$.

The collinear case follows from a ruler computation since a translation adds a constant to each number and a half-turn reverses direction. □

Recall that the description of direction for rays carries over to directed segments and lines as well. Two segments AB and CD have the same direction if the rays $\overrightarrow{AB}$ and $\overrightarrow{CD}$ have the same direction.

The properties of translation make it straightforward to prove some informally evident properties of direction in this corollary.

Corollary. *These properties of direction follow from the theorem.*

(1) *If $\overrightarrow{CD}$ has the same direction as $\overrightarrow{AB}$, then $\overrightarrow{AB}$ has the same direction as $\overrightarrow{CD}$.*

(2) *If $\overrightarrow{CD}$ has the same direction as $\overrightarrow{AB}$ and $\overrightarrow{EF}$ has the same direction as $\overrightarrow{CD}$, then $\overrightarrow{EF}$ has the same direction as $\overrightarrow{AB}$.*

Here is a proof of the second item in the corollary. The assumption is that $\overrightarrow{CD} = \mathcal{T}_{AC}(\overrightarrow{AB})$ and $\overrightarrow{EF} = \mathcal{T}_{CE}(\overrightarrow{CD})$. Then since $\mathcal{T}_{CE}\mathcal{T}_{AC} = \mathcal{T}_{AE}$, $\overrightarrow{EF} = \mathcal{T}_{CE}\mathcal{T}_{AC}(\overrightarrow{AB}) = \mathcal{T}_{AE}(\overrightarrow{AB})$. The rest is left to the reader.

More Parallelograms. This next proposition unifies with translation language some earlier statements about parallel segments proved in Theorems 7.12 and 7.22.

Theorem 7.30 (Direction and Congruent Segments)**.** *Let* AB *and* CD *be congruent segments. If they have the same direction, then* $\mathcal{T}_{AC}$ *maps* AB *to* CD *and* $ABDC$ *is a parallelogram or linear parallelogram. If they have opposite direction, then* $\mathcal{H}_M$ *maps* AB *to* CD*, where* M *is the midpoint of* AC*. In this case* $ABCD$ *is a parallelogram or linear parallelogram.*

As an application of this theorem, we prove a theorem about an adjoining pair of parallelograms.

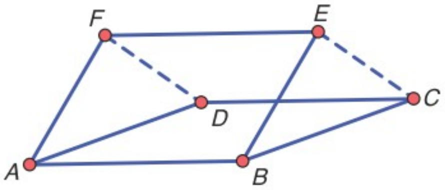

Figure 28. Two Linked Parallelograms Imply a Third

Theorem 7.31 (Third Parallelogram)**.** *Given figures* $ABCD$ *and* $ABEF$*, each a parallelogram or linear parallelogram, the figure* $DCEF$ *is a parallelogram if the lines* $\overline{CD}$ *and* $\overline{EF}$ *are distinct and it is a linear parallelogram if they are equal.*

Proof. Since $ABCD$ is a parallelogram or linear parallelogram, translation $\mathcal{T}_{AB}$ maps D to C. By the same reasoning for $ABEF$, $\mathcal{T}_{AB}$ maps F to E. By Theorem 7.30, this means that $CDFE$ is a parallelogram or a linear parallelogram. ☐

In addition to parallelograms formed by segments and their images, the following theorem is also true.

Theorem 7.32 (Four Half-turn Centers)**.** *The translation* $\mathcal{H}_F\mathcal{H}_E = \mathcal{H}_H\mathcal{H}_G$ *if and only if* $EFHG$ *is a parallelogram or linear parallelogram.*

Proof. From Theorem 7.25, it follows that EF and GH are either parallel or collinear. The hypothesis is equivalent to $\mathcal{H}_G\mathcal{H}_H\mathcal{H}_F\mathcal{H}_E = I$ and this is equivalent to $\mathcal{H}_H\mathcal{H}_F = \mathcal{H}_G\mathcal{H}_E$. Therefore, if the points are not collinear, then FH is parallel to EG, so $EFHG$ is a parallelogram. The linear case follows from a coordinate computation. ☐

Direction and Rotation from Polar Angle

In Chapter 2 protractors and polar angles at a point were introduced. Later, in Definition 5.6, the choice of a protractor at a point A determined signed angle measure $m^+\angle BAC$ as a difference of polar angles. But there was no way to relate polar angles between any two points of the plane. But now, using translations, these angles and measures can be extended uniformly to the whole plane.

Definition 7.33. A **global protractor** δ_* on the plane is a set of protractors δ_P at each point P such that for any real t and any points A and C, $\delta_C(t) = \mathcal{T}_{AC}(\delta_A(t))$.

Given such a global protractor, let $\theta(\overrightarrow{AB})$ denote the polar angle of $\overrightarrow{AB}$ corresponding to δ_A, the protractor at A. For any point C, if $\overrightarrow{CD} = \mathcal{T}_{AC}(\overrightarrow{AB})$, then $\theta(\overrightarrow{CD}) = \theta(\overrightarrow{AB})$ because $\delta_C(\theta(\overrightarrow{AB})) = \mathcal{T}_{AC}\delta_A(\theta(\overrightarrow{AB})) = \mathcal{T}_{AC}(\overrightarrow{AB}) = \overrightarrow{CD}$. Conversely, if these polar angles are equal, by the same relationship $\overrightarrow{CD} = \mathcal{T}_{AC}(\overrightarrow{AB})$.

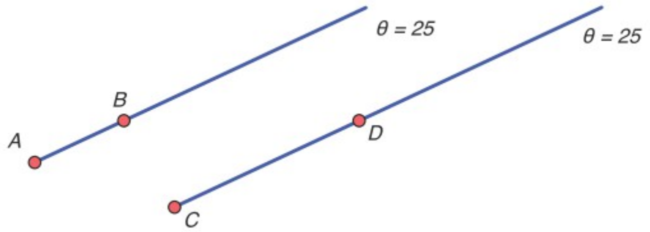

Figure 29. Rays with the Same Direction and Polar Angle

This observation proves the following theorem.

Theorem 7.34 (Direction and Global Polar Angle). *Given a global protractor δ_*, two rays $\overrightarrow{AB}$ and $\overrightarrow{CD}$ have the same direction if and only if they have the same polar angles $\theta(\overrightarrow{AB})$ and $\theta(\overrightarrow{CD})$.*

This implies that two lines $\overline{AB}$ and $\overline{CD}$ are parallel if and only if $\theta(\overrightarrow{AB})$ and $\theta(\overrightarrow{CD})$ are equal or differ by 180 degrees, depending on whether the two rays have the same or opposite direction.

This relationship between polar angles and translation can be used to construct a global protractor from a protractor at a single point.

Theorem 7.35 (Existence of Global Protractors). *For a protractor δ_A at any point A, there is a global protractor δ_* defined by $\delta_C(t) = \mathcal{T}_{AC}(\delta_A(t))$ for all points C.*

Proof. The theorem defines a function δ_C for every C. It must be shown that this function is in fact a protractor at C. For any rays $\overrightarrow{CP}$ and $\overrightarrow{CQ}$, choose values of θ so that $|\theta(\overrightarrow{CP}) - \theta(\overrightarrow{CQ})| \leq 180$. For δ_C to be a protractor, this absolute value must equal $m\angle PCQ$.

Let $\overrightarrow{AP'}$ and $\overrightarrow{AQ'}$ be the images of these rays by translation $\mathcal{T}_{CA}$. The polar angles $\theta(\overrightarrow{CP})$ and $\theta(\overrightarrow{CQ})$ are the same as $\theta(\overrightarrow{AP'})$ and $\theta(\overrightarrow{AQ'})$. Since δ_A is known to be a protractor, $m\angle P'AQ' = |\theta(\overrightarrow{AP'}) - \theta(\overrightarrow{AQ'})| = |\theta(\overrightarrow{CP}) - \theta(\overrightarrow{CQ})|$. Because translations are rigid motions, $m\angle P'AQ' = m\angle PCQ$. Thus δ_C has the properties of a protractor.

What remains to be proved is that any two points satisfy the global protractor relation. If E is another point, then $\delta_E(t) = \mathcal{T}_{CE}(\delta_C(t))$ for every t. By the definition in the theorem statement, $\delta_C(t) = \mathcal{T}_{AC}(\delta_A(t))$, so $\delta_A(t) = \mathcal{T}_{CA}(\delta_C(t))$, since $\mathcal{T}_{CA} = \mathcal{T}_{AC}^{-1}$. Then $\delta_E(t) = \mathcal{T}_{AE}(\delta_A(t)) = \mathcal{T}_{AE}\mathcal{T}_{CA}(\delta_C(t)) = \mathcal{T}_{CE}(\delta_C(t))$, since $\mathcal{T}_{AE}\mathcal{T}_{CA} = \mathcal{T}_{CE}$. ☐

By choosing a global protractor on the plane, one can simplify relationships. For example, in Chapter 5, to define an orientation on the plane without translations, one had to compare protractors along various line segments. With a global protractor, the positive (counterclockwise) rotation direction is determined at every point by the protractor at the point.

Another example, concerning rotations of rays, is given in the next paragraphs.

Direction and Rotation. With a protractor one can measure both unsigned and signed angles at a point P. Assume P_k is a rotation with rotation angle k, with k chosen so that $|k| \leq 180$. We know from Definitions 5.5 and 5.6 that for any ray $\overrightarrow{PQ}$, if $Q' = P_k(Q)$, then $m\angle QPQ' = |k|$ and $m^+\angle QPQ' = k$.

With a global protractor, the same result is true for rays with endpoints different from P.

Theorem 7.36 (Polar Angle Rotation)**.** *Given a global protractor δ_* let a rotation P_k map a ray $\overrightarrow{AB}$ to $\overrightarrow{A'B'}$. Then $\theta(\overrightarrow{A'B'}) = \theta(\overrightarrow{AB}) + k$. If $0 < |k| < 180$, the lines $\overline{AB}$ and $\overline{A'B'}$ intersect at a point C forming an angle of measure $|k|$. More specifically, the lines form an angle $\angle DCE$, where $\overrightarrow{CD} = \mathcal{T}_{AC}(\overrightarrow{AB})$ and $\overrightarrow{CE} = \mathcal{T}_{A'C}(\overrightarrow{A'B'})$, with $m\angle DCE = |k|$ and $m^+\angle DCE = k$.*

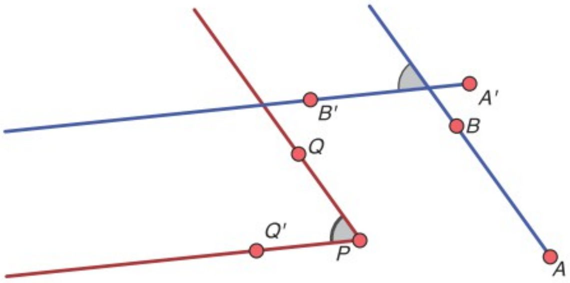

Figure 30. Polar Angle Change by a Ray Rotated about Center P

Proof. The ray $\overrightarrow{AB}$ has the same direction as a ray $\overrightarrow{PQ}$. The rotation maps these rays to a pair of rays $\overrightarrow{A'B'}$ and $\overrightarrow{PQ'}$ that also have the same direction, as illustrated in Figure 30. Therefore, $\theta(\overrightarrow{A'B'}) = \theta(\overrightarrow{PQ'}) = \theta(\overrightarrow{PQ}) + k = \theta(\overrightarrow{AB}) + k$.

If $0 < |k| < 180$, by Theorem 7.34, the lines $\overline{AB}$ and $\overline{A'B'}$ are not parallel so they intersect at a point C.

The ray $\overrightarrow{CD} = \mathcal{T}_{AC}\mathcal{T}_{PA}(\overrightarrow{PQ}) = \mathcal{T}_{PC}(\overrightarrow{PQ})$ and $\overrightarrow{CE} = \mathcal{T}_{AC}(\overrightarrow{PQ'})$, so the translation $\mathcal{T}_{PC}$ takes $\angle QPQ'$ to $\angle DCE$ so the angles have the same measure and signed measure. ☐

This theorem allows one to deduce the nature of products of even (orientation-preserving) rigid motions. An even rigid motion is a rotation with rotation angle k or else a translation, which can be assigned rotation number 0 since translations do not change polar angles. Let T_1 and T_2 be even rigid motions with rotation angles k_1 and

k_2. The product T_2T_1 changes the polar angle of a ray by adding $k = k_1 + k_2$. If $k = 0$ (mod 360), the product is a translation. Otherwise, it is a rotation with rotation angle k but center unknown from this information. Such products will be studied, and the centers of rotation located, in Theorem 10.2.

Symmetries of a Pair of Parallel Lines. Some symmetries of a pair of parallel lines p and q were listed after the Midline Theorem, Theorem 7.17. One line of symmetry was the midline m. The others were reflections in perpendicular transversals and also half-turns with centers on m. It was also mentioned that products of these symmetries are symmetries. Now we know that products of reflections in two perpendicular transversals are translations in a direction parallel to p and q. This is also true of the products of half-turns centered on m. So any translation with direction parallel to these lines is a symmetry.

There is one other reflection product that has not been considered yet. This is the **glide reflection**. A glide reflection is defined to be the product of a line reflection and a translation parallel to the line of reflection. In the case of parallel lines, every glide reflection symmetry is the product of a translation symmetry and $\mathcal{R}_m$. Such a product will translate the lines and then interchange p and q. It is also true that a product of a half-turn symmetry and one of the perpendicular line reflections is also a glide reflection, a different way of writing the same symmetries. Glide reflections will be discussed in detail in Chapter 10.

All these rigid motions are also the symmetries for a single line p, provided one takes $m = p$.

Vectors

When a translation can be written two different ways, as $\mathcal{T}_{AB} = \mathcal{T}_{CD}$, this means that AB and CD are congruent segments with the same direction. This is another case when a relationship is an equivalence relation, and this one is extremely useful in math and science and engineering.

Definition 7.37. Two segments AB and CD represent the same **vector** if $\mathcal{T}_{AB} = \mathcal{T}_{CD}$. The notation for this relation will be $[AB] = [CD]$.

Our use of $[AB]$ to denote a vector is not standard notation. The vector $[AB]$ is usually denoted by an arrow on top, as $\overrightarrow{AB}$, but we are using this notation for rays.

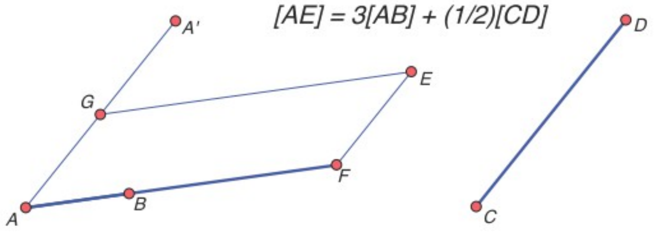

Figure 31. Vector Addition and Multiplication by Real Numbers

It is easy to see from this definition that the vector relation has these equivalence properties.

- For all vectors, $[AB] = [AB]$.
- If $[AB] = [CD]$, then $[CD] = [AB]$.
- If $[AB] = [CD]$ and $[CD] = [EF]$, then $[AB] = [EF]$.

For the last item, given $CD = \mathcal{T}_{AC}(AB)$ and $EF = \mathcal{T}_{CE}(CD)$, then $EF = \mathcal{T}_{CE}\mathcal{T}_{AC}(AB) = \mathcal{T}_{AE}(AB)$.

The vector, the set of equivalent segments, is viewed as an object. Geometrically, the vector can be represented as an arrow with tail at A and head at B. But it is also represented by an infinite number of other arrows, each one with the same length and the same direction. All such arrows are translations of each other.

It is not yet clear just from this definition what value is gained by this concept, especially since the set of vectors is in one-to-one correspondence with the set of translations. We will see vectors in action in later chapters.

There are some operations with vectors that we can define now. The first is addition. If $\mathcal{T}_{CD}\mathcal{T}_{AB} = \mathcal{T}_{EF}$, then $[AB] + [CD] = [EF]$. In particular, since $\mathcal{T}_{BC}\mathcal{T}_{AB} = \mathcal{T}_{AC}$, then $[AB] + [BC] = [AC]$, as pictured in Figure 25. Also, in Figure 26, $[AB] + [AD] = [AC]$. This shows what is called the parallelogram law of addition.

The vector $[AA]$ acts as the zero for this addition; it can just be written as 0. Reversing the segment order is the additive inverse: $[AB] + [BA] = [AA] = 0$. Vector addition is commutative by Theorem 7.28.

The other important vector operation is the multiplication of a vector by a real number. If $r > 0$, the vector $r[AB]$ is the vector CD, where AB and CD have the same direction, but $\|CD\| = r\|AB\|$. If $r < 0$, the direction is reversed and $r[AB] = |r|[BA]$. Also, $0[AB] = 0$.

These operations are illustrated in Figure 31. The vector $[AA'] = [CD]$, $[AG] = (1/2)[CD]$, $[AF] = 3[AB]$, and $[AE] = 3[AB] + (1/2)[CD]$.

Exercises and Explorations

1. (Regular Polygon Angle). Derive the formula for the angles of a regular n-gon.
2. (Quadrilateral with Lines of Symmetry). Show that a quadrilateral with two perpendicular lines of symmetry is either a rectangle or a rhombus.
3. (Intersecting Railroad Tracks). Suppose m and n are parallel lines with distance d between them, and suppose p and q are also parallel lines with the same distance d between them. If the parallel pairs intersect, tell what kind of quadrilateral their intersection points define and prove your claim.

4. (Circles and Parallelograms). Two problems:
   (a) Suppose parallelogram *ABCD* is inscribed in circle *c*. What properties must it have? Must it be a special kind of parallelogram? If so, what kind?
   (b) Suppose a circle *c* is inscribed in a parallelogram *ABCD*. What properties must *ABCD* have? Must it be a special parallelogram? If so, what kind?

5. (Midpoint Quadrilaterals). Theorem 7.19 proves that the midpoint quadrilateral *JKLM* of any quadrilateral *ABCD* is a parallelogram. Some of the figures below have midpoint quadrilaterals that are special kinds of parallelograms. Tell what they are and justify your answer.
   (a) A kite
   (b) A rhombus
   (c) A parallelogram
   (d) A rectangle
   (e) A square

6. (Midpoint Quadrilateral Symmetry). For the quadrilaterals in the previous problem, describe the set of all symmetries of the midpoint figure. Then answer these questions.
   (a) Is every symmetry of *ABCD* also a symmetry of the midpoint quadrilateral *JKLM*?
   (b) Is every symmetry of the midpoint quadrilateral *JKLM* also a symmetry of *ABCD*?
   (c) In either case, if yes, why? If not, is there any other relationship between the groups of symmetries?

7. (Nonconvex Quadrilaterals). In the proof of Theorem 7.19 it was asserted for a quadrilateral *ABCD* that if *B* and *D* are on the same side of $\overline{AC}$, then either *D* is in the interior of $\triangle ABC$ or *B* is in the interior of $\triangle ADC$ because the sides of the quadrilateral do not intersect except at the vertices. Prove this. Hint: Consider the regions of the plane created by the extended sides of $\triangle ABC$. Where can *D* be?

8. (A More General Midpoint Quad). In Figure 32 there is an example on the right of an *ABCD* that is not a parallelogram but for which the midpoint figure *JKLM* is still a parallelogram. Use what we have learned about translations to prove that if *ABCD* is not assumed to be a quadrilateral but is just four distinct points, then

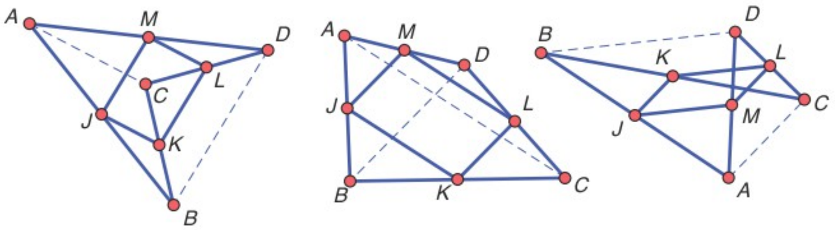

Figure 32. Quadrilateral Midpoints

the midpoint figure $JKLM$ is still either a parallelogram or a linear parallelogram. Hint: Prove the translations $\mathcal{H}_K\mathcal{H}_J$ and $\mathcal{H}_L\mathcal{H}_M$ are equal because they agree at a point. What does this say about $JKLM$?

9. (Translation Experiments). Here are some translation experiments using the midpoint triangle in Figure 13. You may need to sketch your own copy. Answer with points already labeled if possible, but describe and label some new points if needed.
   (a) What point is $\mathcal{T}_{CF}(F)$? How do you know?
   (b) Describe the image $\mathcal{T}_{CF}(\triangle DEF)$.
   (c) Tell some points P and Q for which $\mathcal{T}_{PQ} = \mathcal{H}_E\mathcal{H}_D$.
   (d) Tell some points P and Q for which $\mathcal{T}_{PQ} = \mathcal{T}_{BA}\mathcal{T}_{DF}$.
   (e) For what point P is $\mathcal{H}_P = \mathcal{H}_A\mathcal{H}_E\mathcal{H}_D$?

10. (Fourth Parallelogram Point). Given a parallelogram $ABCD$, we know from Theorem 7.23 that D is uniquely determined when given A, B, C. But the parallelogram $ACBE$, with the same three points in different order, is a different quadrilateral. Choose any noncollinear points A, B, C. Then draw all the parallelograms with these three points as vertices.

11. (Tiled Triangle). The triangle tiled with triangles in Figure 14 was created assuming the Euclidean Parallel Postulate as a theorem. By subdividing further with repeated midpoint triangles and taking limits, this tiled triangle suggests how the Dilation Axiom could be proved by assuming EPP as a postulate instead of the reverse, as we have done.
   (a) Check that the AD/AB and AE/AC equal $\|DE\|/\|BC\|$. Check that $\angle ABC \cong \angle ADE$ and $\angle ACB \cong \angle AED$. Thus, for this example, ratios and angles are preserved.
   (b) The ratios involved are also related to area, or equivalently, to the number of triangles in various figures. What is the total number of small triangles in $\triangle ABC$? What is the number in $\triangle ADE$? How is this related to the ratios of lengths?
   (c) Let $A' = \mathcal{T}_{EC}(A)$ and $D' = \mathcal{T}_{EC}(D)$. Tell how many small triangles are in each of these polygons: $\triangle DBD'$, $\triangle A'D'C$, quadrilateral $ADD'A'$. How are these numbers related to ratios of length?

12. (Parallelograms that Are Rectangles). It was observed that rectangles have congruent diagonals and right vertex angles. Prove these converses.
   (a) Any parallelogram with congruent diagonals is a rectangle.
   (b) Any parallelogram with one vertex angle that is a right angle is a rectangle.

13. (Concurrence of Medians). A median of a triangle is a segment from a vertex to the midpoint of the opposite side. This is the first of several proofs of a theorem about medians of a triangle.
   (a) In a triangle $\triangle ABC$, let the medians be AD, BE, and CF. Let G be the intersection of BE and CF. Consider the midpoint quadrilateral of $ABGC$ and use it to find these ratios: BG/BE and CG/CF.
   (b) Let H be the intersection of BE and AD. Find the ratios BH/BE and AH/AD.
   (c) Explain how these two results prove that the three medians are concurrent at $G = H$.

14. (Translations as Products of Line Reflections). In Figure 33 the large triangle is mapped by one product of two line reflections and the small triangle by another, but the different products are the same translation. Prove that products of reflections in parallel lines $\mathcal{R}_n\mathcal{R}_m$ and $\mathcal{R}_{n'}\mathcal{R}_{m'}$ are equal if and only if there is a translation T such that $T(m) = m'$ and $T(n) = n'$.

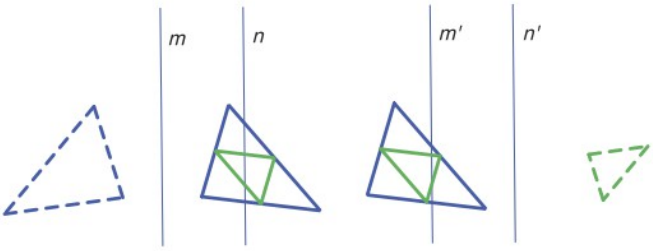

Figure 33. A Translation Shown as Two Different Double Line Reflections

15. (Rotating One Ray to Another). Let $\overrightarrow{AB}$ and $\overrightarrow{CD}$ be two rays that do not have the same direction. Prove that there is a unique rotation P_k that maps $\overrightarrow{AB}$ to $\overrightarrow{CD}$. Hint: How did we prove congruence of segments?
16. (Invariant Lines). A line m is an **invariant line** for a rigid motion T if $T(m) = m$. If the points of the line are all fixed points, the line is invariant, but in general the points of the line will not all be fixed.
    (a) For a reflection $\mathcal{R}_n$, find all the invariant lines, in addition to n. Explain your reasoning.
    (b) For a half-turn $\mathcal{H}_A$, find all the invariant lines. Explain your reasoning.
    (c) For a translation $\mathcal{T}_{AB}$, find all the invariant lines. Explain your reasoning.
    (d) For a glide reflection $\mathcal{G}_{AB}$, find all the invariant lines. Explain your reasoning.
    (e) For a rotation A_{60}, find all the invariant lines? Explain your reasoning.
17. (Transformation Groups). Transformation groups were defined in Definition 5.10. Tell which of the following sets are transformation groups and justify your answer:
    (a) the set of all translations,
    (b) the set of all half-turns,
    (c) the set of all transformations that are either half-turns or translations,
    (d) for a given line m, the set of all translations that map this line into itself,
    (e) for a given ray $\overrightarrow{AB}$, the set of all translations that map this ray into itself.

Chapter 11

Coordinate Geometry

Coordinates attach numbers to points in such a way that algebra can be used to investigate geometry. In the 17th century, Fermat and Descartes developed the beginnings of the coordinate systems that are so familiar today.

To express rigid motions and distance and angle relationships, we will want a Cartesian coordinate system with perpendicular axes and rulers on each axis. But there are applications that do not require such a restricted coordinate system, so we begin more simply with parallel lines and ratios to define what are called affine or linear coordinates. Then we develop formulas for half-turns and translations and equations for lines in affine coordinates. Afterwards, for the metric part of Euclidean geometry, we will restrict ourselves to Cartesian coordinates, which are coordinates with more constraints on angles and distances.

The introduction of coordinates will connect the abstract model of the plane developed up to now with algebra and the (x, y)-plane $\mathbb{R}^2$. This will provide some new algebraic tools for studying geometry, but the geometry will also provide insight into the algebra.

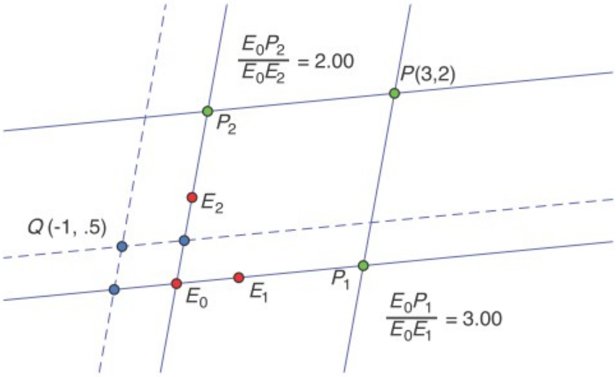
Axes and Coordinates

In the plane, take a triangle $\triangle E_0E_1E_2$ as the reference triangle for a system of coordinates based on parallel lines and signed ratios.

On the line $\overline{E_0E_1}$, let $x(P) = E_0P/E_0E_1$. This ratio is a coordinate proportional to a ruler on the line, with $x(E_0) = 0$ and $x(E_1) = 1$. In the same way, on $\overline{E_0E_2}$, let $y(P) = E_0P/E_0E_2$.

The first axis, or x-**axis**, of the coordinate system is $\overline{E_0E_1}$; the second axis, or y-**axis**, is $\overline{E_0E_2}$. The **origin** of the system is the point E_0.

For any point P in the plane, let p_1 be the line through P parallel to or equal to the y-axis. This line intersects the x-axis at a point P_1. Define $x(P) = x(P_1)$.



$\frac{E_0P_2}{E_0E_2} = 2.00$
P(3,2)
P_2
E_2
Q (-1, .5)
E_0
E_1
P_1
$\frac{E_0P_1}{E_0E_1} = 3.00$

Figure 1. Axes, Parallel Lines, and Coordinates

Again, in the same way, let p_2 be the line through P parallel to the x-axis, intersecting the y-axis at P_2. Define $y(P) = y(P_2)$. The figure $E_0P_1PP_2$ is a parallelogram (or linear parallelogram).

Define the **affine coordinates** of P with respect to this reference triangle, or axis system, to be the pair $(x(P), y(P))$.

Figure 1 shows two points and their coordinates, the point P with coordinates $(3, 2)$ and Q with coordinates $(-1, .5)$.

The coordinates (x, y) define a map of the plane to real 2-space $\mathbb{R}^2$. So long as the coordinate system remains unchanged, we will refer to points by their coordinates, either as $P(2, 3)$ or even by saying $P = (2, 3)$.

Equations for other lines will come soon, but from the definition of coordinates, it is clear that $x = 2$ is the equation of a line parallel to the y-axis, and $y = 3$ is the equation of a line parallel to the x-axis.

Note (Terminology)**.** We have called these coordinates affine coordinates, but such (x, y)-coordinates may also be called linear coordinates. What is the difference? For affine coordinates we must specify three points, the origin and then the unit points on the axes. Linear coordinates have the same definition except that they occur in a space where the origin is already understood, such as $\mathbb{R}^2$, where $(0, 0)$ is normally taken to be the origin, or the vectors in the plane, where the zero vector is understood to be the origin. However, this can seem to be a very fine distinction once an origin E_0 has been settled on and designated as O.

Midpoints, Half-turns, and Translations

For any two points A and B on the plane, one can find the coordinates of the midpoint of AB using what has been proved about parallelograms and parallels. The figure is full of overlapping parallelograms that can be used to prove this formula, but $\overline{AB}$ is also a transversal of two sets of parallel lines (if it is not parallel to an axis), so the Transversal Ratios Theorem, Theorem 8.17 can be applied.

3: D 4 7 +))) A

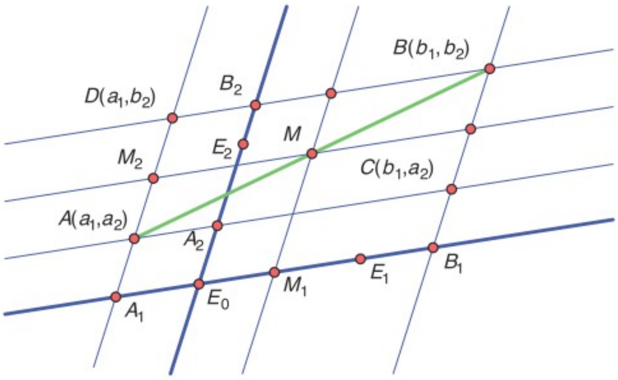


Figure 2. Parallelograms and Midpoints

Theorem 11.1 (Midpoint Formula). *In linear coordinates, the formula for the midpoint M of AB is*

$$(x(M), y(M)) = \frac{1}{2}(x(A) + x(B), y(A) + y(B)).$$

This can also be written more compactly as

$$M = \frac{1}{2}(A + B)$$

where a sum of points here means a sum of number pairs.

Proof. Let $A = (a_1, a_2)$ and $B = (b_1, b_2)$. A point M is the midpoint of AB when the signed ratio $AM/BM = -1$. If AB is not parallel to the y-axis, Theorem 8.17 says that ratios are preserved, so $A_1M_1/B_1M_1 = -1$ and M_1 is also a midpoint. The midpoint of A_1B_1 has coordinate $(1/2)(a_1 + b_1, 0) = (1/2)(x(A) + x(B))$, since the signed ratio

$$\frac{(1/2)(a_1 + b_1) - a_1}{(1/2)(a_1 + b_1) - b_1} = \frac{b_1 - a_1}{a_1 - b_1} = -1.$$

For the case when AB is parallel to the y-axis, then $M_1 = A_1 = B_1$, so the x-coordinates are all equal and it remains true that $x(M) = (1/2)(x(A) + x(B))$.

The same reasoning applies to the other axis so $y(M) = (1/2)(y(A) + y(B))$. ☐

A formula for any half-turn is an immediate consequence of the midpoint formula.

Theorem 11.2 (Half-turn Formula). *For any half-turn $\mathcal{H}_P$, the formula for the image of a point A is $\mathcal{H}_P(A) = 2P - A$.*

Proof. This is the midpoint formula rearranged. If $B = \mathcal{H}_P(A)$, then P is the midpoint of AB, so $P = (1/2)(A + B)$. If A and P are known, this becomes a formula for the image of A: $B = 2P - A$. ☐

Figure 3 shows examples of $\mathcal{H}_P$ for $P(0, 2)$. If $D = (-1, 1)$, then $\mathcal{H}_P(D) = 2(0, 2) - (-1, 1) = (1, 3)$ and $\mathcal{H}_P(E_1) = 2(0, 2) - (1, 0) = (-1, 4)$.

3: D 4)) 4)) + +*

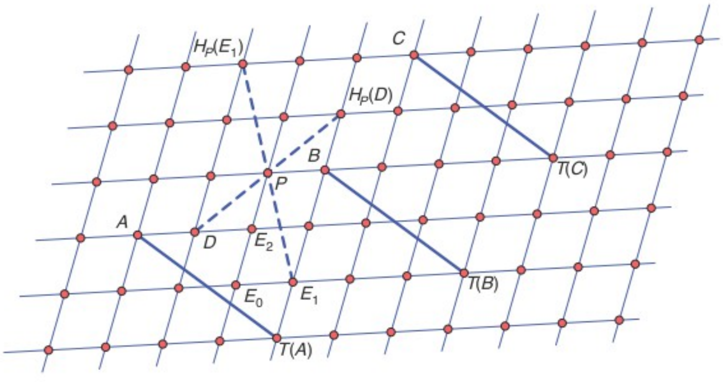

Figure 3. Examples: A Half-turn and a Translation

Since translations are compositions of half-turns, this also provides a formula for translations.

Theorem 11.3 (Translation Formula)**.** *The formula for translation* $T = \mathcal{H}_B\mathcal{H}_A$ *is* $T(P) = P + 2(B - A)$. *If* T *is written as* $\mathcal{T}_{CD}$, *then* $T(P) = P + (D - C)$.

Proof. The first formula is simply a substitution: $\mathcal{H}_B\mathcal{H}_A(P) = \mathcal{H}_B(2A - P) = P + 2(B - A)$. If $T(C) = D$, then $D = C + 2(B - A)$. □

The example in Figure 3 shows $T(A) - A = (1, -1) - (-2, 1) = (3, -2)$. Then $T(B) = (1, 2) + (3, -2) = (4, 0)$ and $T(C) = (2, 4) + (3, -2) = (5, 2)$. The translation is represented by three directed segments that are translates of one another.

The translation formula suggests a way to represent vectors by means of number pairs. Since $\mathcal{T}_{AB} = \mathcal{T}_{CD}$ if and only if $B - A = D - C$, then representing $[AB]$ with the number pair $B - A$ would be consistent with the vector concept that two vectors are equal if their associated translations are equal. In the example in Figure 3, $T = \mathcal{T}_v = \mathcal{T}_{[3,-2]}$.

This list of formulas has a lot of consequences, some of which we have seen before and some not.

As a starting point, consider what the translation formula means for parallelograms. We learned in Theorem 7.30 that $ABCD$ is a parallelogram (or linear parallelogram) if and only if the segment DC is a translate of AB. This means that $C = \mathcal{T}_{AD}(B)$, or $C - B = D - A$. This is consistent with the fact that the midpoints of the diagonals are the same: $(1/2)(A + C) = (1/2)(B + D)$.

Theorem 7.19 proved that the midpoint quadrilateral $JKLM$ of any quadrilateral $ABCD$ is a parallelogram. Using coordinates and the midpoint formula, the following computation shows $JKLM$ is a parallelogram or linear parallelogram for any four points A, B, C, D (with the caveat that a pair of sides may have length 0 if $J = K$ or $J = M$):

$$J - K = \frac{1}{2}(A + B) - \frac{1}{2}(B + C) = \frac{1}{2}(A - C) = \frac{1}{2}(A + D) - \frac{1}{2}(D + C) = M - L.$$

Lines, Dilations, and Equations

How are lines represented in this coordinate system? Let's begin with lines through the origin E_0. Also, since we will be referring to the origin a lot, to avoid so many subscripts, let's use O as another name for this point.

In thinking about points on a line through the origin O, it is natural to think of dilations with center O. For every t, the dilations $\mathcal{D}_{O,t}(P)$ lie on $\overleftrightarrow{OP}$; in fact, every point on this line is one of these dilation images. What are the coordinates of these points?

Theorem 11.4 (A Dilation Formula). *If* $P = (a, b)$*, then* $\mathcal{D}_{O,t}(P) = (ta, tb)$*. In more compact notation,* $\mathcal{D}_{O,t}(P) = tP$*.*

Proof. For P, consider the coordinate parallelogram OP_1PP_2 from Figure 1. The dilation not only maps P to a point, it also maps the entire parellogram to a new coordinate parallelogram.

For example, $P_1 = (a, 0)$ is the point on $\overleftrightarrow{OE_1}$ with $OP_1/OE_1 = a$. If P_1' denotes the dilation image of P_1 and E_1' denotes the dilation image of E_1, then, since signed ratios are preserved by dilations, $OP_1'/OE_1' = a$. But $OE_1'/OE_1 = t$, so $OP_1'/OE_1 = (OP_1'/OE_1')(OE_1'/OE_1) = ta$, and $P_1' = (ta, 0)$. In the same way the image of P_2, $P_2' = (0, tb)$, so $\mathcal{D}_{O,t}(P) = (ta, tb)$. □

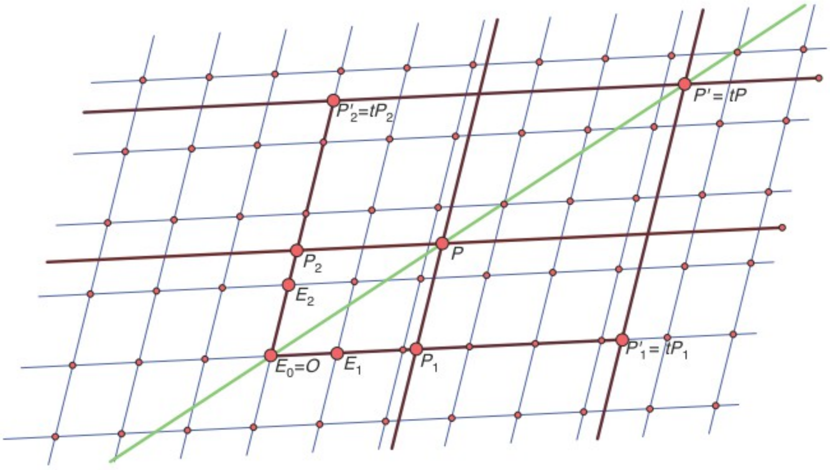

Figure 4. Dilation of P by Ratio t

Thus, the function $L(t) = tP$ from $\mathbb{R}$ to $\overleftrightarrow{OP}$ is a **parametrization of this line through the origin**. It is not a ruler, since the difference of the parameters does not measure the distance between points, but it is proportional to a ruler by a scale factor.

3: D 4 ")) :/ 1) A ( )) 9) 4 4

Line Equation and Slope. When $P = (a, b)$, according to this parametrization, for any point (x, y) on $\overline{OP}$, there is a t so that $(x, y) = \mathcal{D}_{O,t}(P) = (ta, tb)$. The equation $x = ta$ says that $t = x/a$, provided $a \neq 0$, so the second coordinate satisfies the equation $y = bt = (b/a)x$. Conversely, any point $(x, (b/a)x)$ is the dilation of P by ratio x/a.

Therefore, the points (x, y), where x and y are in the solution set of the equation $y = (b/a)x$, is the set of points on the line $\overline{OP}$.

If $a = 0$, the line is the y-axis, so the equation for the line is $x = 0$ since the dilations of P have coordinates $(0, tb)$.

Here is another way to picture the constant b/a. If a line through O is not the y-axis, then the line is a transversal for all lines parallel to this axis and so intersects the parallel line through E_1 with equation $x = 1$. Let the intersection point be $(1, m)$. Then $m = (b/a)1 = b/a$. So the y-coordinate of the intersection with the line $x = 1$ is $m = b/a$. This constant m is given the name the **slope** of the line, and the letter m is often used for this number. Using this slope notation, the equation for a line through O looks like this:

$$y = mx.$$

Note (Meaning of Slope)**.** We have used the slope terminology here since that is what one rather universally calls m in this equation. However, for affine coordinates, slope need not indicate steepness or even whether a line is rising from left to right on a computer screen or a piece of paper. The triangle defining the coordinates may be oriented in directions very different from graph paper. If the E_1 is very far from E_0 in a vaguely northwest direction and E_2 is close to E_0 in an easterly direction, the meaning of slope $m = 1$ will be very different from what it means for more familiar coordinate systems.

Line Parametrization. Now that we have a parametrization for lines through the origin, what is a parametrization for a general line $q = \overline{Q_1Q_2}$?

Theorem 11.5 (Affine Parametrization of a Line)**.** *A parametrization of the line $\overline{Q_1Q_2}$ is*

$$P(t) = Q_1 + t(Q_2 - Q_1) = (1 - t)Q_1 + tQ_2.$$

The signed ratio $P(t)Q_1/Q_2Q_1 = t$.

Proof. The translation $\mathcal{T}_{Q_1O}$ maps q to the parallel line q' though the origin O. The point $\mathcal{T}_{Q_1O}(Q_2) = Q_2' = Q_2 - Q_1$ is on q'. By the parametrization for lines through O, all points P on q' are of the form $t(Q_2 - Q_1)$ for some t, where $t = PO/Q_2'O$. The inverse translation T^{-1} maps this point to the point $Q_1 + t(Q_2 - Q_1)$. Thus, we have a parametrization for the line $\overline{Q_1Q_2}$. The signed ratio is preserved by translation. ☐

Note: Since the sum of the real coefficients is 1, this is a weighted average of the two points. This property was hidden in the formula, tP, which really should be written $(1 - t)O + tP$.

Equation for a Line Through Two Points. What is an equation satisfied by the points of q? Of course, if the line is parallel to the y-axis, the equation is $x = x_1$ and there is no slope m. So from now on, assume that q is not such a line.

Consider the slope of the parallel line q' through O. If $Q_1 = (x_1, y_1)$ and $Q_2 = (x_2, y_2)$, then the point with coordinates $Q_2 - Q_1 = (x_2 - x_1, y_2 - y_1)$ is on the line, so the equation $y = mx$ becomes

$$y = mx = \frac{(y_2 - y_1)}{(x_2 - x_1)}x.$$

This slope m can be computed from any two points Q_1 and Q_2 on the line, since the value of m is determined by the slope of the parallel line through O.

Now, to find an equation satisfied by every point $Q = (x, y)$ on the line, pick any point Q_0 on q (which may be Q_1 or Q_2 but need not be). Then the translation $\mathcal{T}_{Q_0O}$ maps q to q', the parallel line through O, and maps Q to $Q - Q_0 = (x - x_0, y - y_0)$. Since this point is on q', it satisfies this equation:

$$y - y_0 = m(x - x_0) = \frac{(y_2 - y_1)}{(x_2 - x_1)}(x - x_0).$$

This equation is the point-slope form of the equation of a line. If one picks $Q_0 = Q_1$, then there are fewer symbols in the formula, for then $y - y_1 = m(x - x_1)$.

Two General Line Equations. If the constant terms in this equation are collected together, then the equation above takes on a simpler form. This is an equation for a line not parallel to the y-axis:

$$y = mx + b.$$

The intersection $(0, b)$ of this line with the y-axis is obtained by setting $x = 0$. This point is the y-intercept, and this is the **slope-intercept** form of the equation of a line.

There is one other common form of the equation, for real constants a, b c, with $(a, b) \neq (0, 0)$. This form includes lines parallel to the y-axis, since these lines have equation $x = c$:

$$ax + by = c.$$

This equation is not unique, since any multiple of it by a nonzero k has the same solution set: $kax + kby = kc$.

But if the coefficients a and b are not changed, then each change of constant c has as solution a different line parallel to m, since for $c_1 \neq c_2$, the equations $ax + by = c_1$ and $ax + by = c_2$ have no common solution.

This completes the derivation of the equation of a line in affine coordinates.

Euclidean Geometry and Cartesian Coordinates

Now we move on to the more familiar picture of perpendicular Cartesian coordinates. To work with distances and angles, we need a more restricted kind of coordinates. These Cartesian coordinates are simply affine coordinates where $\triangle E_0E_1E_2$, the reference triangle, is a right isosceles triangle, with right angle at E_0 and sides of length 1. Again, we will write the origin $O = E_0$.

Then the coordinates on each axis are ruler coordinates that are signed distances, not just ratios. The coordinate parallelograms OP_1PP_2 are now rectangles.

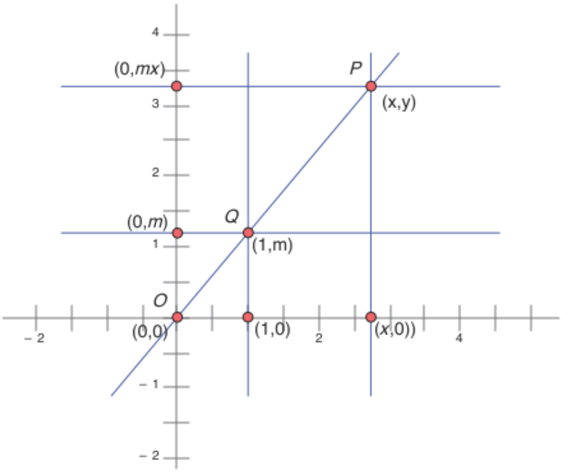

Figure 5. Slope of a Line Through the Origin

Everything that we proved for affine coordinates remains true in the Cartesian case, but some features look different enough that we will revisit them.

For the equation $y = mx$, the slope m is now a ratio of side lengths of a rectangle, as illustrated in Figure 5. It indicates steepness in a way that the general affine case did not.

Also, the similar triangles, attached to a line to derive the point-slope form of the line equation, are now right triangles, all of which are similar and have the same internal ratio of side length, which is the slope. This is illustrated in Figure 6.

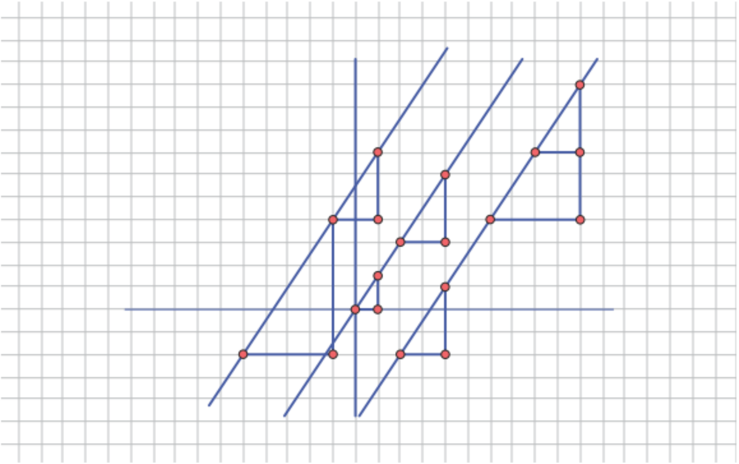

Figure 6. Similar Triangles Dangling from Parallel Lines

Distance Formula. Let P_1 and P_2 be points in the plane with coordinates (x_1, y_1) and (x_2, y_2). Then if M is the point with coordinates (x_2, y_1) and N is the point with coordinates (x_1, y_2), then P_1MP_2N is a rectangle, with sides parallel to the axes, as shown in Figure 7.

By the Pythagorean Theorem, $\|P_1P_2\|^2 = \|P_1M\|^2 + \|MP_2\|^2$.

Since P_1M is parallel to the x-axis, the coordinate x is a ruler, so the length of this segment is $|x_2 - x_1|$. Likewise, the length of MP_2 is $|y_2 - y_1|$. This gives the formula for the distance in terms of coordinates:

$$\|P_1P_2\| = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}.$$

Now that there is a way to measure distance, one can identify a few rigid motions without much calculation. Again, let's denote E_0 by O. The reflection $\mathcal{R}_{OE_1}(x, y) = (x, -y)$. This clearly fixes the points of the x-axis and it also preserves distance, since the change of sign does not change the value of the square terms in the distance formula. The reflection in the y-axis maps (x, y) to $(-x, y)$.

Another simple reflection formula is reflection in the diagonal line s with equation $y = x$. The reflection $\mathcal{R}_s(x, y) = (y, x)$ fixes the points of this line and again does not change the value of the expressions in the distance formula. This reflection also maps each axis to the other.

The general formula for reflections is more complicated. We will take it up when we consider the general formula for rotations.

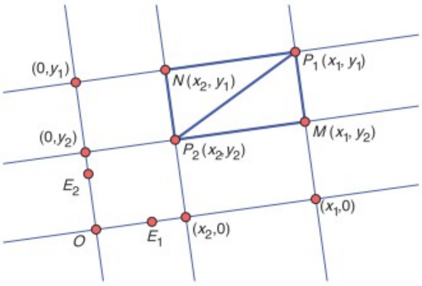

Figure 7. Coordinates and Distance

Perpendicular Lines in the Coordinate Plane

The formula for O_{90}, the 90-degree rotation centered at O, can be deduced in several ways. Given $P = (a, b)$, the rotation will rotate the entire coordinate rectangle for P to a new rectangle. The point $(a, 0)$ is rotated to the point $(0, a)$ on the y-axis. The point $(0, b)$ is rotated to $(-b, 0)$ on the x-axis. Therefore, this new rectangle is the coordinate rectangle for $(-b, a)$. This gives a formula $O_{90}(a, b) = (-b, a)$ valid for all points in the plane.

A second way to see this is from a product formula. Let s be the line $x = y$ as in the previous section. We know that $O_{90} = \mathcal{R}_s\mathcal{R}_{OE1}$, and $\mathcal{R}_s\mathcal{R}_{OE1}(x, y) = \mathcal{R}_s(x, -y) = (-y, x)$.

The rotation of this rectangle for a point P with positive coordinates is pictured in Figure 8. From this, one can already see the coordinates of P'.

This formula is consistent with the formula for half-turns, for $O_{90}^2(a, b) = O_{90}(-b, a) = (-a, -b)$, which is the formula for $\mathcal{H}_O$.

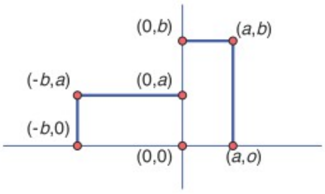

Figure 8. Rotation by 90 Degrees

This tells us something about the slope of perpendicular lines. The line OP has slope b/a, but the rotated line OP' has slope $-a/b$. Since every line is parallel to a line through O, this proves this result:

Theorem 11.6 (Perpendicular Line Equation)**.** *If the equation of a line is* $y = mx + b$, *the equation for every line perpendicular to this line is* $y = (-1/m)x + c$, *for some* c.

Euclidean Geometry of the General Line Equation. All the equations for a line can be converted to the form

$$ax + by = c.$$

If $b \neq 0$, this line has slope $-a/b$. Let m be the line through O with equation $ax + by = 0$.

If one plots the point $N = (a, b)$, the line $\overline{ON}$ has slope b/a, so it is perpendicular to m by the previous theorem. Thus, the direction from O towards N is perpendicular to m; this is sometimes called the **normal direction**.

The point N satisfies the equation $ax+by = a^2+b^2$, so this equation is the equation of a line parallel to m at distance $d = \|ON\| = \sqrt{a^2 + b^2}$ from m, since ON is a segment perpendicular to both lines.

Any point tN satisfies $ax+by = (a^2+b^2)t = d^2t$ and is on a parallel line at distance $|t|d$ from m. The point $N_c = (c/(a^2 + b^2))N$ is the intersection point of $\overline{ON}$ and the line with equation $ax + by = c$.

We can replace the original coefficient pair (a, b) with a **unit normal** point U on $\overline{ON}$ at distance 1 from O. Let $U = (p, q) = (1/d)N = (a/d, b/d)$. This is the equation of a line parallel to m at distance $|c|$ from m:

$$px + qy = \frac{a}{\sqrt{a^2 + b^2}}x + \frac{b}{\sqrt{a^2 + b^2}}y = c.$$

The lines with $c > 0$ are the lines on the same side of m as (a, b). The lines with $c = 0, 1, 2, 3, \ldots$ are parallel lines spaced a unit distance apart.

For any point $M = (m, n)$ on the line $ax + by = c$, $c \geq 0$, consider the right triangle $\triangle MON_c$. If $\theta = m\angle MON_c$, then the distance

$$|c|/\sqrt{a^2 + b^2} = \|ON_c\| = \|OM\| \cos\theta = \sqrt{m^2 + n^2}\cos\theta$$

or $am + bn = c = \sqrt{a^2 + b^2}\sqrt{m^2 + n^2}\cos\theta$.

Definition 11.7. The expression $am + bn$ is called the **dot product** $N \cdot M$, with $N = (a, b)$ and $M = (m, n)$.

From our interpretation of the equation $am + bn = c$, the value of the dot product c is given by this equation:

$$N \cdot M = \|ON\|\|OM\| \cos\theta.$$

This formula is also true for a negative dot product when the angle θ will be obtuse. This case is left to the exercises.

The dot product has been introduced here as an algebraic formula applied to number pairs. The geometric interpretation of $N \cdot M$ given in the equation does not come into play unless an origin O has been designated. Therefore, the dot product is not really a function of two points, since it implicitly requires more information. The resolution of this awkward situation is that **the dot product is really a pairing of vectors, not points**! So the dot product of two vectors, $[AB] \cdot [CD]$ is the algebraic formula $(B - A) \cdot (D - C)$. For vectors, the formula with $\cos\theta$ still holds if θ is interpreted as the difference between the polar angles of the two vectors. This agrees with what has gone before if one interprets $N \cdot M$ as $[ON] \cdot [OM]$.

The dot denoting this product is the same notation used earlier for signed products of collinear segments. This should not lead to confusion since for such segments the product $AB \cdot CD$ equals $[AB] \cdot [CD]$ because for such segments θ is 0 or 180, so $\cos\theta = \pm 1$.

Algebraic properties of the dot product simplify calculations with number pairs. Here M, N, P, Q are any points. The demonstrations of these formulas are either substitution calculations or were already carried out in the paragraphs above.

Commutative Property: $N \cdot M = M \cdot N$.

Distributive Property: $(aM + bN) \cdot P = aM \cdot P + bN \cdot P$.

Perpendicular Directions: $(M - P) \cdot (N - Q) = 0$ if and only if $\overline{MP}$ is perpendicular to $\overline{NQ}$.

Distance: $\|PQ\|^2 = (P - Q) \cdot (P - Q)$.

Graphs and Transformations

If f is a function from the real numbers to the real numbers, we graph this function by plotting the points (x, y) such that $y = f(x)$.

This is closely related to the geometry of the plane; in fact, the equation of a line can be interpreted as the graph of the function $f(x) = mx + b$. It is also true that certain transformations are performed on graphs, with the transformed graphs then interpreted as functions. Here are some examples.

- The transformation $R(x, y) = (y, x)$ maps the graph to its reflection in the line with equation $x = y$; the image can be interpreted as the graph of f^{-1}.
- The transformation $S(x, y) = (x + a, y + b)$ maps the graph to the graph of the function $f(x - a) + b$.
- The transformation $T(x, y) = (-x, y)$ maps the graph to the graph of the function $f(-x)$.
- The transformation $U(x, y) = (2x, 2y)$ maps the graph to the graph of the function $2f(x/2)$.
- The transformation $V(x, y) = (2x, y)$ maps the graph to the graph of the function $f(x/2)$.

This looks a lot like the geometry of the Euclidean plane. Almost all of these transformations are ones we have seen. But there are several fundamental ways in which the space of graphing is not the plane that we have been studying.

First, most of the transformations of the Euclidean plane are not allowable in the space of graphs. It does not make sense to rotate a graph by 30 degrees or reflect it in the line with equation $y = 2x$.

Second, while some of the transformations applied to graphs are similitudes, others are not and do not preserve angles or scale distance. Transformation V in the list above is an example. Also, in the graph world, the slope has units and can change if the units change from seconds to hours or from dollars to euros.

There is a reason for this difference. The Euclidean plane is a homogeneous space. All locations and all directions are equivalent. Even when we place coordinates on the plane, if we are in Euclidean geometry, we still have no preferred directions, just simplified equations perhaps.

However, the space of graphing is not a unified two-dimensional space; rather it is the joining of two one-dimensional spaces as a product. This is seen most clearly when the function being graphed is not a function of a distance to a distance but a function of time to money, or temperature to density. The quantities measured by the x and the y can be completely different, and the scales on the axes can be different. If one is plotting time versus billions of dollars, then the visual slope of the graph on the page depends on whether one unit on the graph paper is one million or ten billion.

Just because two mathematical quantities are described by two real numbers, they need not be the same thing. Even points and vectors are not the same kind of objects. The space of graphing is not really $\mathbb{R}^2$ but $\mathbb{R}^1 \times \mathbb{R}^1$, a product. This means that the space consists of pairs, with the first element a number from one space, the x-space, and the second from a second space, the y-space. The first element may be time measured in years and the second may be dollars measured in megabucks. Just because both spaces are $\mathbb{R}$, there is no reason that the two are otherwise related.

So, in short, one can learn something about graphs from geometry about slope and other properties, but one should be very cautious when applying geometrical relationships to the world of graphs.

Unit Circle and Rotation Formula

Rotations O_θ map each circle centered at O onto itself. The **unit circle**, the circle of radius 1 with center O, will play an important role in the formula for rotations.

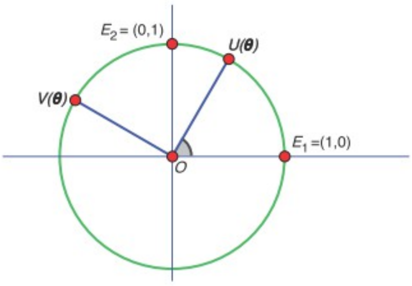

Figure 9. Points on Unit Circle

Let polar angles at O be measured with a protractor that maps the angle 0 to $\overrightarrow{OE_1}$, with 90 being the polar angle of $\overrightarrow{OE_2}$. Then every point on the unit circle has an angle that can be taken to be in the range from 0 to 360, or from −180 to 180.

A point $U(\theta)$ corresponding to polar angle θ on the unit circle has coordinates (c, s), with $c^2 + s^2 = 1$. We can extend the definition of trigonometric functions from acute angles to all of these angles by setting $U(\theta) = (\cos\theta, \sin\theta)$.

One way of thinking about the point $U(\theta)$ is that it is a rotated point, namely $O_\theta(E_1)$.

Denote by $V(\theta)$ the rotation of $U(\theta)$ by 90 degrees; by the formula for this rotation, $V(\theta) = (-\sin\theta, \cos\theta) = O_\theta(E_2)$.

Rotation Formula for Center O. One can rotate a point $P = (x, y)$ by angle θ along with its coordinate rectangle OP_1PP_2, with diagonal OP and vertices at $(x, 0)$ and $(0, y)$ as shown in Figure 10.

The rotation images by O_θ of the points on the axes are multiples of $U(\theta)$ and $V(\theta)$: $P_1' = O_\theta(x, 0) = xU(\theta)$ and $P_2' = O_\theta(0, y) = yV(\theta)$. This is clear from the direction and length of the segments OP_1' and OP_2'.

Then $P' = O_\theta(P)$ is a translate of O: $P' = \mathcal{T}_{OP_1'}\mathcal{T}_{P_1'P'}(O)$, which equals $\mathcal{T}_{OP_1'}\mathcal{T}_{OP_2'}(O)$ since $OP_1'P'P_2'$ is a rectangle. Thus,

$$P' = O + P_1' + P_2' = xU(\theta) + yV(\theta)$$

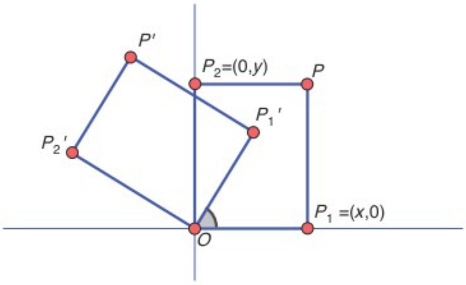

Figure 10. Rotation of P and Its Coordinate Rectangle

and so

$$O_\theta(P) = O_\theta(x, y) = x(\cos\theta, \sin\theta) + y(-\sin\theta, \cos\theta).$$

For a formula for A_θ, centered at a point A that is not O, simply translate by $\mathcal{T}_{AO}$, then rotate with center O, then translate back: $\mathcal{T}_{OA}O_\theta\mathcal{T}_{AO}(P) = A + O_\theta(P - A)$. From the Product of Rotations Theorem, Theorem 10.2, this is a rotation by angle θ. Since A is a fixed point, the product must be A_θ.

The rotation formula implies the addition formulas for cosine and sine. First apply the formula:

$$U(\theta + \phi) = O_\theta(U(\phi)) = O_\theta(\cos\phi, \sin\phi) = \cos\phi(\cos\theta, \sin\theta) + \sin\phi(-\sin\theta, \cos\theta).$$

Then note the value of $U(\theta + \phi)$:

$$(\cos(\theta + \phi), \sin(\theta + \phi)) = (\cos\phi\cos\theta - \sin\phi\sin\theta, \cos\phi\sin\theta + \sin\phi\cos\theta).$$

For the special case $\theta = \phi$, this gives formulas for $\cos 2\theta$ and $\sin 2\theta$.

Line Reflection Formula. A formula for reflection in a line m through O can be derived in the same way. Let $m = \overline{OU(\theta)}$.

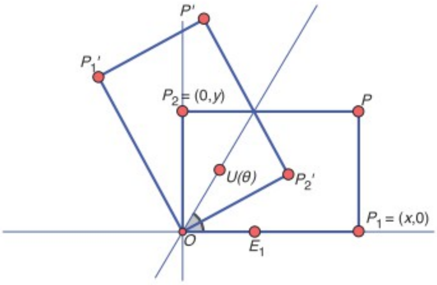

Figure 11. Reflection of P and Its Coordinate Rectangle

- The reflection image $P_1' = \mathcal{R}_m(P_1)$ is also the rotation image $O_{2\theta}(P_1)$, since $\angle P_1OU(\theta) \cong P_1'OU(\theta)$ and $OP_1 \cong OP_1'$, with $\theta = m\angle P_1OU(\theta)$. Therefore, $P_1' = xU(2\theta)$.

- The reflection image $P_2' = \mathcal{R}_m(P_2)$ is also the rotation image $O_{2(\theta-90)}(P_2)$, since $\angle P_2OU(\theta) \cong P_2'OU(\theta)$ and $OP_2 \cong OP_2'$ with $|\theta - 90| = m\angle P_2OU(\theta)$. Therefore, $P_2' = yV(2\theta - 180) = -yV(2\theta)$.

As for rotations, this leads to a formula for $P' = \mathcal{R}_m P = P_1' + P_2'$:

$$\mathcal{R}_{OU(\theta)}(P) = xU(2\theta) + yV(2\theta) = x(\cos 2\theta, \sin 2\theta) + y(\sin 2\theta, -\cos 2\theta).$$

We relied on Figure 11 to derive this formula. But now that we have a formula, we can check directly that the function is the correct reflection for all θ. Let F be the function with the formula given in the displayed equation. One can check by a calculation that this F preserves distance, so it is a rigid motion. Also one can calculate $F(O) = O$, $F(U(\theta)) = U(\theta)$, and $F(V(\theta)) = -V(\theta)$. Thus, F agrees with the line reflection $\mathcal{R}_{OU(\theta)}$ at these three points, so it must be the same rigid motion. Some details of this calculation will appear in the exercises.

Reflections in Lines Not Through O. Again, for a reflection in a line n not through O, let A be a point of n, and let $n' = \mathcal{T}_{AO}(n)$. Then $\mathcal{T}_{OA}\mathcal{R}_{n'}\mathcal{T}_{AO}$ is reflection in n, so $\mathcal{R}_{n'}(P) = A + \mathcal{R}_{n'}(P - A)$.

With this formula, we now have formulas for translation, dilation, rotation, and reflection. In the next two sections, we will show how these formulas can be expressed with different mathematical tools or in different mathematical language.

Complex Numbers and Transformations of the Plane

The complex numbers have the form $z = a + ib$, where a and b are real numbers and $i^2 = -1$. The numbers can be represented by points in the Cartesian coordinate plane by identifying this number with (a, b).

Addition agrees with coordinatewise addition of points in the plane: $(a+ib)+(c+id) = (a+c) + i(b+d)$. Multiplication is $(a+ib)(c+id) = ac + i(ad+bc) + i^2bd = (ac - bd) + i(ad + bc)$.

The complex conjugate $\overline{z}$ of $z = a + ib$ is $a - ib$. The product $z\overline{z}$ is a nonnegative real number: $z\overline{z} = (a+ib)(a-ib) = a^2 + b^2$. The square root of this number is the modulus, the distance to 0: $|z| = |a + ib| = \sqrt{a^2 + b^2}$.

Since the product $i(a + ib) = -b + ia$, the function that maps a complex number z to iz is the rotation O_{90} of the plane, since the formulas are the same.

More generally, if $|w| = 1$, then the complex number w is on the unit circle and has the form $w = u(\theta) = \cos\theta + i\sin\theta$ for some θ. (For the rest of this section, the temporary notation $u(\theta)$ will denote this complex number with modulus 1.)

For $z = (x + iy)$, the formula for this product is the formula for $O_\theta(z)$:

$$u(\theta)(x+iy) = (\cos\theta + i\sin\theta)(x+iy) = x(\cos\theta + i\sin\theta) + y(-\sin\theta + i\cos\theta).$$

More generally, the function $S_\alpha(z) = \alpha z$, where $\alpha = a + ib$ is a constant nonzero complex number, is a transformation of the plane. The inverse of the transformation is multiplication by $\alpha^{-1} = \overline{\alpha}/|\alpha|^2$.

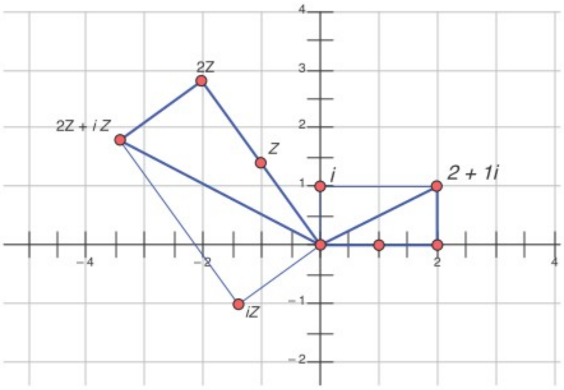

Figure 12. Geometry of Complex Product $(2 + 1i)z$

Any nonzero complex number $\alpha = |\alpha|(\alpha/|\alpha|)$, where $(\alpha/|\alpha|) = u(\theta)$ has modulus 1. Multiplication by the real number $|\alpha|$ is dilation with center O and dilation ratio $|\alpha|$. Therefore, the transformation $S_\alpha(z)$ can be factored into $\mathcal{D}_{O,|\alpha|}O_\theta$, the product of a dilation and a rotation. This is an orientation-preserving similitude.

The example of complex multiplication in Figure 12 can be viewed two ways. It is a dilation rotation by z of $2 + 1i$, scaling the coordinate rectangle of $2 + 1i$ by $|z|$ and rotating by $z/|z|$. One can also view this as a dilation rotation of z by $2 + 1i$ as a construction, starting with a triangle $\triangle 0\,2\,(2+1i)$ and then building a similar triangle with base segment $0\,2z$ in place of segment $0\,2$ as the base, then adding a perpendicular segment $0\,iz$ of length $|z|$ instead of the side of length 1 in the original triangle. This second interpretation constructs a rectangle similar to the coordinate rectangle of $2 + 1i$ and shows how the angle of rotation and the length of $(2 + 1i)z$ emerge from the geometry.

Translations have the form $T(z) = z + \beta$, for some complex number β. Therefore, $U(z) = \alpha z + \beta$ is an orientation-preserving similitude and is a rigid motion if $|\alpha| = 1$. In fact, every such similitude and rigid motion can be written in this form. A proof will be explored in the exercises.

The complex conjugate map $C(z) = \overline{z}$ is reflection in the x-axis. Then $S_\alpha C S_\alpha^{-1}$ is reflection in line $\overline{0\alpha}$. The formula for this map is

$$S_\alpha C S_\alpha^{-1}(z) = S_\alpha C(\overline{\alpha} z/|\alpha|^2) = S_\alpha(\alpha \overline{z}/|\alpha|^2) = (\alpha/|\alpha|)^2 \overline{z} = u(\theta)^2 \overline{z} = u(2\theta)\overline{z}.$$

This agrees with the formula derived in the previous section. The composition of this map with translations provides a complex expression for any line reflection.

The flexibility provided by the algebra of complex numbers makes some geometrical theorems easier to prove.

Theorem 11.8 (Similitude Fixed Point)**.** *Every orientation-preserving similitude that is not a translation has a unique fixed point.*

Proof. Such a transformation has the form $U(z) = \alpha z + \beta$, with $\alpha \neq 1$. A fixed point z satisfies $z = \alpha z + \beta$. A unique solution of this equation is found by elementary algebra: $z_0 = \beta/(1-\alpha)$. ☐

One can check that if $|\alpha| < 1$, then for any z, the sequence of images $U^k(z)$ approaches z_0 as a limit. This is illustrated by the spiral in Figure 8.40.

Functions of complex numbers can also be used to describe additional geometrical transformations of the plane. For example, $J(z) = 1/\overline{z}$ is a transformation called reflection in the unit circle; this fixes the points on the unit circle but exchanges the interior with the exterior, much as line reflection does. Inversion leads to some beautiful geometry of circles that is beyond the scope of this book. Subsets of complex numbers are also used to model non-Euclidean plane geometry. References include Hahn [**10**].

Barycentric Coordinates

In this section we will introduce barycentric coordinates, which locate points as barycenters, or centers of mass.

In Theorem 11.5, we saw that any point on $\overline{PQ}$ can be written as $(1-t)P + tQ$ for some real t. This expression represents the same point whatever the coordinate system.

Other expressions in the coordinates of P and Q will not define points on the plane in a way that is independent of the coordinate system. For example, the expression $P+Q$ denotes the point N such that $POQN$ is a parallelogram. If the origin O is changed, so is N. In contrast, $(1-t)P + tQ$ always denotes the point A on $\overline{PQ}$ with $AP/QP = t$.

Center of Mass of a Segment. A more symmetric way of writing the parametric expression for a point G on a line P_1P_2 is to say that $G = c_1P_1 + c_2P_2$, where $c_1 + c_2 = 1$.

The point G is the center of mass, the **barycenter**, of a system consisting of a mass c_1 at P_1 and c_2 at P_2. This follows from the law of levers of Archimedes: at the barycenter, the products of mass times lever arm are equal and opposite. In this case, $c_1(P_1 - G) = -c_2(P_2 - G)$.

If there are masses m_1 and m_2 at these points that do not sum to 1, there is still a center of mass. Let $M = m_1 + m_2$; then set $G = (m_1/M)P_1 + (m_2/M)P_2$.

For example, if one puts 2 grams at P_1 and 5 grams at P_2, then the center of mass is $(2/7)P_1 + (5/7)P_2$; this is the point on the segment with $GP_1/GP_2 = -5/2$.

When speaking of masses, the numbers c_i are nonnegative and the point G will belong to the segment P_1P_2. In the formula for G, negative real numbers are allowed, with G possibly located at any point of $\overline{P_1P_2}$. But the physical analogy must be extended to springs or balloons that pull upward, opposite from gravity.

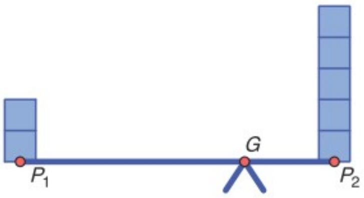

Figure 13. Barycenter of Masses 2 and 5

Affine Combinations and Barycenters. We will extend this idea of a center of mass to a system of more than two points. The next theorem will set the stage.

Theorem 11.9 (Affine Combinations). *Concerning* $c_1P_1 + c_2P_2 + \cdots + c_nP_n$*:*

- *An expression* $c_1P_1 + c_2P_2 + \cdots + c_nP_n$ *is called an* ***affine combination*** *of points if* $c_1 + c_2 + \cdots + c_n = 1$*. Such an expression equals a point* G *independent of the coordinate system.*
- *If the sum* $c_1 + c_2 + \cdots + c_n = 0$*, the expression* $c_1P_1 + c_2P_2 + \cdots + c_nP_n$ *equals a vector independent of the coordinate system.*
- *If* $c_1 + c_2 + \cdots + c_n = 1$*, the vector* $c_1(P_1 - G) + c_2(P_2 - G) + \cdots + c_n(P_n - G)$ *is the zero vector. This is the sum of the masses times the lever arm at* G*.*

Proof. Here is a proof for three points, $G = c_1P_1 + c_2P_2 + c_3P_3$, where $c_1 + c_2 + c_3 = 1$.

If $c_1 + c_2 = 0$, then $c_1(P_1 - P_2) = v$ is a vector and $G = \mathcal{T}_v(P_3)$ is a point independent of coordinates. This completes the proof in this case.

Now assuming that $c_1 + c_2 \neq 0$, let $Q = 1/(c_1 + c_2)(c_1P_1 + c_2P_2)$, a point on $\overline{P_1P_2}$. Then $G = (1 - c_3)Q + c_3P_3$ since $c_1 + c_2 = 1 - c_3$; this G is a point on $\overline{QP_3}$. Both Q and G are independent of the coordinate system, by Theorem 11.5.

Next, if $c_1 + c_2 + c_3 = 0$, let $v = c_1P_1 + c_2P_2 + c_3P_3$ be computed by adding coordinates in some coordinate system. Let $E = P_1$. The point $F = E + v = (1 + c_1)P_1 + c_2P_2 + c_3P_3$ is a well-defined point independent of any coordinate system, since $1 + c_1 + c_2 + c_3 = 1$. Therefore, $v = [EF]$ is a vector independent of the coordinate system.

Lastly, if $c_1 + c_2 + c_3 = 1$, the vector $c_1(P_1 - G) + c_2(P_2 - G) + c_3(P_3 - G) = c_1P_1 + c_2P_2 + c_3P_3 - (c_1 + c_2 + c_3)G = G - G = 0$.

This proves the theorem for $n = 3$ by using the already-known result for $n = 2$. This reasoning can be continued inductively, step by step in the same manner, for any number of summands, but we will leave the details to the reader. In what follows, the case $n = 3$ is the case we will need. ☐

Example 11.10. For a parallelogram $ABCD$, the center of symmetry M can be written in an infinite number of ways: for example, $(1/2)(A + C)$, $(1/4)(A + B + C + D)$, or $(1/2)(2A - B + 2C - D)$.

In Theorem 8.50 we learned that the medians of a triangle are concurrent at a point called the centroid of the triangle. The centroid of $\triangle ABC$ is $G = (1/3)(A + B + C)$. To see this, let $M = (1/2)(A + B)$ be the midpoint of AB. Then CM is a median, and

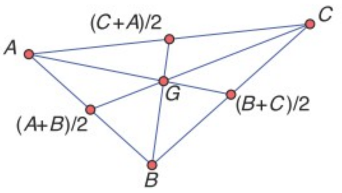

Figure 14. Centroid $G = (1/3)(A + B + C)$

$G = (2/3)M + (1/3)C$ is the point on the median CM with $GM/CM = 1/3$. By the same reasoning, this G is on any median, so the medians are concurrent at G. Unlike the example of the parallelogram, there is no other affine combination of the vertices that equals G. Why this is unique will be shown in Theorem 11.11.

Barycenter of Masses on a Triangle. Given a triangle $\triangle P_1P_2P_3$, a triple of numbers (c_1, c_2, c_3), with $c_1 + c_2 + c_3 = 1$, defines a point $G = c_1P_1 + c_2P_2 + c_3P_3$.

This points can be interpreted as the center of mass for three masses located at P_i when the $c_i \geq 0$. This follows from the third point in Theorem 11.9 by the lever principle of Archimedes. As a physical example, imagine supporting and balancing a rigid triangle on the edge of a ruler that passes under P_3. With a mass at each vertex, to balance the remaining two masses, the ruler should pass under the center of mass Q of the side P_1P_2. Then to balance the whole structure on a fingertip at a point of QP_3, one can conceptually replace the segment P_1P_2 with masses at each endpoint by its center of mass Q with mass $c_1 + c_2$. This is the reasoning used in the proof of Theorem 11.9 to find the balance point at G. This is the same balance principle used in a hanging mobile, where every pair of objects is hung from a stick attached by a thread at the center of mass of the two objects.

Theorem 11.11 (Barycentric Coordinates)**.** *Given a triangle $\triangle P_1P_2P_3$, every point P of the plane can be expressed in exactly one way as $P = c_1P_1 + c_2P_2 + c_3P_3$, where $c_1 + c_2 + c_3 = 1$. This unique triple of numbers can be used as coordinates for P. These are called the* ***normalized barycentric coordinates*** *of P with respect to this triangle.*

Proof. This is actually not new; these are affine coordinates in disguise. If we set $P_3 = O$, then

$$c_1P_1 + c_2P_2 + c_3P_3 = (1 - c_1 - c_2)O + c_1P_1 + c_2P_2).$$

Then (c_1, c_2) are the affine coordinates of P with respect to $\triangle OP_1P_2$. ☐

One may wonder what is the point of repackaging affine coordinates. We will see that treating the three vertices of the coordinate triangle symmetrically has interesting consequences.

In the case of masses at the vertices P_i where the nonzero sum of the masses is not 1, the masses (m_1, m_2, m_3) still determine a point. Let $M = m_1 + m_2 + m_3$ and let $c_i = m_i/M$. Then

$$G = (1/M)(m_1P_1 + m_2P_2 + m_3P_3)$$

is a point that is a center of mass when the $m_i \geq 0$. The numbers (m_1, m_2, m_3) are **barycentric coordinates** of G. Unlike (x, y)-coordinates, barycentric coordinates are homogeneous. The number triples (km_1, km_2, km_3) define barycentric coordinates that are considered the same for any $k \neq 0$, and they determine the same point. The one restriction is that $M = m_1 + m_2 + m_3 \neq 0$.

Example 11.12. On the left side of Figure 15 there is shown a $\triangle ABC$ with masses 1, 2, and 4, at the respective vertices. So $(1, 2, 4)$ are barycentric coordinates for a point, with $M = 7$. The barycenters of each pair of masses on the sides are

$$D = (2/6)B + (4/6)C,$$
$$E = (4/5)C + (1/5)A,$$
$$F = (1/3)A + (2/3)B$$

with the barycenter for three masses $G = (1/7)A + (2/7)B + (4/7)C$.

The ratios on the sides are $DB/DC = -2$, $EC/EA = -1/4$, $FA/FB = -2$.

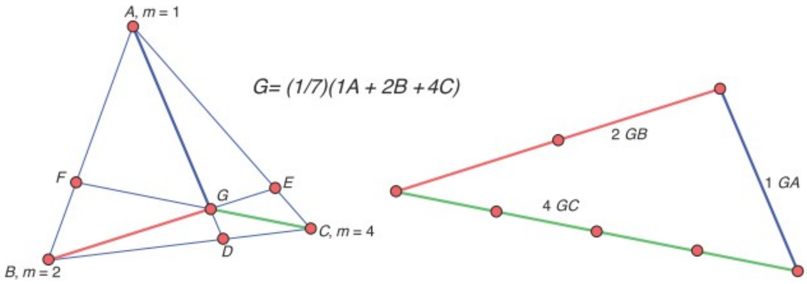

Figure 15. Barycenter and Vector Sum

Segments representing the three vectors from G to the vertices are shown in different colors. On the right side of the figure there is plotted the sum of the three vector lever arms using the same colors: $1(A - G) + 2(B - G) + 4(C - G)$, which is 0 as it should be, since $0 = c_1(P_1 - G) + c_2(P_2 - G) + c_3(P_3 - G)$.

We can see in this example a way to show that the barycenter is inside the triangle if the masses are positive. On the segments AD, BE, and CF, the negative signed ratios $GD/GA = -1/6$, $GE/GB = -2/5$, and $GF/GC = -4/3$ show that G is an interior point of each segment.

Cevians and Ceva's Theorems. In Example 11.12, the segments AD, BE, and CF are called cevians. The signed ratios of the endpoint of the cevians on the sides satisfied this equation: $(DB/DC)(EC/EA)(FA/FB) = (-2)(-1/4)(-2) = -1$. We will now look at cevians and these ratios in general.

Definition 11.13. A segment joining any vertex of $\triangle ABC$ to a point of the (extended) opposite side is called a **cevian**. A cevian line is a line containing a cevian.

For a point G with normalized barycentric coordinates (c_1, c_2, c_3) with respect to $\triangle ABC$, the line $\overline{AG}$ will intersect $\overline{BC}$ at a point $D = (1 - t)A + tG$ where $c_1 = 0$.

This means that the barycentric coordinates of D will be $(0, c_2, c_3)$ and the normalized barycentric coordinates will be $(0, c_2/(1-c_1), c_3/(1-c_1))$. The point of intersection will not exist, and $\overline{AG}$ will be parallel to $\overline{BC}$ when $c_1 = 1$. The signed ratio DB/DC will equal $-c_3/c_2$ except when $c_2 = 0$ and the ratio is not defined.

Now let point G have coordinates (c_1, c_2, c_3) with respect to $\triangle P_1P_2P_3$ for which none of the c_i equals 0 or 1. Then the triangle has three cevian lines $\overline{P_iQ_i}$ concurrent at G and with this relationship among the ratios on the sides:

$$\frac{Q_1P_2}{Q_1P_3}\,\frac{Q_2P_3}{Q_2P_1}\,\frac{Q_3P_1}{Q_3P_2} = \frac{-c_3}{c_2}\,\frac{-c_1}{c_3}\,\frac{-c_2}{c_1} = -1.$$

If all the $c_i > 0$, then the cevian segments concur at G at a point inside the triangle.

The converse is an important triangle concurrence theorem. To avoid the special cases, the theorem is stated for cevian segments.

Theorem 11.14 (Ceva's Theorem). *In $\triangle P_1P_2P_3$, let the three cevians P_1Q_1, P_2Q_2, P_3Q_3 have endpoints Q_1, Q_2, Q_3 on the sides of the triangle, not at a vertex. Then the cevians are concurrent at a point G if and only if*

$$\frac{Q_1P_2}{Q_1P_3}\,\frac{Q_2P_3}{Q_2P_1}\,\frac{Q_3P_1}{Q_3P_2} = -1.$$

Proof. The"only if" claim is all that is left to prove, given what has already been proved,

The first step of the proof is to use two ratios on the sides, r_2 and r_3, to find the barycentric coordinates of G, the point of concurrence of two of the cevians P_2Q_2 and P_3Q_3.

Assume that there is mass $m_1 = 1$ at P_1; then $r_2 = Q_2P_3/Q_2P_1 = -m_1/m_3$, so $m_3 = -1/r_2$. Also, $r_3 = Q_3P_1/Q_3P_2 = -m_2/m_1$, so $m_2 = -r_3$. Therefore, $(1, -r_3, -1/r_2)$ are barycentric coordinates for the intersection point.

Then let $M = 1 - (1/r_2) - r_3$. Since $M > 1$, we can set $c_1 = 1/M$, $c_2 = -r_3/M$, $c_3 = -1/(r_2M)$ as the normalized barycentric coordinates for a point G that is the intersection of the cevians through P_2 and P_3.

The last part of the proof is to show that the intersection J of $\overline{P_1G}$ with $\overline{P_2P_3}$ is the point Q_1. Since we have the barycentric coordinates of G, we know J is the barycenter of P_2P_3 with mass $-r_3$ at P_2 and $-1/r_2$ at P_3. The point J divides the segment in the ratio $JP_2/JP_3 = -(1/r_3)/r_2 = -1/r_2r_3$. Since $r_1r_2r_3 = -1$, this ratio is r_1 and $J = Q_1$. $\square$

Note. This proof also applies to cases when two of the Q_i are on extended sides of the triangle, but for some cases the $\overline{P_iQ_i}$ will be parallel and not concurrent.

We have encountered a number of special lines in triangles. Perpendicular bisectors are not cevians. But medians, angle bisectors, and altitudes are all cevians, and this theorem applies to them.

Figure 16 shows another barycentric coordinate example with one coordinate negative. The point S has barycentric coordinates $(4, -1, 3)$, or $(2/3, -1/6, 1/2)$, relative to $\triangle ABC$. Since the second coordinate is negative, the vertices B and S are on opposite sides of $\overline{AC}$. The segment ratios on the sides and their product are shown in the figure.

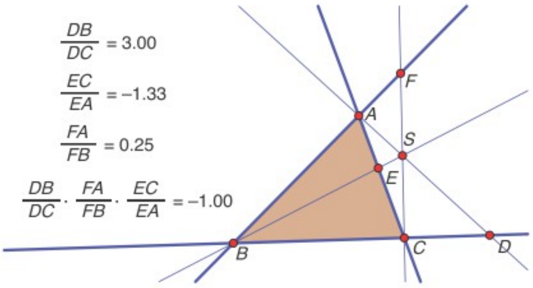

Figure 16. Cevian Lines and Ratios of Mixed Sign

Note. The Menelaus Theorem, Theorem 8.29, asserts that when the product of ratios is positive instead of negative, the three points Q_i are collinear. This provides a straightedge construction of harmonic division, as shown in Figure 8.26.

Areal Coordinates. The normalized barycentric coordinates of points in a triangle are sometimes called **areal coordinates**.

The reason for this can be seen in the example in Figure 15. In this figure, the ratio $DG/DA = 1/7$. This means that the height of $\triangle GBC$ is 1/7 the height of $\triangle ABC$. Since the base of each triangle is BC, the area $\mathcal{A}(\triangle GBC) = (1/7)\mathcal{A}(\triangle ABC)$.

By the same reasoning,

$$\mathcal{A}(\triangle GCA) = (2/7)\mathcal{A}(\triangle ABC) \quad \text{and} \quad \mathcal{A}(\triangle GAB) = (4/7)\mathcal{A}(\triangle ABC).$$

Thus, the three numbers $(1/7, 2/7, /4/7)$ are the normalized barycentric coordinates but also represent the fractions of the total area $\mathcal{A}(\triangle ABC)$ that are the areas of the three subtriangles with vertex G. And the sum of these coordinates is 1, since the sum of the three triangle areas is $\mathcal{A}(\triangle ABC)$.

In Figure 16 the area ratios can be computed in the same way. Let $\mathbb{A} = \mathcal{A}(\triangle ABC)$. The area ratios are $\mathcal{A}(\triangle SBC)/\mathbb{A} = 2/3$, $\mathcal{A}(\triangle SCA)/\mathbb{A} = 1/6$, and $\mathcal{A}(\triangle SAB)/\mathbb{A} = 1/2$.

This time $2/3+1/6+1/2 \neq 1$ since the three triangles do not subdivide the original triangle. Instead, the sum of two of their areas is the area of the quadrilateral $ABCS$.

However, the sum of the ratios will still be 1 if $\mathcal{A}(\triangle SCA)$ is considered negative. This makes sense since the orientation of the triangle is opposite that of all the other triangles. In the figure one sees that removing this area from the area of the quadrilateral $ABCS$ does equal the area of $\triangle ABC$. And the calculation shows this also: $2/3 - 1/6 + 1/2 = 6/6 = 1$.

This idea of **signed area**, of setting area to be negative if a figure has negative orientation, is an idea that appears in many guises in geometry.

Example 11.15. For $\triangle ABC$ with angle measures α, β, and γ at the vertices A, B, and C, the barycentric coordinates of the circumcenter can be deduced from the areas of $\triangle OAB$, $\triangle OBC$, and $\triangle OBC$ as shown in Figure 17. For instance, $\triangle OAB$ is an isosceles triangle with angle measure 2γ at O, since $\angle BAC$ is an inscribed angle. The equal sides of the triangle have length r, the radius of the circle. The area of this isosceles triangle is twice the area of the right triangle $\triangle AOF$. The legs of this triangle are $r\sin\gamma$ and $r\cos\gamma$, so the area is $r^2\sin\gamma\cos\gamma = (r^2/2)\sin 2\gamma$. Dividing each area by r^2, the barycentric coordinates of O are $(\sin 2\alpha, \sin 2\beta, \sin 2\gamma)$. This formula remains true when one of the angles is obtuse, though the area of the corresponding isosceles triangle will be negative. To get the areal or normalized barycentric coordinates, one must either divide by the sum of these numbers or use the area of $\triangle ABC$.

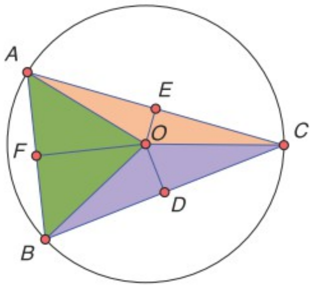

Figure 17. The Arial Coordinates of the Circumcenter

Intersections from Barycentric Coordinates. Confronted by points E and F on the sides of a triangle, as in Figure 18, one can use barycentric coordinates to find the coordinates of the intersection G. If we know that $AE/AB = 1/5$ and $AF/AC = 2/5$, then each point can be viewed as a barycenter on a side. The point E is the barycenter of a mass $4m$ at A and $1m$ at B, while F is the barycenter of mass $3n$ at A and $2n$ at C. If we set $m = 3$ and $n = 4$, we get barycentric coordinates $(12, 3, 8)$ with respect to $\triangle ABC$. Now it is also immediate to see that the intersection of $\overline{AG}$ with BC has coordinates $(0, 3, 8)$.

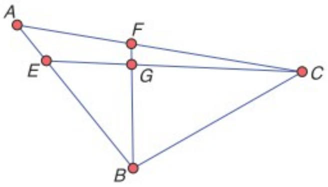

Figure 18. Barycentric Coordinates of G from Ratios AE/AB and AF/AC

Of course this is not the only way to find these coordinates. A very sure way is to choose affine coordinates, then find the equations for the lines $\overline{BF}$ and $\overline{CE}$, and then solve the pair of equations. But for some simple problems the method with masses is more direct and is perhaps more insightful.

This method can be used to find the barycentric coordinates of all the points in the Marion Walters figure, Figure 9.21. Then the arial coordinates can be used to find areas of regions in the figure to solve the problem. That figure exhibits affine symmetry in that many points have symmetric coordinates because the coordinate and area ratios are the same as they would be for the figure in an equilateral triangle.

Another application of barycentric coordinates is to the intersection of sides of a triangle with a line parallel to a side. In Figure 19, we begin with the point P_1 on AB, then intersect AC with the line through P_1 parallel to BC to get P_2. Then we repeat the same procedure to get point P_3 on BC and then P_4 on AB. The point P_4 will not be the same as P_1 (unless P_1 is the midpoint), but if we continue, the next time the point that should be P_7 is equal to P_1.

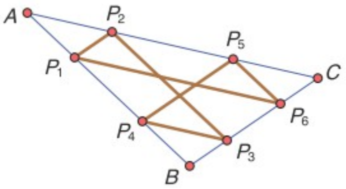

Figure 19. Repeating Parallel Paths in a Triangle

It is not too difficult to see why this works without using barycentric coordinates, but it is very clear with them. If the barycentric coordinates of P_1 with respect to $\triangle ABC$ are $(p, q, 0)$, then the parallel intersection at P_2 has coordinates $(p, 0, q)$, since the mass at A does not change and the mass at B moves to C. Continuing, we get the repeating sequence

$$(p, q, 0), (p, 0, q), (0, p, q), (q, p, 0), (q, 0, p), (0, q, p), (p, q, 0).$$

This repeated pattern also holds, with the same coordinate reasoning, for a point P_1 on the extended side of the triangle, though the figure will now be a polygon. If one does the construction with dynamic geometry software, it can be animated,

Vectors and Affine Transformations

In this section, we will use vectors to study some transformations more general than similitudes. We begin with a brief recapitulation of what we have said about vectors so far, beginning with the definition and notation in Chapter 7.

Vectors and Coordinates. Vectors appear as objects with direction and magnitude in many areas of geometry. As we have seen, in the Euclidean plane there is a one-to-one correspondence between the set of vectors and the set of translations: an ordered segment AB represents both the vector $[AB]$ and the translation $\mathcal{T}_{AB}$. The coordinate formula for $\mathcal{T}_{AB}(P)$ is $P+(B-A)$, so $[AB]$ can also be represented by the number pair $B - A$.

Both the vector and the translation can be represented visually by arrows with tail at A and head at B. But if CD is another ordered segment so that $ABDC$ is a parallelogram or linear parallelogram, then the arrow from C to D also represents the same vector and translation: $[AB] = [CD]$.

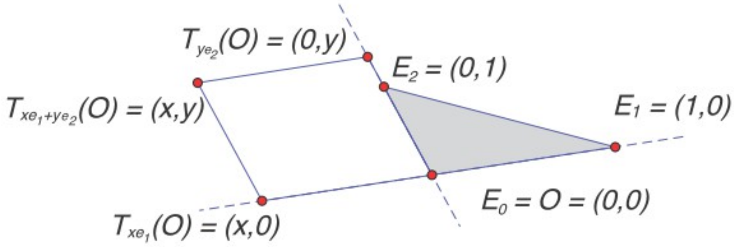

Figure 20. Coordinates Expressed Using Vectors or Translations

Addition of vectors corresponds to composition of transformations, so $u = v + w$ when $\mathcal{T}_u = \mathcal{T}_v\mathcal{T}_w$. In coordinates, this is just addition of number pairs: $(B - A) + (D - C)$. Geometrically, starting at any point A, let $B = \mathcal{T}_v(A)$ and $D = \mathcal{T}_w(A)$; then $u = v + w = [AC]$, where C is the unique point so that $ABCD$ is a parallelogram or linear parallelogram.

Multiplication by a real number k, e.g., $k[AB]$, corresponds to translation $\mathcal{T}_{AC}$, where $C = \mathcal{D}_{A,k}(B)$.

For a linear coordinate system based on $\triangle E_0E_1E_2$, let vectors $e_1 = [E_0E_1]$ and $e_2 = [E_0E_2]$. For a point P with coordinates (x, y), $P = E_0 + x(E_1 - E_0) + y(E_2 - E_0)$. Or in vector terms, $[E_0P] = xe_1 + ye_2$. The points within $\triangle E_0E_1E_2$ have $0 \leq x + y \leq 1$. This is the shaded triangle in Figure 20.

Shear Transformations. Shear transformations were defined in Chapter 9 and depicted in Figure 9.20. Let us consider a shear transformation S related to the linear coordinate system defined by $\triangle E_0E_1E_2$.

The base will stay fixed, so $S(E_0) = E_0$ and $S(E_1) = E_1$, but $S(E_2) = E_2'$, where E_2E_2' is parallel to E_0E_1. In other words, $[E_2E_2'] = ke_1$ for some real k, so $[E_0E_2'] = ke_1 + e_2$.

This transformation of the triangle vertices determines the images of the other points in the plane:

$$S(E_0 + xe_1 + ye_2) = E_0 + xe_1 + y(ke_1 + e_2).$$

This says $S(x, y) = (x + ky, y)$ is the coordinate formula for S.

Each line parallel to the x-axis with equation $y = c$ is translated to itself by the vector cke_1. And any point $(0, y) = E_0 + ye_2$ on the y-axis maps to the point $E_0 + y(ke_1 + e_2) = (ky, y)$, as prescribed in Chapter 9.

One way to picture this is to imagine the coordinate tessellation of the plane by $\triangle E_0E_1E_2$ and triangles congruent to it, with vertices being all the points with integer coordinates. Then all the triangles are transformed consistently so that the tessellation of the plane is mapped to the coordinate tessellation defined by $\triangle E_0E_1E_2'$. In other words, a point with affine coordinates in the $\triangle E_0E_1E_2$ system is mapped to the point with the same coordinates in the $\triangle E_0E_1E_2'$ system.

One important property of this shear transformation is that all areas are preserved. **The area of a figure and its sheared image are the same.** If one tessellates the

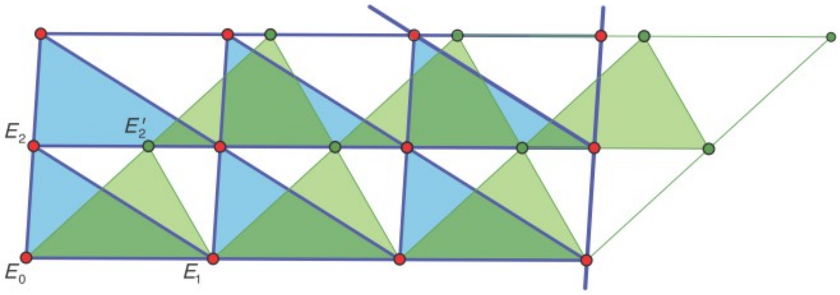

Figure 21. Tessellation by Triangles and Sheared Images

plane with triangles congruent to $\triangle E_0E_1E_2$, then this tessellation is transformed to a tessellation by triangles congruent to $S(\triangle E_0E_1E_2)$ and so each has the same area. Moreover, the plane can be tessellated by arbitrarily small triangles similar to $\triangle E_0E_1E_2$ by taking midpoint triangles and then midpoint triangles of those to get triangles smaller than any pre-determined size. Thus, for a figure like a circle or a regular pentagon, the area can be approximated by a sum of areas of small triangles; then the area of the image is approximated in the same way by the image triangles that have the same areas as the originals.

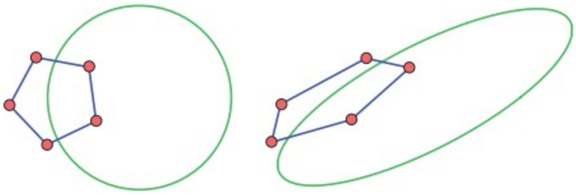

Figure 22. Sheared and Translated Circle and Regular Pentagon

The sheared images in Figure 22 have also been translated, not changing the area but making them easier to see. The image of the circle (which can be shown to be an ellipse) has the same area as the circle. And the irregular pentagon has the same area as the regular pentagon.

Shear transformations in other directions can be defined with respect to any other triangles. And more general transformations can be defined as products of various shears and rigid motions. These products will also preserve area.

Affine Transformations. As products of shears and rigid motions and other similitudes are formed, the analysis of their behavior will be more complex, but the products will always map collinear points to collinear points and preserve signed ratio on each line. This property will be used as a definition.

Definition 11.16. An **affine transformation** of the plane is a transformation that maps lines to lines and preserves signed ratio.

All rigid motions and other similitudes are affine transformations. It is not hard to show that products and inverses of affine transformations are also affine transformations.

Theorem 11.17 (Affine Transformation Formula). *Given affine coordinates, any transformation T that has a coordinate formula $T(x, y) = (ax + by, cx + dy) + (e, f)$ is an affine transformation, and conversely.*

Note: T is assumed to be a transformation. A function with $a = b = c = d = 1$ will not have an inverse. The necessary condition on a, b, c, d for T to be a transformation will be considered below.

Proof. It is sufficient to show that the image of a point $sP + tQ$ has the same form, where $P = (p_1, p_2)$, $Q = (q_1, q_2)$, and $s + t = 1$.

$T(sP+tQ) = (a(sp_1+tq_1)+b(sp_2+tq_2), c(sp_1+tq_1)+d(sp_2+tq_2))+s(e, f)+t(e, f)$, for $(e, f) = s(e, f) + t(e, f)$ since $s + t = 1$.

Collecting like terms, this equals $sT(P) + tT(Q)$.

To see the converse, let T be an affine transformation and let E_0, E_1, E_2 be the vertices of the triangle defining the affine coordinates. If the coordinates of the images of these points are (e, f), $(a + e, c + f)$, and $(b + e, d + f)$, then any point $P = (1 - x - y)E_0 + xE_1 + yE_2$ with coordinates (x, y) has T-image with coordinates $(1 - x - y)(e, f) + x(a, c) + x(e, f) + y(b, d) + y(e, f) = (ax + by, cx + dy) + (e, f)$. ☐

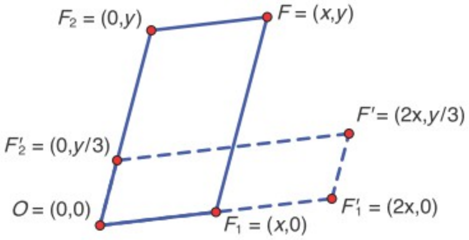

Figure 23. Compression-Expansion Scaling $(2x, y/3)$

One example of such an affine transformation is a **scaling transformation** $T(x, y) = (ax, by)$, where $ab \neq 0$. This differs from a dilation in that the scaling in the x and y directions is not the same. In directions when a or b is greater than 1, this is an expansion in the direction of e_1 or e_2. When less than one, it is compression.

Linear Transformations. Affine transformations induce transformations on vectors. If we write PQ in coordinates as $Q - P = (v_1, v_2)$, then applying T yields $T(Q) - T(P) = (av_1 + bv_2, cv_1 + dv_2)$. The coefficients a, b, c, d are the same, but the translation part of the formula disappears. This is consistent with the property of vectors that they have no fixed location.

In fact, as we saw when we derived the rotation formula, it may be clearer to work with transformations that map the origin O to itself and then add translations later.

Definition 11.18. A **linear transformation** is an affine transformation that has the origin O as a fixed point.

Thus, any linear transformation has the form $T(x, y) = (ax + by, cx + dy)$.

In a note above, it was observed that while we have shown that any linear transformation has this form, for some coefficients this formula is not a transformation. We will explore this by looking at the image of $\triangle E_0E_1E_2$.

We see that $T(E_0) = (0, 0)$, $T(E_1) = (a, c)$, and $T(E_2) = (b, d)$. We wish to find out more about this set of points by applying a couple of shear transformations. This is illustrated by Figure 24, with $(a, c) = (2, -1)$ and $(b, d) = (1, 1)$.

We will assume that $a \neq 0$. If this is not true, we can interchange the role of E_1 and E_2 and then assume $b \neq 0$. If both $a = 0$ and $b = 0$, then the points all are on the y-axis $\overline{E_0E_2}$, so this function T is not a transformation, since transformations map noncollinear point to noncollinear points.

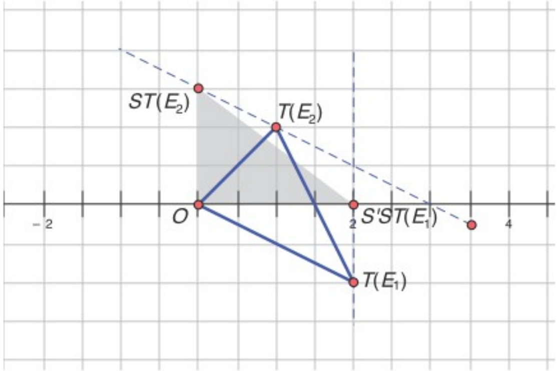

Figure 24. Shearing the Image of the Coordinate Triangle

Now assuming $a \neq 0$, let S be the shear parallel to $\overline{E_0T(E_1)}$ such that S-image of $T(E_2)$ will be on the line through $T(E_2)$ parallel to $\overline{E_0T(E_1)}$. Chose the shear S to be the shear that takes $T(E_2)$ to a point on the y-axis. This point will have the form $S(b, d) = (b, d) + k(a, c) = (0, t)$, so $k = -b/a$. This means that the image

$$ST(E_2) = S(b, d) = (b, d) - (b/a)(a, c) = (0, (ad - bc)/a).$$

In Figure 24, this is the point $ST(E_2) = (1, 1) + (-1/2)(2, -1) = (0, 3/2)$.

There is one exception: if this line through (b, d) intersects the y-axis at $(0, 0)$, then $ad - bc = 0$, the shear is not defined, and T is not a transformation since the images of E_0, E_1, E_2 are collinear. Henceforth, we assume $ad - bc \neq 0$. In the example in Figure 24, this quantity equals 3.

Next applying a shear S' parallel to the y-axis that will map $T(E_1)$ to a point on the x-axis will not change the points on the y-axis but will have $S'ST(E_1) = (a, 0)$. In Figure 24 this point is $(2, 0)$.

Let

$$H(x, y) = \left(\frac{x}{a}, \frac{ay}{ad - bc}\right).$$

Then $HS'ST = I$, the identity map, since it fixes the vertices of $\triangle E_0E_1E_2$. This means T has an inverse $S^{-1}S'^{-1}H^{-1}$ and so is a transformation when $ad - bc \neq 0$.

The Determinant of an Affine Transformation. The coefficients in the formula $T(x, y) = (ax + by, cx + dy)$ are commonly presented in the form of a matrix:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix}.$$

The quantity $ad - bc$ is called the **determinant of the matrix** or, in this case, the determinant of the transformation T. The determinant of an affine transformation is defined by the same formula as well; we will interpret this quantity in terms of area.

Continuing with the notation above, the $SS'T$ image of $\triangle E_0E_1E_2$ is a triangle with base a and height $|ad - bc|/a$, with area $(1/2)|ad - bc|$. Thus, the ratio of the area of the image to the original area is $|ad - bc|$, the absolute value of the determinant. By reasoning similar to that which showed shears do not change area, one can conclude that **an affine transformation T scales the area of any shape by the factor $|ad - bc|$.**

The sign of the determinant also has meaning. Since shears are orientation-preserving transformations of the plane, the product $SS'T$ is orientation-preserving if and only if T is orientation-preserving and the triangles $T(\triangle E_0E_1E_2)$ and $SS'T(\triangle E_0E_1E_2)$ have the same orientation. But the latter triangle has vertices $(0, 0)$, $(a, 0)$, and $(0, (ad - bc)/a)$.

For a triangle ABC with $A = O$, $B = (x_0, 0)$, and $C = (0, y_0)$, the triangle has positive orientation when $x_0y_0 > 0$. In the case of T, this means that T is orientation-preserving if $(ad - bc) > 0$ and it is orientation-reversing otherwise.

If we take unit area to be the area of $\triangle E_0E_1E_2$, then $T(\triangle E_0E_1E_2)$ has signed area equal to the determinant $ad - bc$. The absolute value $|ad - bc| = \mathcal{A}(T(\triangle E_0E_1E_2))/\mathcal{A}(\triangle E_0E_1E_2)$ while the sign indicates whether the two triangles have the same orientation. If one thinks in terms of the unit square, the determinant is the signed area of the parallelogram that is the image of the square.

Axioms and Models

To end the book, we would like to complete the circle that began by assuming a set of six axioms for Euclidean geometry and conclude by proving that there is a model for this geometry based on the real numbers.

When one creates a set of axioms for a mathematical structure, one has to be concerned about whether there actually exist any examples of the structure, or whether from contradictions or excessive restrictions in the axioms one is proving theorems about nothing. An example of this genuine concern was the early period of discovery in non-Euclidean plane geometry. Mathematicians such as Lobachevsky assumed that there could be more than one parallel to a line through a given point and proved beautiful and surprising theorems. But some mathematicians were very concerned that this purported non-Euclidean plane had some as yet undiscovered contradiction that meant it did not really exist, even as a mathematical abstraction. It was not until some models for the non-Euclidean plane were constructed by Poincaré and Klein that the geometry was accepted to be on a sound footing.

While the soundness of the concept of the Euclidean plane is not in question here, it is a satisfying exercise to see that one can define a mathematical model for the plane and prove our six axioms as theorems.

Theorem 11.19 (Plane Model $\mathcal{E}$ for the Six Axioms). *Let a model $\mathcal{E}$ for plane geometry be given by taking the points of $\mathbb{R}^2$ as the points of the plane and with lines, distance, and angle measure as specified in the following definitions. Then this is a model for Euclidean geometry in which the six axioms of Chapter 2 are valid.*

The points of $\mathcal{E}$ are number pairs such as $A = (a_1, a_2)$. We will add such points and multiply them by real numbers in our usual manner. We will also rely on computations with coordinates from earlier in the chapter to avoid needless repetition.

The First Three Axioms.

Definition 11.20 (Lines in $\mathcal{E}$). An $\mathcal{E}$-line, or simply line, is the set of solutions of an equation $ax + by = c$, for real numbers a, b, c with $(a, b) \neq (0, 0)$.

Proposition 11.21 (Axiom 1). *$\mathcal{E}$ consists of a nonempty set of elements called points and a nonempty set of subsets called lines. For distinct points P and Q, there is exactly one $\mathcal{E}$-line containing P and Q.*

Proof. The sets of points and lines are clearly not empty. For distinct $P = (p_1, p_2)$ and $Q = (q_1, q_2)$, let us consider the set of points $(1 - t)P + tQ$, where t is any real number. Then the points (x, y) of this set are solutions of

$$-(q_2 - p_2)x + (q_1 - p_1)y = -(q_2 - p_2)p_1 + (q_1 - p_1)p_2.$$

This equation, obtained by eliminating t from the parametrization, can be expressed more transparently with a dot product. If we set the normal direction

$$N = (-(q_2 - p_2), q_1 - p_1),$$

then $N \cdot (Q - P) = 0$, and the equation is $N \cdot (x, y) = N \cdot P$. In the development of the equation of a line earlier in this chapter, it was shown by computations in $\mathbb{R}^2$ that the solution set not only contains $\overleftrightarrow{PQ}$ but equals this set. □

Definition 11.22. The **norm** of a pair $A = (a_1, a_2)$ is $|A| = \sqrt{a_1^2 + a_2^2}$. The distance function in $\mathcal{E}$ is $\|AB\| = |B - A| = \sqrt{(b_1 - a_1)^2 + (b_2 - a_2)^2}$ for A and $B = (b_1, b_2)$.

Proposition 11.23 (Axiom 2). *The plane $\mathcal{E}$ has a distance function.*

- *Distance is a function that maps any two points A and B in the plane to a nonnegative real number $\|AB\|$.*

- *Every line m in the plane has a ruler, a mapping of the real numbers $\mathbb{R}$ onto m so that distances are preserved.*

Proof. Distance was defined above. Let the line $m = \overline{AB}$. If $d = \|AB\|$, then we claim $\rho(t) = (1-(t/d))A + (t/d)B$ is a ruler. To see this for any real numbers u, v, $\rho(v) - \rho(u) = ((v-u)/d)(B-A)$. Therefore, $\|\rho(v), \rho(u)\| = (|v-u|/d)|B-A| = |v-u|$, proving distance preservation as required. $\square$

Before moving on to the next axiom, we will introduce translations into the model with the usual formula.

Definition 11.24. A translation is a transformation T of $\mathbb{R}^2$ of the form $T(X) = X + C$ for some C in $\mathbb{R}^2$.

Note. For any translation, $|T(X) - T(Y)| = |X - Y|$ so translations preserve $\mathcal{E}$-distance. As usual, $\mathcal{T}_{AB}(X) = X + B - A$.

Definition 11.25. As before, for any real θ, let $U(\theta) = (\cos\theta, \sin\theta)$ and let $O = (0,0)$. Then the $\mathcal{E}$-protractor at O is the mapping $\delta(\theta) = \overrightarrow{OU(\theta)}$ and the protractor δ_A at point A is $\mathcal{T}_{OA}(\delta(\theta)) = \overrightarrow{A(A+U(\theta))}$.

Definition 11.26. Angle measure is defined in $\mathcal{E}$ as follows: $m\angle BAC = |b-c|$ when $\delta_A(b) = \overrightarrow{AB}$ and $\delta_A(c) = \overrightarrow{AC}$, provided that $|b-c| \leq 180$.

Proposition 11.27 (Axiom 3)**.** *The $\mathcal{E}$-plane has an **angle measure** that maps any two rays $\overrightarrow{AB}$ and $\overrightarrow{AC}$ with common endpoint to a real number $m\angle BAC$.*

- *The angle measure maps any angle $\angle BAC$ to a positive number $m\angle BAC$, with $0 < m\angle BAC < 180$.*
- *In addition, when $\overrightarrow{AB} = \overrightarrow{AC}$, the angle measure of this zero angle is $m\angle BAC = 0$. If the rays $\overrightarrow{AB}$ and $\overrightarrow{AC}$ are opposite rays, the angle measure of this straight angle is $m\angle BAC = 180$.*
- *For any point A, there exists a **protractor** at A. This is a mapping δ from the real numbers onto the rays with endpoint A, such that $\delta(t) = \delta(t+360)$ for every t, with the property that $m\angle BAC = |b-c|$ when $\delta(b) = \overrightarrow{AB}$ and $\delta(c) = \overrightarrow{AC}$, provided that $|b-c| \leq 180$.*

Proof. This all follows immediately from the definitions of protractor and angle measure, noting that $\overrightarrow{OU(\theta+180)}$ is the opposite ray of $\overrightarrow{OU(\theta)}$. $\square$

This short proof for what is arguably the most complicated of the axioms may seem unsettling, but if one thinks about it, it is a setup. The candidate for protractor is defined. Then angle measure is defined so that this protractor precisely fulfills the requirements of the axiom. The only point that is left to well-known mathematics is that the mapping $U(\theta)$ from $\mathbb{R}$ to the unit circle is periodic and onto. If one accepts this, there is nothing left to prove.

But perhaps the nagging question is whether this is really the angle measure that we expect in the Cartesian plane. Yes, it is. For example, if $A = (1,0)$ and $B = (3,4)$, what is $m\angle AOB$? Since $|(3,4)| = 5$, $\overrightarrow{OB} = \overrightarrow{OU(\theta)}$, where $U(\theta) = (3/5, 4/5)$. Then $m\angle AOB = \arccos(3/5)$, converted from radians to degrees.

So there is really substance in the proof, but the substance is in U and the trigonometric functions.

Before considering the final three axioms, we will introduce rotations as rigid motions in $\mathcal{E}$.

Definition 11.28. The rotation O_θ is the transformation defined as $O_\theta(x,y) = xU(\theta)+ yV(\theta)$, where $V(\theta) = (-\sin\theta, \cos\theta)$. For any point A, $A_\theta = \mathcal{T}_{OA} O_\theta \mathcal{T}_{AO}$.

Proposition 11.29. *Translations and rotations are both rigid motions of $\mathcal{E}$, meaning that they preserve distance and angle measure.*

Proof. It was already noted that translations preserve distance. They preserve angle measure because angle measure was defined as translation invariant. Rotations preserve distance by the same computation given earlier for the Cartesian plane. And they preserve measure since they just add a constant to each polar angle. ☐

The Final Three Axioms — In Part. For the final three axioms, we will follow a different strategy. We will prove each of Axioms 4 and 5 only for a line that is the x-axis and we will prove Axiom 6 only for the point O. Then we will transport the x-axis to any line or O to any point by means of a rigid motion.

Definition 11.30 (Half-planes of the x-axis)**.** For the x-axis, the set of points $(x, 0)$, the upper half-plane is the set of points (x, y) with $y > 0$ and the lower half-plane is the set with $y < 0$.

Proposition 11.31 (Axiom 4 for the x-axis)**.** *Let m denote the x-axis; then any point not on line m belongs to one of two disjoint sets called the **half-planes of the line**.*

- *Points P and Q are in different half-planes when PQ intersects m. They are in the same half-plane if PQ does not intersect m.*
- *Let $m = \overline{AB}$. If a protractor is chosen so that $\theta(\overrightarrow{AB}) = 0$, the points P for which $0 < \theta(\overrightarrow{AP}) < 180$ lie in one half-plane, and the Q for which $-180 < \theta(\overrightarrow{AQ}) < 0$ are in the other half-plane.*

Proof. The segment PQ intersects the x-axis when $(1-t)P + tQ$ at $t = p_2/(p_2 - q_2)$, a number between 0 and 1 when p_2 and q_2 have opposite sign. Also, $U(\theta)$ is in the upper half-plane when $0 < \theta < 180$ and in the lower half-plane when $-180 < \theta < 0$. ☐

Proposition 11.32 (Axiom 5 for the x-axis)**.** *For the x-axis, there exists a rigid motion distinct from the identity transformation that fixes the points of the x-axis.*

Proof. Let $R(x, y) = (x, -y)$. This is clearly a rigid motion that fixes the points of the x-axis. ☐

Definition 11.33. The $\mathcal{E}$-dilation $\mathcal{D}_{O,k}$ is the mapping $\mathcal{D}_{O,k}(x, y) = (kx, ky) = k(x, y)$.

Proposition 11.34 (Axiom 6 for O)**.** *For every point O and every $k > 0$, the dilation $\mathcal{D}_{O,k}$ preserves angle measure and scales every distance by k: for all $P' = \mathcal{D}_{O,k}(P)$ and $Q' = \mathcal{D}_{O,k}(Q)$, $\|P'Q'\| = k\|PQ\|$.*

Proof. A direct substitution proves the scaling statement. $P' = \mathcal{D}_{O,k}(P) = kP$ and $Q' = \mathcal{D}_{O,k}(Q) = kQ$, so $\|P'Q'\| = |P' - Q'| = k|P - Q| = k\|PQ\|$. As for angles, $\mathcal{D}_{O,k}$ maps a ray $\overrightarrow{AB}$ to a parallel ray $\overrightarrow{A'B'}$ in the same direction. Therefore, $\mathcal{D}_{O,k}(\overrightarrow{AB}) = \mathcal{T}_{AA'}(\overrightarrow{AB})$. This means that the dilation image of an angle $\angle BAC$ is also a translation image of this angle, so the measures are the same. □

The Final Three Axioms. To complete the proof that the final three axioms hold in $\mathcal{E}$, we will use translations and rotations, which are known to be rigid motions in $\mathcal{E}$.

To prove the Plane Separation Axiom, Axiom 4, for any line m, first rotate the x-axis so that it is parallel to m; then translate the rotated line to m. Then the half-planes and all the relations are preserved by the rigid motion S that is the composition of these two rigid motions.

To prove the Reflection Axiom for a line m, again choose the same rigid motion S that takes the x-axis to m. Then if R is the reflection that we defined for the x-axis, the rigid motion SRS^{-1} is a rigid motion that fixes the points of m.

Finally, the dilation $\mathcal{D}_{A,k}$ with the usual definition equals $\mathcal{T}_{OA}\mathcal{D}_{O,k}\mathcal{T}_{AO}$. Since translations are rigid motions, the scaling relation will remain true.

Thus we have connected back to the beginning with a model that satisfies Axioms 1–6 of Chapter 2.

Conclusion

While the geometry in this chapter is interesting in its own right, the concepts and tools introduced here extend to areas of geometry that would require several more books to pursue. In plane geometry, the complex numbers are essential for the geometry of circles and inversions, which can in turn be used to model non-Euclidean geometry. Barycentric coordinates can be extended to include a line at infinity with $c_1+c_2+c_3 = 0$, leading to projective geometry. Beyond the plane, affine and Cartesian coordinates can be extended to any dimension. Matrices and vectors in all dimensions are everywhere in mathematics and its applications. Our hope is that this introduction to these tools and concepts through plane Euclidean and affine geometry will provide background and motivation for further exploration, either in the deeper regions of Euclidean geometry itself or in other areas beyond.

Exercises and Explorations

1. (Pencils of Lines). For two functions $f_0(x,y) = a_0x + b_0y - c_0$ and $f_1(x,y) = a_1x + b_1y - c_1$, the equations $f_0(x,y) = 0$ and $f_1(x,y) = 0$ are the equations of lines m_0 and m_1. Let t be any real number; then $(1-t)f_0(x,y) + tf_1(x,y) = 0$ is also the equation of a line m_t.
   (a) Prove that if m_0 and m_1 intersect at a point P, then all the m_t pass through P.

(b) Prove that if m_0 and m_1 are parallel, then all the m_t are parallel (or equal) to these lines.

(c) The set of all lines that pass through a point P is called the **pencil of lines through** P. The set of lines parallel to or the same as a line m is called the **pencil of lines parallel to** m. Explain why any two lines belong to a unique pencil and any distinct pencils either intersect in one line or no lines. (If the words line and pencil are interchanged in this sentence, do these words sound familiar?)

(d) Let $m \parallel n$ mean that m and n belong to the same parallel pencil. Show that this relation satisfies the three criteria in Theorem 1.4 when $\cong$ is replaced by $\parallel$. Such a relation is called an equivalence relation. Why is $m \parallel n$ an equivalence relation while the relation "m is parallel to n" is not?

2. (Ruler for a Line). For constants m and b, the map $P(x) = (x, mx+b)$ is a parametrization of a line p but not necessarily a ruler.
   (a) For what values of m and b will this be a ruler?
   (b) Find rulers for some lines with equations such as $x + y = 1$ and $3x + 4y = 5$.

3. (Negative Dot Product). If $m\angle MON = \theta$, show that the dot product $N \cdot M = \|ON\|\|OM\| \cos\theta$, even when the dot product is 0 or negative.

4. (Reflection Formula). Using the notation $O = (0, 0)$, $U(\theta) = (\cos\theta, \sin\theta)$, and $V(\theta) = (-\sin\theta, \cos\theta)$, let F be the function with this coordinate formula:

$$F(x, y) = xU(2\theta) + yV(2\theta) = x(\cos 2\theta, \sin 2\theta) + y(\sin 2\theta, -\cos 2\theta).$$

   (a) Confirm that $F(O) = O$, $F(U(\theta)) = U(\theta)$, and $F(V(\theta)) = -V(\theta)$.
   (b) Show that F preserves distance.
   (c) Explain why this proves that $F = \mathcal{R}_{OU(\theta)}$.

5. (Area and Barycentric Coordinates). For the point S in Figure 16, check by computing barycenters and ratios on each triangle side that the areas are what was stated in the text.

6. (Radical Axis). Given a circle c with center A and radius r, the power of a point P with respect to c is $\|AP\|^2 - r^2$. The radical axis of two circles c_1 and c_2 is the set of points P for which the two powers are.equal.
   (a) Use coordinates to write a formula for the the radical axis of two circles. Show this set is a line perpendicular to the line of centers when the circle centers are distinct.
   (b) Compare this coordinate proof with the proof of Theorem 8.46. How are they similar, and how do they differ?

7. (Transformation Conjugation and Complex Numbers). Let $S(z) = \alpha z$ and $T(z) = z + \beta$. Use complex numbers to compute two transformation conjugations from these transformations (not to be confused with complex conjugate).
   (a) Generalize the corollary on page 181 by computing the conjugation TST^{-1} and finding its fixed point using Theorem 11.8. Since T is a translation and S can be a rotation or a dilation, this generalizes the corollary.
   (b) Compute also the conjugate STS^{-1}. What kind of transformation is this? Draw a picture of this when $\alpha = 2$.

   (c) Let $R(z) = \overline{z}$ (yes, complex conjugate!). Compute RSR^{-1}. What kind of transformation is this? How does this result differ from that of the corollary when $|\alpha| = 1$?

8. (Incenter Barycentric Coordinates). For a triangle $\triangle ABC$, let a, b, and c be the lengths of the sides opposite A, B, C.
   (a) Show that (a, b, c) are the barycentric coordinates of the incenter, the point of concurrence of the angle bisectors.
   (b) What are the barycentric coordinates for the three excenters, the points of concurrence of two exterior angle bisectors and one interior bisector? Hint: Theorem 8.18.

9. (Midpoints and Affine Transformations). T is an affine transformation that maps segment AB to CD.
   (a) If $P(t) = (1-t)A + tB$, show that $T(P(t)) = Q(t)$, where $Q(t) = (1-t)C + tD$, for $0 \le t \le 1$.
   (b) Prove that the set of midpoints of $P(t)Q(t)$ is a segment or a point. (For an isometry T, this is called Hjelmslev's Theorem, Coxeter [5, Section 3.6].)

10. (Affine Congruence). Prove that in affine geometry all triangles are alike ("affine-congruent"). In other words, for any two triangles, there is an affine transformation that takes one to the other. Hint: Rather than try to find a formula in one step, you can write the affine transformation as the product of simpler transformations that step by step transform one triangle to coincide with the other one.

11. (Uniqueness of Affine Transformations). Prove that if two affine transformations S and T map the vertices of a triangle $\triangle ABC$ to the same points, then $S = T$. Hint: To simplify the problem, let $\triangle ABC$ define a coordinate system.

12. (Area and Determinants). In a Cartesian coordinate system, let $A = (a_1, a_2)$ and $B = (b_1, b_2)$. If $C = A + B$, prove that the area of a parallelogram $OACB$ is the absolute value of the determinant of $\begin{pmatrix} a_1 & b_1 \\ a_2 & b_2 \end{pmatrix}$, with the sign of the determinant indicating the orientation of this parallelogram.

13. (Bézier Curve). For three points A, B, C, let $F(t) = (1-t)A + tB$ and $G(t) = (1-t)B + tC$. The image curve of the function $P(t) = (1-t)F(t) + tG(t)$ is called the Bézier curve with A, B, C as control points. The curve is used in computer graphics.

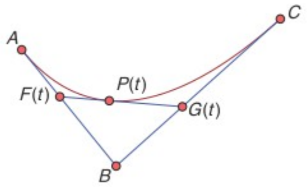

Figure 25. Bézier Curve for $0 \le t \le 1$

(a) Draw three points A, B, C, then several examples of $F(t)$, $G(t)$, and $P(t)$ for several values of t. It would be best if you could do this with dynamic geometry software and let t vary, but it is otherwise helpful to see an example with several points plotted.

(b) For the points $A = (-c, 1)$, $B = (0, 0)$, and $C = (c, 1)$, show that this curve satisfies the equation $y = ax^2 - b$ for some a and b. This is the equation for a parabola. Note: There is an affine transformation that will map these control points to any distinct and noncollinear A, B, C and so will map this parabola to the corresponding Bézier curve. Therefore, all such Bézier curves are parabolas.

14. In Figure 26, one sees on the left how a one-dimensional object, a segment, is translated to another segment that is the opposite side of a parallelogram. In the middle figure, a parallelogram is translated to what looks like the opposite face of the plane projection of a three-dimensional object, such as a cube or a parallelepiped. This figure is repeated on the right, without the arrows.
    (a) In the figure on the right, show that the four "diagonals" indicated by the dashed lines are concurrent. Is this point a center of mass?
    (b) Draw a new figure in this sequence by translating the figure on the right to produce a figure with 16 vertices that appears to be the projection of a four-dimensional object such as a hypercube.
    (c) In this new figure, describe 8 diagonals that generalize the diagonals from the previous case; then show that they are concurrent.

Areas, Angles, and Polyhedra

The first goal of trigonometry—to solve any triangle given some information about its sides and angles—has been accomplished, so it is at this point that most textbooks stop. This is a pity, because while the straightforward practical work has been completed, a wealth of mathematical pleasures that might have spurred a lot of curiosity lies just around the corner. Fortunately we are not bound by early 20th-century mathematics curricula, so we shall press onward and taste some of these delights.

We begin with a seemingly practical problem that we have so far carefully ignored: to find the area of a spherical triangle or polygon. In fact, the applications of finding areas on the sphere are somewhat limited. Hardly anyone has ever needed to calculate areas of tracts of land or ocean so vast that the curvature of the Earth needed to be accounted for. And in astronomy, predicting the positions of the Sun, Moon, and planets does not rely on knowledge of areas of sections of the sky. So historically, scientists simply didn't care. However, there is a mathematical motive: an exploration of areas leads quickly, and rather unexpectedly, to a tour of some of the greatest geometrical theorems ever discovered. So for this chapter we shall depart from our usual physical contexts and take a journey for the sake of pure geometric pleasure.

Recall from chapter 2 that it is possible to form a spherical polygon with only two sides. A *lune* is the part of a sphere captured between two great semicircles joined at their ends (figure 7.1), named because of its resemblance to a crescent moon. Its area is easy to find, since the ratio of the angle θ between the two great circles to 360° is equal to the ratio of the area of the lune to the surface area of the sphere. In the standard unit sphere the surface area is $4\pi r^2 = 4\pi$, so

$$\frac{\text{area of lune}}{4\pi} = \frac{\theta}{360^\circ}.$$

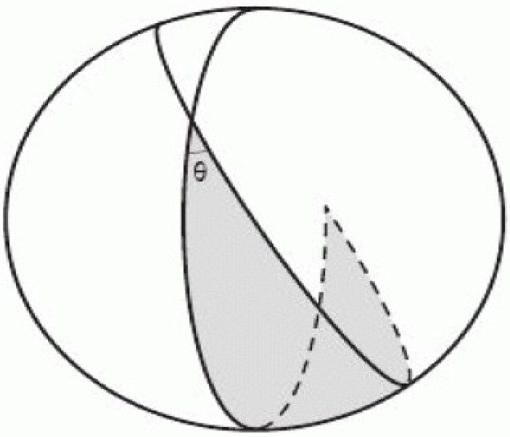

Figure 7.1. Finding the area of a lune.

Thus, measuring θ in degrees,

$$\text{area of lune} = \frac{\pi\theta}{90}.$$

The formula for the area of a spherical triangle is named after Albert Girard (1595–1632), a French mathematician whose Protestant faith likely forced him to flee his home country and settle in the Netherlands. He appears to have struggled to make a living there, with no patron and eleven children. Whether or not this difficult circumstance led to his early death is left to the reader to speculate. Girard lived at a time when the symbols we use today for algebra were in the process of being formulated. He was one of the first to use the abbreviations "sin," "tan," and "sec," and in his *Invention nouvelle en l'algebre* (1629) he invented the $\sqrt[3]{}$ notation for cube roots. Surprisingly, his theorem on the areas of spherical triangles is found not in his *Trigonométrie* (1626), but in the *Invention nouvelle*. He was not happy with his own demonstration; a full proof written by Bonaventura Cavalieri would eventually appear three years later.

> →Girard's idea is simple: extend all three sides of the given triangle into great circles and consider the triangles and lunes that result. In figure 7.2 the original triangle is ΔABC, and the $'$ symbols represent antipodal points. The triangle may be extended in three different ways to form lunes (colunar triangles): extend the sides departing from A all the way to the antipodal point A', forming $ABA'C$; or extend the sides from B; or extend the sides from C. If we add these three lunes together, we get

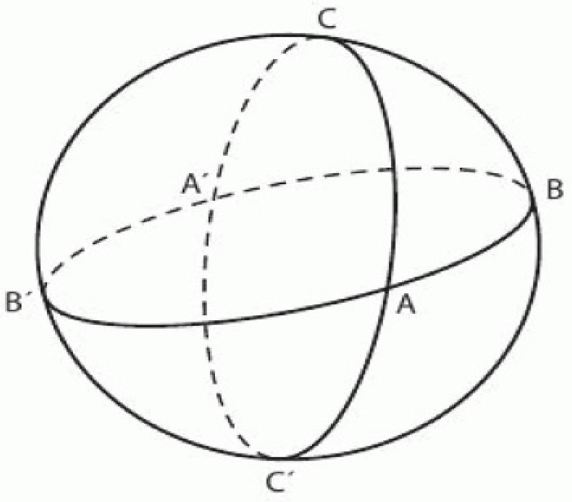

Figure 7.2. Proving Girard's Theorem.

$$2\Delta ABC + (\Delta ABC + \Delta A'BC + \Delta AB'C + \Delta ABC').$$

By symmetry we can replace $\Delta A'BC$ with $\Delta AB'C'$; then the four triangles grouped in parentheses will form the hemisphere at the front of figure 7.2, with area 2π. But the areas of the three lunes, considered separately, may be found using the area formula we derived a few moments ago. So

$$2\Delta ABC + 2\pi = \frac{\pi}{90}(A + B + C),$$

which simplifies to

$$\Delta ABC = \frac{\pi}{180}(A + B + C - 180^\circ).\rightarrow$$

In other words, the area of a spherical triangle is proportional to the amount by which the sum of its angles exceeds 180°. This *spherical excess*, which we call $2E$ in anticipation of events to come in the next chapter, thus plays a meaningful role here, and its significance will continue to grow.

We can extend this result to find the area of any convex spherical polygon. Choose any point in the polygon's interior (figure 7.3) and connect it with each vertex, thereby breaking the polygon into triangles. Let n be the number of sides, and add up the areas of the triangles:

$$\text{Area} = \frac{\pi}{180}[(\text{Sum of triangles' angles}) - n \cdot 180^\circ]$$

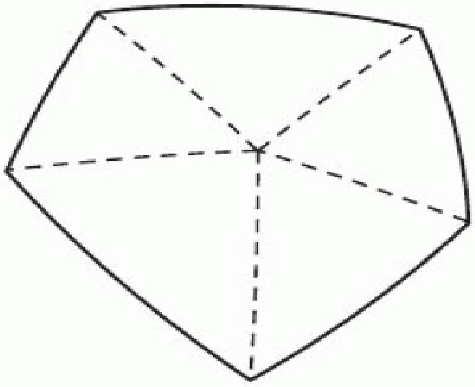

Figure 7.3. Decomposing a spherical polygon into triangles.

$$= \frac{\pi}{180}[(\text{Sum of polygon's angles}) + 360^\circ - n \cdot 180^\circ]$$

$$= \frac{\pi}{180}[(\text{Sum of polygon's angles}) - (n - 2) \cdot 180^\circ].$$

Since the angles of a planar polygon sum to $(n-2) \cdot 180^\circ$, it makes sense to refer to the square-bracketed quantity as the *spherical excess of the polygon*.

Euler's Polyhedral Formula

Here our subject takes a surprising turn, apparently away from spheres altogether. Consider any *convex polyhedron*, that is, a solid consisting of polygons as faces and having no inward "dents." Five such polyhedra can be constructed using identical regular polygons for each face: using triangles, we get the tetrahedron, octahedron, and icosahedron; using squares, the cube; and using pentagons, the dodecahedron (figure 7.4). These are known as the *regular polyhedra*. But there are plenty other polyhedra that are not regular, such as the square pyramid and the cuboctahedron in figure 7.5. Pick any of these shapes, say, the cuboctahedron. It has $V = 12$ vertices, $E = 24$ edges, and $F = 14$ faces (six squares and eight triangles). So $V - E + F = 2$. Try this for the other polyhedra shown here, or indeed any convex polyhedron whatever, and you will always get $V - E + F = 2$.

This curious fact is known today as Euler's polyhedral formula, named after the dominant 18th century mathematician Leonhard Euler (1707–1783). Much of the notation and form of the algebra that we use

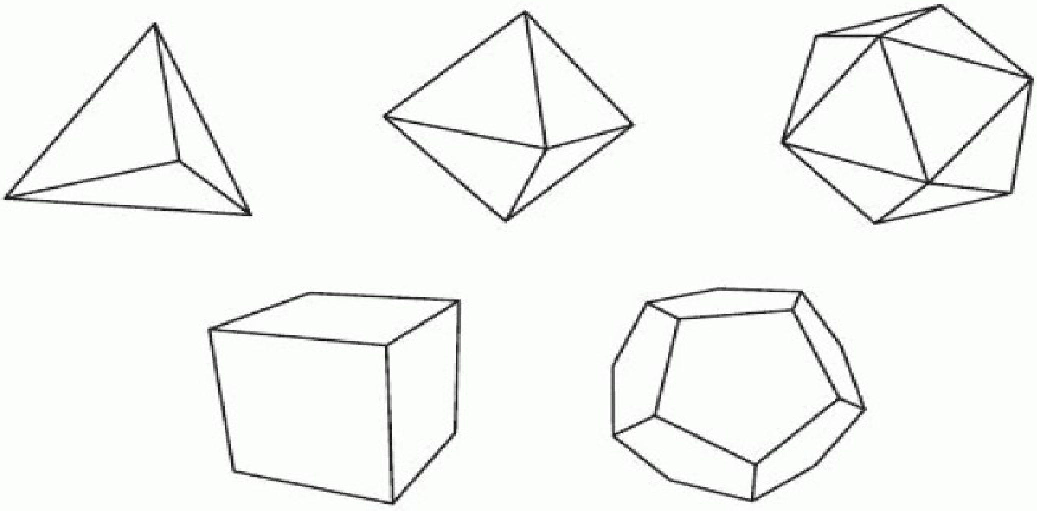

Figure 7.4. The five regular polyhedra—tetrahedron, octahedron, icosahedron, cube, dodecahedron.

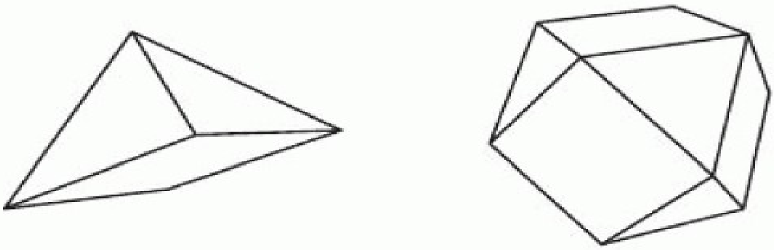

Figure 7.5. Two non-regular polyhedra—the square pyramid and the cuboctahedron.

today in calculus, such as functions and exponentials, was formulated by Euler. His accomplishments are incredibly varied: from geometry and number theory to calculus and differential equations, and onward to astronomy, optics, and navigation, including spherical trigonometry. There is scarcely an area of 18th-century mathematics that Euler did not affect deeply. During his life he wrote an average of almost three pages of published mathematics *per day*—not including the huge volume of work that was released after his death. The onset of blindness in his later life did not slow him down; he simply continued to dictate his mathematics, fully formed, to his assistants.

In 1750 Euler wrote to his colleague Christian Goldbach about the relation $V - E + F = 2$. Eventually he produced an argument that this equation must hold for any convex polyhedron, but his reasoning did not meet the mettle of a full-scale proof. Today, there are at least 19 different proofs. Perhaps the most common approach uses *graph theory*, an area

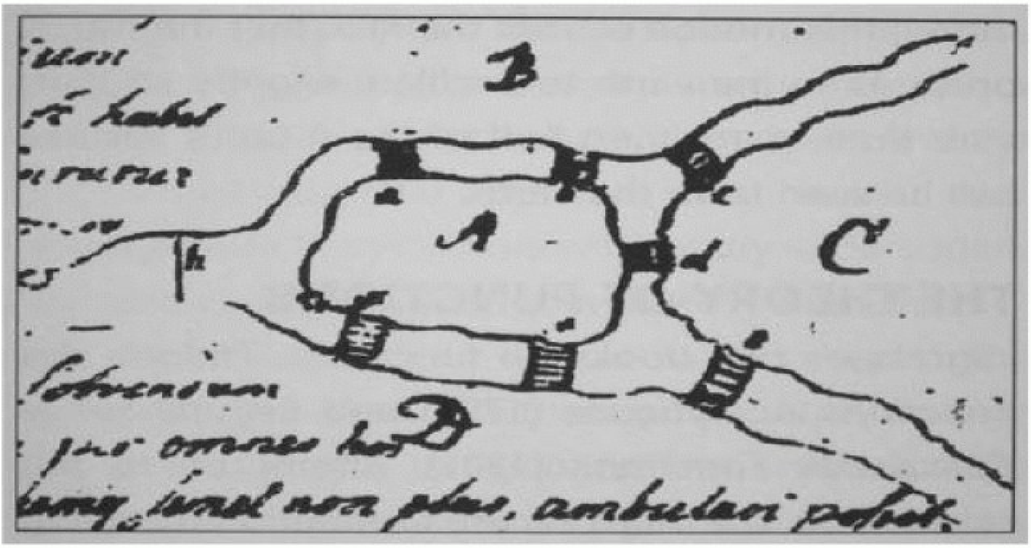

Figure 7.6. The bridges of Königsberg as they appeared in Euler's paper on the subject. See the original paper at the Euler Archive (http://eulerarchive.maa.org/pages/E053.html).

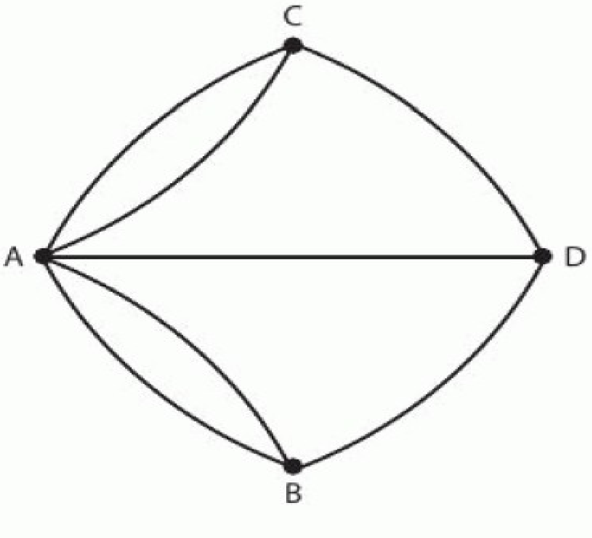

Figure 7.7. A graph representing the Bridges of Königsberg problem.

of mathematics sometimes attributed (mostly falsely) to Euler. The story goes that the citizens of Königsberg enjoyed weekend strolls through their town, which is located along a river with two islands (figure 7.6). Naturally, they wished for a journey that took them across each bridge exactly once without retracing their path, making for a more interesting walk. We begin our search for the ideal path by considering each location (the two river banks and the two islands) to be just a single point called a *node*, and each bridge to be an *edge*. This leads to the *graph* in figure 7.7. We may verify quickly that departing from each of the four nodes is an odd number of edges. Imagine that the ideal path exists; if so, the citizen would both enter *and* depart each node (other than the start and finish) some number of times; therefore only the start and finish may have an odd number of departing edges. But all four nodes in our graph have an odd number of departing edges; therefore, the ideal path cannot exist. Euler's argument was something like this, although it would be more than a century before diagrams such as figure 7.7 were drawn.

The proof of $V - E + F = 2$ using graph theory works as follows. Remove one face of the polyhedron, and stretch out the edges to produce a graph on a flat surface (so that the edges of the missing face form the outer boundary). For instance, in figure 7.8(a) we have removed the square base of the pyramid. Since one face has been removed, we must show that $V - E + F = 1$ for this graph. For each face that is not a triangle, add an edge to the graph by joining two non-adjacent vertices; continue doing this until only triangles remain. Each time we add an edge, E and F increase by one, leaving $V - E + F$ unchanged. (In our case each face is already a triangle, so we do not have to perform this procedure.) Now choose a triangle on the outer boundary of the graph. If only one of the triangle's edges is on the boundary, then remove that edge (figure 7.8(b)). Then E decreases by one and F decreases by one, leaving $V - E + F$ unchanged. If two of the triangle's edges are on the boundary, remove them and their shared vertex (figure 7.8(c)). This action decreases E by two, V by one, and F by one, again leaving $V - E + F$ unchanged. Repeat these steps until all that remains is a single triangle. For that triangle, $V - E + F = 3 - 3 + 1 = 1$, and the theorem is proved.

Oddly, however, the first rigorous proof of Euler's polyhedral formula came from an entirely different and seemingly unrelated corner

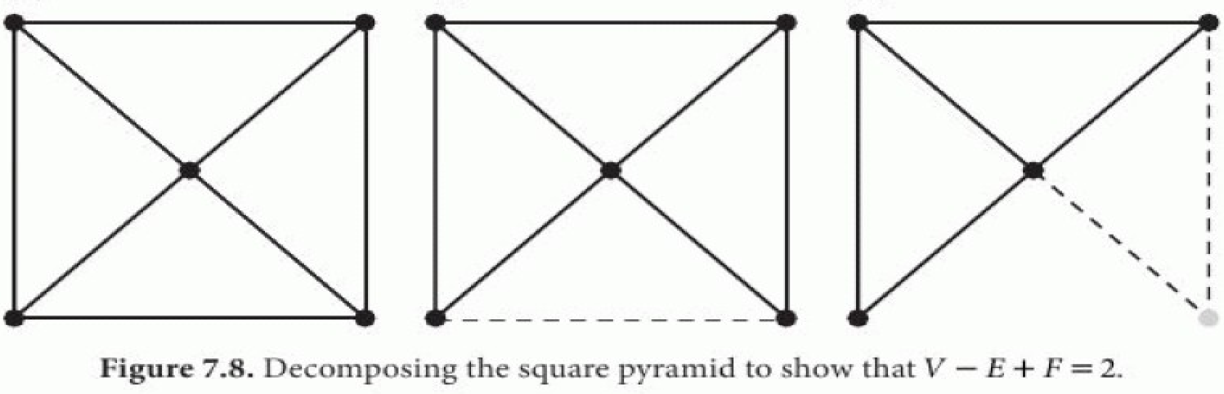

Figure 7.8. Decomposing the square pyramid to show that $V - E + F = 2$.

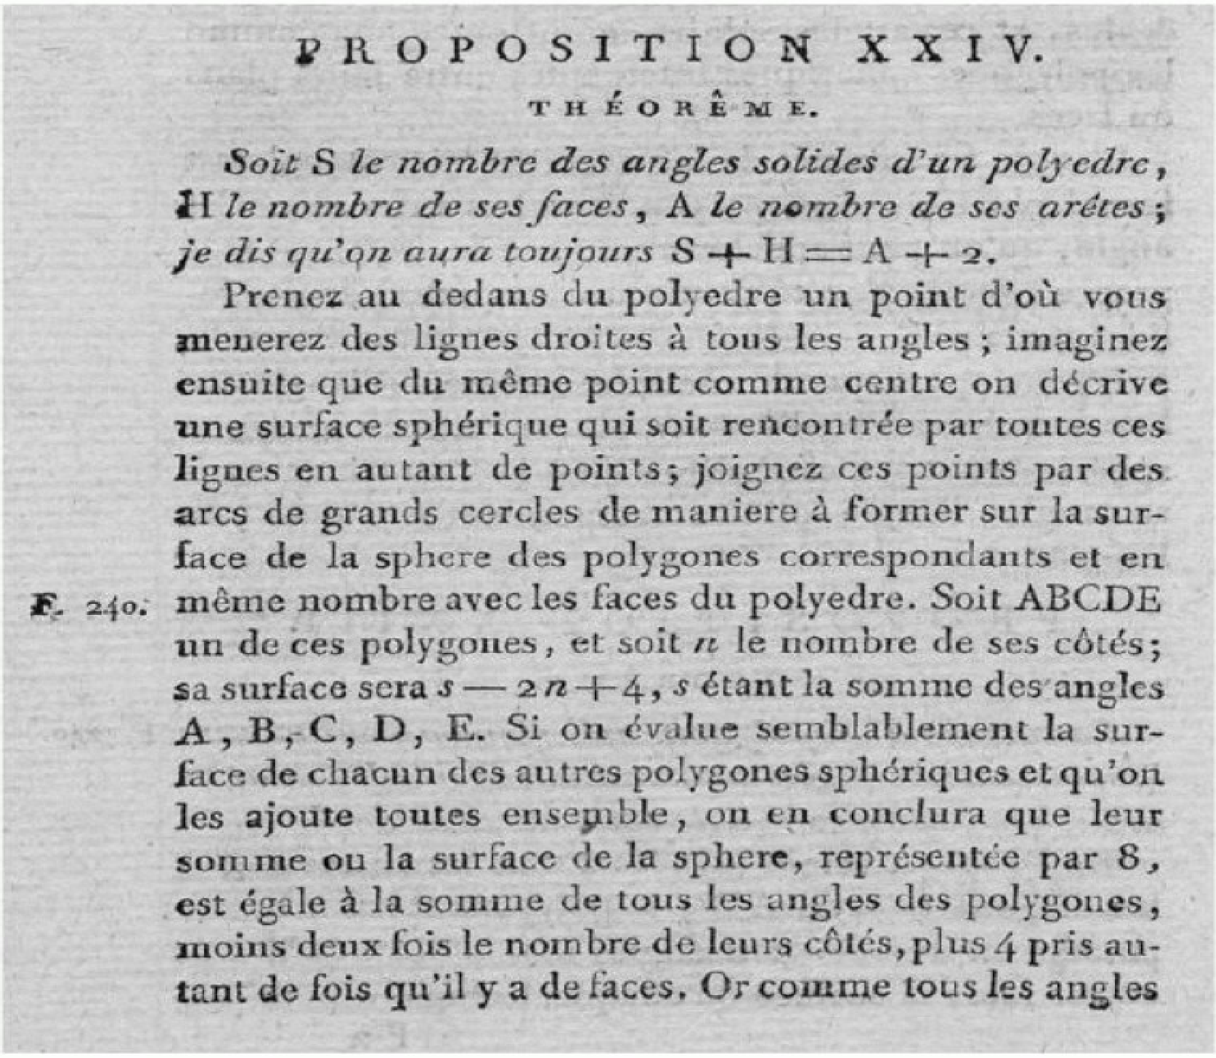
of mathematics: spherical trigonometry. Forty-four years after Euler's letter to Goldbach, the great French analyst Adrien-Marie Legendre (1752–1833) published his *Éléments de Géométrie*, one of the most successful textbooks ever written. In various versions and translations it swept through Europe and America, in many cases replacing Euclid's *Elements*, and became the standard geometry text for over a century. It contains the first proof that π^2 is irrational, as well as the first proof that $V - E + F = 2$.

The argument appears in the middle of Legendre's Book 7 entitled "The Sphere" (figure 7.9), where no one would think to look for it.



PROPOSITION XXIV.

THÉORÊME.

Soit S *le nombre des angles solides d'un polyedre,* H *le nombre de ses faces,* A *le nombre de ses arêtes; je dis qu'on aura toujours* $S + H = A + 2$.

Prenez au dedans du polyedre un point d'où vous menerez des lignes droites à tous les angles ; imaginez ensuite que du même point comme centre on décrive une surface sphérique qui soit rencontrée par toutes ces lignes en autant de points; joignez ces points par des arcs de grands cercles de maniere à former sur la surface de la sphere des polygones correspondants et en

F. 240. même nombre avec les faces du polyedre. Soit ABCDE un de ces polygones, et soit n le nombre de ses côtés; sa surface sera $s - 2n + 4$, s étant la somme des angles A, B, C, D, E. Si on évalue semblablement la surface de chacun des autres polygones sphériques et qu'on les ajoute toutes ensemble, on en conclura que leur somme ou la surface de la sphere, représentée par 8, est égale à la somme de tous les angles des polygones, moins deux fois le nombre de leurs côtés, plus 4 pris autant de fois qu'il y a de faces. Or comme tous les angles

Figure 7.9. The beginning of the proof of $V - E + F = 2$ in the first edition of Legendre's *Éléments de Géométrie*, the first time a correct proof appeared in print. This item is reproduced by permission of The Huntington Library, San Marino, California.

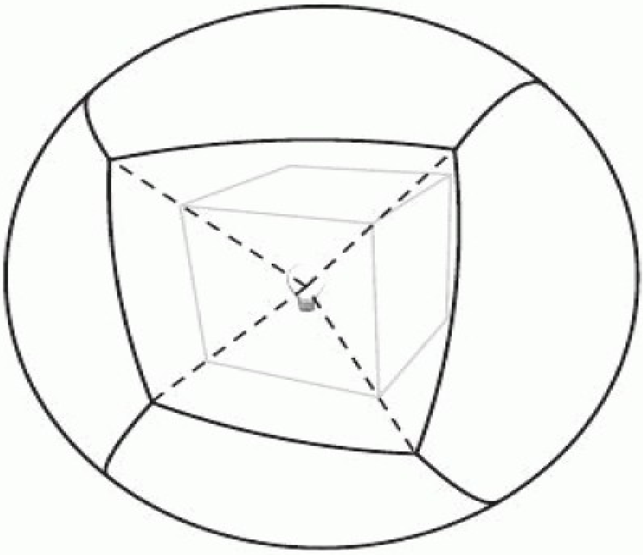


Figure 7.10. Legendre's projection of a polyhedron outward onto the surface of a sphere, in this case a cube. The projected cube is the entire sphere; only the projections of the edges and vertices facing forward are visible.

Legendre begins in a manner similar to the proof we just saw, by projecting the polyhedron—but not onto a flat surface, rather outwards onto an enclosing sphere (figure 7.10). Imagine a point source of light within the polyhedron, with each vertex casting its shadow on the sphere. Connect the "shadowed" vertices on the surface of the sphere with great circle arcs; we now have a *spherical polyhedron*.

> →Assuming that the sphere has a unit radius, its surface area is 4π. But we can find the surface area another way, by adding together the areas of each face of the spherical polyhedron. We happen to have a formula for these areas. In our notation,
>
> $$\sum \frac{\pi}{180}[(\text{Sum of polygon's angles}) - (n-2)\cdot 180^\circ] = 4\pi.$$
>
> Cleaning up a bit and expanding out the sum produces
>
> $$(\text{Sum of all angles}) - \sum n \cdot 180^\circ + 2F \cdot 180^\circ = 720^\circ.$$
>
> But the angles encompass each of the vertices, so the sum of the angles is just $V \cdot 360^\circ$. And since every edge is counted as part of exactly two polygons, $\sum n = 2E$. So
>
> $$V \cdot 360^\circ - 2E \cdot 180^\circ + 2F \cdot 180^\circ = 720^\circ.$$

Canceling 360° brings us to our goal:

$$V - E + F = 2.\rightarrow$$

The Regular Polyhedra

Having Euler's polyhedral formula in our possession brings us very close to yet another of the most famous theorems in mathematics: that the five regular polyhedra in figure 7.4 are the *only* regular polyhedra. This fact has been known since ancient Greece; it is demonstrated by Euclid (in a manner entirely different from what we shall see here) as the culmination of the thirteenth and last book of the *Elements*. Euclid's masterpiece is not a mere logically-ordered listing of theorems; it is arranged to cultivate a sense of suspense. We saw in the previous chapter that Euclid builds Book I to a climax in the Pythagorean Theorem and its converse. He maintains a similar sense of drama with his last three books on solid geometry. As he goes into the home stretch, Euclid shows how to construct each of the five regular polyhedra embedded within a sphere, and gives their dimensions. Finally, just after the last numbered proposition, he concludes with a flourish: there can be no regular polyhedra other than the five he has just constructed.

The regular polyhedra are sometimes called the *Platonic solids*, referring to their appearance in Plato's dialogue, *Timaeus*. In this cosmological work Plato identifies each of the regular polyhedra with one of the Greek elements: fire with the tetrahedron, air with the octahedron, water with the icosahedron, earth with the cube, and the celestial firmament with the dodecahedron. Euclid's proof, then, demonstrated that the analogy between the cosmological elements and the polyhedra was perfect.

Of course Euclid did not have access to $V - E + F = 2$, but we do. Its use makes the path to the conclusion that there are only five regular polyhedra quite short.

> →Let m be the number of sides in a face of a regular polyhedron, and let n be the number of faces that meet at each vertex. Then the number of edges E is equal to $mF/2$, since each edge is the side of two faces; and E is also equal to $nV/2$, since each edge touches two

vertices. From $V - E + F = 2$ and $E = mF/2 = nV/2$, a little algebra gets us to

$$V = \frac{4m}{2(m+n)-mn},\ E = \frac{2mn}{2(m+n)-mn},\ \text{and } F = \frac{4n}{2(m+n)-mn}.$$

The denominator of this expression must be positive, so $2(m + n) > mn$, or (dividing through by $2mn$) $\frac{1}{m} + \frac{1}{n} > \frac{1}{2}$. But both m and n must be greater than 2. A bit of plugging and chugging quickly reveals that the only possible pairs m, n that satisfy the inequality are 3,3 (tetrahedron); 3,4 (octahedron); 4,3 (cube); 3,5 (icosahedron); and 5,3 (dodecahedron).→

The mysticism associated with the regular polyhedra didn't stop with the Greeks. Consider late 16th-century astronomer Johannes Kepler, known today as one of the fathers of modern science for having demonstrated that the planets travel around the Sun in ellipses rather than in combinations of circles. None of the 17th-century natural philosophers really fit the impassive, objective lab-coated image that we conjure when we think of scientists today. Kepler was a deeply committed Christian, and he believed that harmonies were encoded in God's mathematically-inspired creation of the universe. He took the word "harmony" both figuratively and literally: in his *Harmonices mundi* (*Harmony of the World*) he tried to find resonances between musical chords and astronomical ratios. His earlier astronomical work, *Mysterium cosmographicum* (*Cosmic Mystery*), brought to light a peculiar relation between the five regular polyhedra and the six then-known planets. If we nest the five regular polyhedra within spheres, one inside of the other, in just the right order, the ratios of their distances from the center mirror (more or less) the ratios of the distances of the planets from the Sun. Kepler's cosmology, illustrated in the famous drawing of figure 7.11, cannot work beyond the planets visible to the naked eye (for one, there are no more regular polyhedra left to nest), but of course he was not to know that. Uranus would be discovered by Sir William Herschel almost two centuries later.

It doesn't sound easy to work out the dimensions of planetary orbits by calculating the sizes of polyhedra nested in spheres. But by now, it should come as no surprise that spherical trigonometry is the key to a manageable solution. Imagine a regular polyhedron enclosed within a

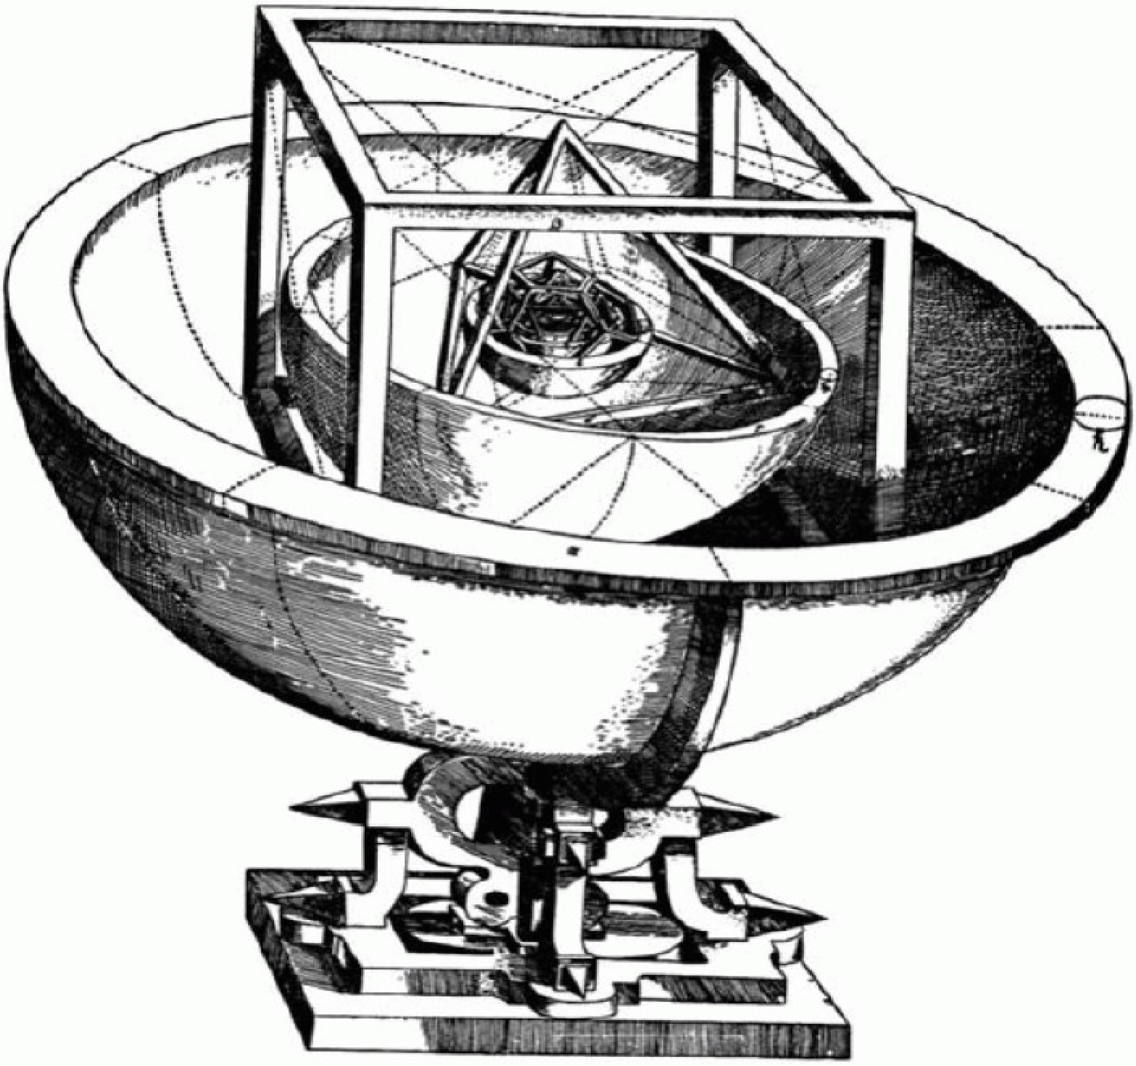

Figure 7.11. Kepler's polyhedral model of the solar system. Courtesy Wikimedia Commons.

unit sphere, meeting the polyhedron at the vertices. Then a sphere inscribed *within* the polyhedron will contact the polyhedron at the center of each face. What is the radius, *r*, of this inscribed sphere?

> →Figure 7.12 illustrates one face (portrayed here as a triangle, but it could be a square or pentagon) of a regular polyhedron, with O at the center. $OA = 1$, and since the inscribed sphere touches the polyhedron at C, $OC = r$. Let E be the end of the perpendicular dropped from C to the midpoint of AB. Imagine OC and OE extended to C' and E' on the circumscribed sphere, forming the right-angled spherical triangle $AC'E'$. Then since $\measuredangle OCA$ is right,

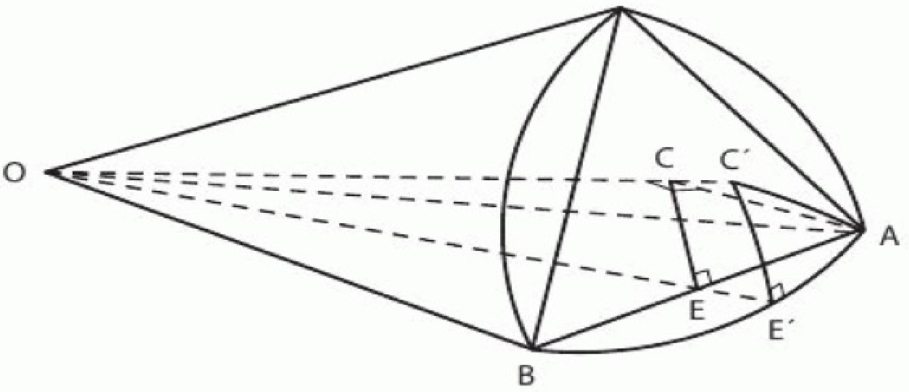

Figure 7.12. Determining the radius of a sphere inscribed within a regular polyhedron.

$$r = \cos\measuredangle AOC = \cos\widehat{AC'}.$$

But from the second of the identities in the first column of Napier's Rules,

$$\cos\widehat{AC'} = \cot\measuredangle AC'E' \cot\measuredangle C'AE'.$$

Now, imagine dropping perpendiculars from C to *every* side of the face we're considering, not just AB. We end up with $2m$ identical angles around C', each equal to $\measuredangle AC'E'$. So $\measuredangle AC'E' = 360°/2m = 180°/m$. Similarly, if we imagine arcs drawn from A to the centers of each of the faces containing A as a vertex, we end up with $2n$ identical angles around A, each equal to $\measuredangle C'AE'$. But $\measuredangle C'AE' = 360°/2n = 180°/n$. We are left with the pleasingly compact relation

$$r = \cot\left(\frac{180°}{m}\right)\cot\left(\frac{180°}{n}\right).\rightarrow$$

The values of r for the regular polyhedra are tabulated in figure 7.13. Notice that the symmetry of our formula with respect to m and n implies that the inscribed spheres for the octahedron and cube, and likewise for the dodecahedron and icosahedron, are identical. This relation is one aspect of the duality of these respective pairs of polyhedra. Another, more commonly expressed aspect of this same duality was discussed in chapter 2: within a regular polyhedron if you connect the central points C of each face, you generate a smaller copy of its dual polyhedron inside.

Kepler ordered his planets and polyhedra, from inside to out, as follows: Mercury-icosahedron-Venus-octahedron-Earth-dodecahedron-

	m	n	r	i	a	Volume
Tetrahedron	3	3	1/3	70.529°	1.633	0.5132 (12.3%)
Cube	4	3	$\sqrt{3}/3 = 0.5774$	90°	$\frac{2\sqrt{3}}{3} = 1.155$	1.5397 (36.8%)
Octahedron	3	4	$\sqrt{3}/3 = 0.5774$	109.471°	$\sqrt{2} = 1.414$	1.3333 (31.8%)
Dodecahedron	5	3	$\frac{(\sqrt{5}+1)\sqrt{6}}{6\sqrt{5-\sqrt{5}}} = 0.7947$	116.565°	0.7136	2.7852 (66.5%)
Icosahedron	3	5	$\frac{(\sqrt{5}+1)\sqrt{6}}{6\sqrt{5-\sqrt{5}}} = 0.7947$	138.190°	1.052	2.5362 (60.5%)

Figure 7.13. The dimensions of regular polyhedra inscribed within the unit sphere.

Mars-tetrahedron-Jupiter-cube-Saturn. From our modern point of view we can see that the large gap caused by the tetrahedron's relatively small value of r nicely fills the space in the solar system occupied by the asteroids between Mars and Jupiter. In fact, if we allow for a small fudge in the gap between Mercury and Venus, the differences between Kepler's polyhedral distances and the planetary distances based on Copernicus's data were on average only about 3%. Given the observational accuracy of this era, that is an impressive match.

Let's follow in Euclid's footsteps in the *Elements* and consider the dimensions of regular polyhedra inscribed in a unit sphere. In particular, what are the lengths a of the edges? It turns out that first we must consider a related question: what is the angular inclination i between two faces of a regular polyhedron?

> →In figure 7.14 one face of the polyhedron is drawn as a pentagon (although, as before, a square or a triangle are also possible). The adjoining face below edge AB (not drawn) has DE on its surface. C is the center of the face above AB, and we drop CE perpendicularly onto AB. Segment DE is the result of doing the same thing to the face below AB. So, the inclination between the two faces is $i = \measuredangle CED$, and $\measuredangle CEO = i/2$.
>
> As before, the spherical trigonometry arises by "popping" ΔACE outwards onto the circumscribed sphere, producing the spherical

3: E) C *)))) * ? &)

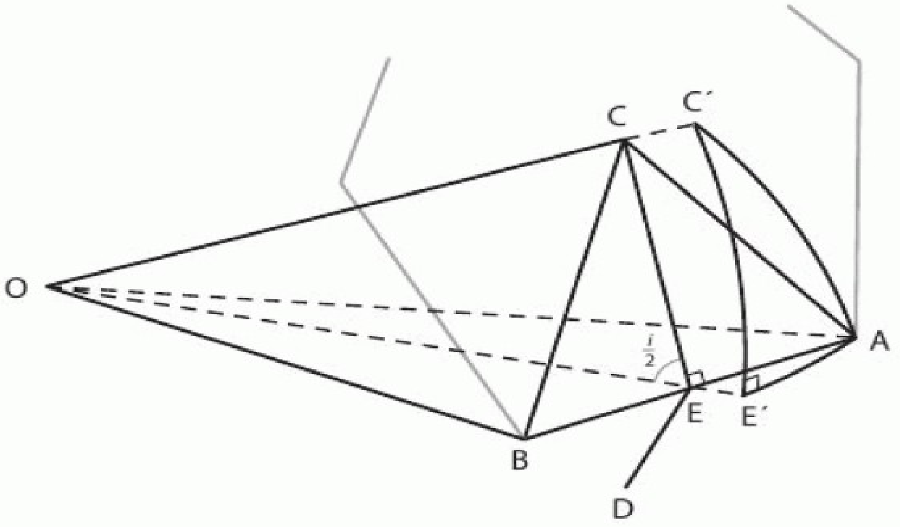

Figure 7.14. Determining the inclination between two faces of a regular polyhedron.

right triangle $AC'E'$. From the second identity in column II of Napier's Rules,

$$\cos\measuredangle C'AE' = \sin\measuredangle AC'E' \cos\widehat{C'E'}.$$

But if we consider (as before) the same sorts of constructions drawn on all faces with a vertex at A, we see that $\measuredangle C'AE' = 360°/2n = 180°/n$. And considering arcs drawn from C' to every vertex and the midpoint of every edge of the visible face, we see that $\measuredangle AC'E' = 360°/2m = 180°/m$. Finally $\widehat{C'E'} = \measuredangle COE$; but $\measuredangle OCE$ is right, so $\widehat{C'E'} = 90° - i/2$. Putting all these results into our Napier's Rule formula above, we get

$$\cos\frac{180°}{n} = \sin\frac{180°}{m}\cos(90° - i/2).$$

A bit of algebraic cleanup provides a pleasing formula for the inclination between two faces:

$$\sin\frac{i}{2} = \frac{\cos(180°/n)}{\sin(180°/m)}.\rightarrow$$

The various angles of inclination are tabulated in figure 7.13. The fact that the octahedron's angle of 109.471° is the same as the "tetrahedral" bond angle at the center of several molecules, including methane, is no coincidence. We leave it to the interested reader to discover why.

→We are now ready to determine a, the length of a side of a regular polyhedron inscribed in a unit sphere. We can reuse figure 7.14. Consider ΔACE; we notice that

$$\frac{CE}{AE} = \cot\measuredangle ACE = \cot\frac{180^\circ}{m}.$$

But $AE = a/2$, so $CE = \frac{a}{2}\cot\frac{180^\circ}{m}$. On the other hand, from ΔCEO we have

$$r = CE\tan\measuredangle CEO = CE\tan i/2.$$

Combining these two results gives us $r = \frac{a}{2}\cot\frac{180^\circ}{m}\tan\frac{i}{2}$. But we already know that $r = \cot\frac{180^\circ}{m}\cot\frac{180^\circ}{n}$. Setting these two equations equal to each other and solving for a brings us home:

$$a = 2\cot\frac{180^\circ}{n}\cot\frac{i}{2}.\rightarrow$$

Once again, the side lengths a are tabulated in figure 7.13.

We find irresistible one last excursion into the geometry of the regular polyhedra. Exactly what proportion of the volume of the unit sphere do the various regular polyhedra occupy?

→This problem turns out to be relatively simple. Connect the center of the sphere to each of the vertices of the polyhedron. This splits the polyhedron into F pyramids with the faces as bases. The volume of each pyramid is $\frac{1}{3}$(area of base)(height). The height of the pyramid is just the radius r of the inscribed sphere. The area of the base, i.e., a face of the polyhedron, may be found by joining the face's central point to each of the vertices. We leave it as an exercise to show that the area of the base is $\frac{ma^2}{4}\cot\frac{180^\circ}{m}$. By combining this information, we arrive at

$$\text{Volume} = \frac{mFra^2}{12}\cot\frac{180^\circ}{m}.\rightarrow$$

Divide by $\frac{4}{3}\pi$ (the volume of the unit sphere), and we have the proportion of the sphere filled by the polyhedron. The tabulations in figure 7.13 reveal a surprising fact: although the icosahedron appears to adhere most closely to its circumscribed sphere, the dodecahedron actually fills about 10% more of the sphere's volume. Sometimes, appearances can be deceiving.

Exercises

1. (a) Find the area of a spherical triangle whose angles are 63°, 84.35°, and 79°, if the radius of the sphere is 10 inches.
   (b) The sides of a spherical triangle are 6.47 in., 8.39 in., and 9.43 in. If the radius of the sphere is 25 in., find the area of the triangle. [Granville 1908, 230]
2. Verify that a spherical equilateral triangle with 60° angles has no area, and that the largest possible triangle is a hemisphere.
3. The state of Colorado is close to a spherical rectangle, ranging from 37° N to 41° N latitude and from 102.05° W to 109.05° W. Find Colorado's area.

   (There are two reasons why Colorado is not quite a spherical rectangle. Firstly, its northern and southern boundaries are actually circles of latitude rather than great circle arcs, i.e., they bend slightly to the left as you walk eastward along them. Secondly, surveying errors led to some small irregularities in the legal borders.)
4. The Bermuda triangle is a region of the Atlantic Ocean traditionally formed by vertices at Puerto Rico (18.5° N, 66° W), Bermuda (32.3° N, 64.9° W), and the southern tip of Florida (25° N, 80.5° W). It holds a reputation, deserved or not, for being the location of an inordinate number of disappearances of ships and planes. The Earth's radius is 3960 miles. Assuming it is a sphere, how many square miles does the Bermuda triangle enclose? (*Hint:* Join all three vertices to the North Pole.)
5. The area of an isosceles right-angled spherical triangle is $\frac{1}{12}$ of the surface of the sphere: calculate the hypotenuse. [Todhunter/Leathem 1907, 107]
6. Prove that in a right-angled spherical triangle $\tan E = \tan\frac{1}{2}a\tan\frac{1}{2}b$. [Casey 1889, 90]
7. Prove the following analogy from Breitschneider:

$$\frac{\sin\frac{1}{2}E\cos\frac{1}{2}(A-E)}{\sin\frac{1}{2}A} = \frac{\sin\frac{1}{2}s\sin\frac{1}{2}(s-a)}{\cos\frac{1}{2}a},$$

   where s is the half perimeter of the triangle. [Casey 1889, 47] (Enterprising readers may look up a hint and Breitschneider's other seven analogies on page 47 of Casey's book, available online, all derivable from Delambre's analogies.)
8. If E, E_A, E_B, and E_C denote the half spherical excesses of a spherical triangle and its three colunar triangles respectively, show that

$E + E_A + E_B + E_C = 180°$, and hence that the sum of the areas of these triangles is equal to half the area of the sphere. [Moritz 1913, 50]

9. Problem 4 would have been easier if we had had a formula for the area of a triangle in terms of its *sides*, rather than in terms of its *angles*. Fortunately there is such a formula, named after Simon Lhuilier (1750–1840), who among other achievements corrected Euler's solution to the Königsberg bridge problem and worked on Euler's polyhedral formula and its exceptions. We shall derive Lhuilier's formula in stages.

   (a) Deduce the following identity from Delambre's first analogy:

$$\frac{\cos\frac{1}{2}(C-\frac{E}{2})-\cos\frac{1}{2}C}{\cos\frac{1}{2}(C-\frac{E}{2})+\cos\frac{1}{2}C} = \frac{\cos\frac{1}{2}(a-b)-\cos\frac{1}{2}c}{\cos\frac{1}{2}(a-b)+\cos\frac{1}{2}c}.$$

   (b) Use the cosine sum-to-product formulas from plane trigonometry, i.e.,

$$\cos x \pm \cos y = \pm 2 \begin{matrix}\cos\\ \sin\end{matrix}\left(\frac{x+y}{2}\right)\begin{matrix}\cos\\ \sin\end{matrix}\left(\frac{x-y}{2}\right),$$

   to derive

$$\tan\tfrac{1}{2}E\tan\tfrac{1}{2}(C-E) = \tan\tfrac{1}{2}(s-a)\tan\tfrac{1}{2}(s-b),$$

   where s is the half perimeter of the triangle.

   (c) Apply the process of (a) and (b) to Delambre's third analogy, instead of the first. Combine your results to obtain Lhuilier's formula:

$$\tan\tfrac{1}{2}E = \sqrt{\tan\tfrac{1}{2}s\tan\tfrac{1}{2}(s-a)\tan\tfrac{1}{2}(s-b)\tan\tfrac{1}{2}(s-c)}.$$

   We may now calculate E directly from the side lengths, and from this find the area using Girard's Theorem. [Todhunter/Leathem 1907, 101–102]

10. (a) If a and b are the radii of the spheres inscribed in and described about a regular tetrahedron, show that $b = 3a$.

    (b) If a is the radius of a sphere inscribed in a regular tetrahedron, and R the radius of the sphere that touches (i.e., is tangent to) the edges, show that $R^2 = 3a^2$. [Todhunter/Leathem 1907, 216]

11. In any convex polyhedron (regular or irregular), prove that the number of faces having an odd number of sides is even, and that the number of vertices having an odd number of edges is odd. [Casey 1889, 131]

12. If a dodecahedron and an icosahedron were each described about a given sphere, the sphere described about these polyhedra will be the same. [Todhunter/Leathen 1907, 216]

13. A regular octahedron is inscribed in a cube so that the corners of the octahedron are at the centers of the faces of the cube: show that the volume of the cube is six times that of the octahedron. [Todhunter/Leathem 1907, 217]
14. Derive precise expressions (that is, containing no decimal approximations) for the volumes of the regular polyhedra in terms of their side lengths a. [Hann 1849, 65–67]

Explanation: (See figure 1.29) By "base," Gunter means the hypotenuse of the spherical triangle. Gunter's first example is a standard astronomical problem: find the sun's declination δ from its ecliptic longitude λ. The solution is $\sin\delta = \sin\lambda \sin\epsilon$ (where $\epsilon = 23°30'$ is the obliquity of the ecliptic), equivalent to the modern formula $\sin a = \sin A \sin c$ for a right triangle. But Gunter expresses it as $\frac{\text{Sin}\,90°}{\text{Sin}\,\epsilon} = \frac{\text{Sin}\,\lambda}{\text{Sin}\,\delta}$ for good reason.

The "line of sines" is the unequally marked scale near the middle in figure 1.28, ending at 90°, displayed on both arms of the sector. Set a compass

[147] [Gunter 1624, 76].

along the line of sines so that the distance between the two tips is equal to Sin 23°30′, that is, the distance along the line of sines from zero to 23°30′. Move the compass to the end of the sector, and spread the sector's arms so that their ends touch both ends of the compass. Without changing the angle of the pivot, move the compass inward (narrowing the gap between its tips) so that its two ends touch the two locations on the sector corresponding to 30°. We now have two similar triangles; from them, we have $\sin 90°/\sin 23°30' = \sin 30°/x$, where x is the new distance between the compass tips. From Gunter's ratio above, we know that x is equal to $\sin \delta$. Move the compass so that one of its tips is at the pivot. On the line of sines, the point corresponding to the other tip (11°30′) is δ.[148]

Figure 5.6
Serret's plane triangle. Multiply each of the three sides by $\cos\frac{b}{2}\cos\frac{c}{2}$, and we have Cesàro's triangle of elements.

values for the sides and angles. He begins by applying the planar Law of Cosines:

$$a'^2 = b'^2 + c'^2 - 2b'c' \cos A.$$

Substituting the values of (5.12) into this equation and applying the sine half-angle formula to the terms in front of cos A, he gets

$$\sin^2\frac{a}{2} = \sin^2\frac{b}{2}\cos^2\frac{c}{2} + \sin^2\frac{c}{2}\cos^2\frac{b}{2} - \frac{\sin b \sin c}{2}\cos A.$$

From here, applying some more algebraic manipulation (replacing $\cos^2$ terms with $1 - \sin^2$ terms), he arrives at

$$1 - 2\sin^2\frac{a}{2} = \left(1 - 2\sin^2\frac{b}{2}\right)\left(1 - 2\sin^2\frac{c}{2}\right) + \sin b \ \sin c \ \cos A.$$

Finally, applying the cosine half-angle formula, he has the spherical Law of Cosines:

$$\cos a = \cos b \cos c + \sin b \sin c \cos A. \tag{5.13}$$

5

Plane Curves in Rectangular Coordinates

There are many ways to classify curves. One of them is to think of curves as either *algebraic* or *transcendental*. An algebraic (plane) curve is given by a polynomial equation $P(x, y) = 0$. Its degree $n = \deg P$ is called the *order of the curve*. *Curves of order* $n = 2$ are studied in analytic geometry. The first classification of *curves of order* $n = 3$ was obtained by Newton. The case $n > 3$ is more difficult. But among easily obtained curves, there are many that are nonalgebraic, for example, the cycloid and spiral of Archimedes; we study them using parametrized or implicit equations (Chapter 5) or polar coordinates (see Chapter 6).

The names of curves, like the names of geographical objects, contain much interesting information. Let us group some curves by the meaning of their names:

By the name of a scientist: Dinostratus' quadratrix, conchoid of Nicomedes, Pascal's limaçon, lemniscate of Bernoulli, cissoid of Diocles.

By the method of construction: caustics, equidistant (parallel), pedal, evolutes, evolvents.

By an important property: trisectrices, quadratrices, tractrices.

By an essential property of their shape: astroid (star-shaped), deltoid (Greek letter Δ), cardioid (heart-shaped), nephroid (kidney-shaped).

By historical factors: ellipse, parabola, hyperbola.

By the structure of the formula: (semi)cubical parabola, logarithmic spiral, exponential and logarithmic curves, integral sine (cosine).

In Section 5.1 we consider the basic notion of a regular curve (for analogous definitions for surfaces, see Sections 19.1 and 19.2).

In Sections 5.2–5.4 we investigate cycloidal curves and other remarkable parametrized curves, and we provide tables with interesting figures.

In Section 5.5 we study implicitly given curves (appearing as level curves of functions in two variables); another family of curves is given by trajectories of vector fields (continued in Section 8.4 for trajectories in space).

In Section 5.6 level sets are used in solving problems with conditional extrema. Three approaches are compared: experimental, geometrical and analytical (using Lagrange multipliers).

In Chapter 5 the reader will become acquainted with the commands

```
solve, dsolve, numer, Diff, grad, allvalues;
implicitplot, contourplot, densityplot, fieldplot,
gradplot, odeplot, DEplot,  disk, ellipse, arc, line.
```

5.1 What Is a Curve?

Intuitively, from Euclid, a *curve* is the trajectory of a moving point, a boundary of a surface, a one-dimensional figure. The mathematically correct definition of a curve is based on notions from *topology*, but it starts with the key notion of an *elementary curve*, which can be imagined as an *interval* $I = (a, b)$ (or a *segment* $\bar{I} = [a, b]$) of the straight line after continuous deformation.

Definition 5.1.1 A set γ in $\mathbb{R}^2$ is called a *curve* if it can be covered by a finite or countable number of elementary curves.

One can distinguish *self-intersecting, simple* (i.e., without self-intersections; for example, graphs), *closed, connected* curves.

If we fix rectangular coordinates (with orthonormal base $\{\mathbf{i}, \mathbf{j}\}$) in the plane $\mathbb{R}^2$ with origin O, then the coordinates x, y of a point on the elementary curve γ given by the map $\vec{\mathbf{r}}(t) = [x(t), y(t)]$ (a *parametrization*) are functions of $t \in I$:

$$x = x(t), \quad y = y(t). \tag{5.1}$$

In other words, the position vector $\vec{\mathbf{r}} = \vec{OP}$ of the point $P(x, y)$ on the curve γ is the following vector-valued function:

$$\vec{\mathbf{r}} = \vec{\mathbf{r}}(t) = x(t)\,\mathbf{i} + y(t)\,\mathbf{j}, \qquad t \in I. \tag{5.1 a}$$

We define functions $x(t), y(t)$ and then use the following command:

```
> r:=[x(t), y(t)];
```

For example, a straight line in a plane is given by a linear vector-valued function in the variable t: $\vec{\mathbf{r}}(t) = [a_1 t + b_1,\ a_2 t + b_2]$.

Remark 5.1.1 We can derive in MAPLE some calculus type of operations on vector-valued functions $\vec{\mathbf{r}}(t) = [x(t),\ y(t)]$ of the class C^k, $(k \geq 0)$.

The *limit* $\vec{\mathbf{r}}(t_0) = \lim\limits_{t \to t_0} \vec{\mathbf{r}}(t)$,

```
> r0:=[subs({t=t0}, x(t)), subs({t=t0}, y(t))];
```

The *first derivative* $\vec{\mathbf{r}}\,'(t) = \lim\limits_{\Delta t \to 0} \frac{\vec{\mathbf{r}}(t+\Delta t)-\vec{\mathbf{r}}(t)}{\Delta t}$.

```
> rt:=[Diff(x(t),t), Diff(y(t),t)];
```

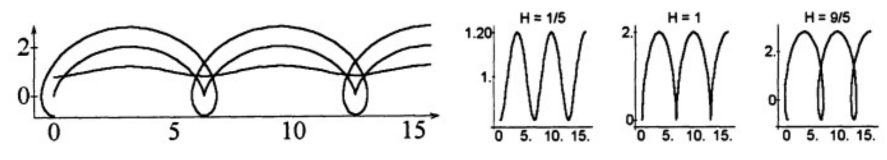
Analogously, we calculate higher order derivatives $\vec{\mathbf{r}}\,''$, $\vec{\mathbf{r}}^{\,(3)}$, etc. and *Taylor series* (see Section 1.1).

Definition 5.1.2 A point P on a simple curve $\gamma \in \mathbb{R}^2$ is called *regular of the class* C^k (C^∞ or C^ω) if some neighborhood of this point admits a parametrization $\vec{\mathbf{r}}(t) = [x(t),\ y(t)]$, $(t \in I)$, where the functions $x(t)$ and $y(t)$ belong to the class C^k (C^∞ or C^ω) and the vector $\vec{\mathbf{r}}\,'(t)$ is nonzero at P. For the opposite case, a point P on a curve γ is called a *singular point* (see Fig. 1.14 with a tractrix). A curve consisting of regular points is called a *regular curve of the class* C^k (C^∞ or C^ω) (*smooth* when $k = 1$).

Definitions 5.1.1 and 5.1.2 can be generalized for the space curves studied in Chapter 8.

5.2 Plotting Cycloidal Curves

The trajectory of a point on the circle of radius R traveling (without sliding) along another circle of radius $R\,'$ (or along a straight line) is called a *cycloidal curve* (Greek, *κυκλο ειδης*, circle-shaped). If the circle drives along and inside of motionless circle, then such a curve is called a *hypocycloid*; if outside, then the curve is called an *epicycloid*. If we follow a point not on the border of the wheel but on its spoke or on the spoke's continuation, then we obtain a *curtate* or *prolate trochoid* (Greek, *τροχο ειδης*, wheel-shaped).



Figs. 5.1–5.2. Common cycloid, curtate and prolate cycloids

8

Space Curves

Section 8.1 is a short introduction to the basic `MAPLE` support for plotting space curves using various coordinate systems. Section 8.2 is devoted to helix type curves lying on a cylinder, a sphere, a torus and other surfaces of revolution. In Section 8.3 we study remarkable `MAPLE` strategies for producing splendid views (of three-dimensional objects) with coloring, shadows and moving. We plot curves that are intersections of two surfaces: the Viviani curve, bicylindrical curves, and solutions of Euler's equations from mechanics. In the final Section 8.4, we deal with vector fields and their trajectories in space (see Section 5.4 for two-dimensional case).

In Chapter 8 the reader will become acquainted with the commands

`spacecurve, tubeplot, plot3d, display3d, DEplot3d, textplot3d, fieldplot3d, gradplot3d, polygonplot3d, PLOT3D, ANIMATE;`

`det, cosh, sinh, JacobiCN, JacobiSN, JacobiDN, transform.`

We begin using the options of 3D plotting:

`light, ambientlight, projection, orientation.`

8.1 Introduction

8.1.1 Commands `spacecurve` *and* `tubeplot`

A space curve $\vec{\mathbf{r}}(t) = [x(t),\ y(t),\ z(t)]$ is plotted using one of the following commands from the library `plots`:

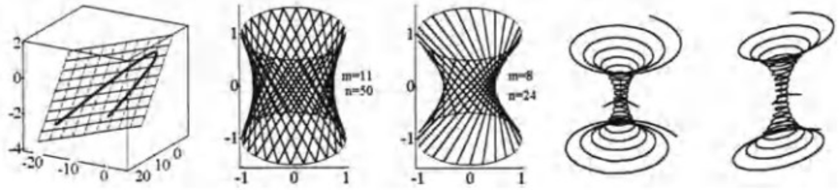
```
spacecurve(one or several curves, options);
```

```
tubeplot(one or several curves, options);
```

Their syntax is similar; the difference is that `tubeplot` plots a *tubular surface* around the given curve, so the options with lighting are effective.

Example 8.1.1

1. Let us show that the curve $\vec{\mathbf{r}}\,(t) = [1+3t+2t^2,\ 2-2t-4t^2,\ 1-t^2]$ lies on a plane and describe it.



Figs. 8.1–8.5. Plane curve in space. Hyperboloid. Curve on a catenoid

Hints. Note that the curve $\vec{\mathbf{r}}\,(t) = \vec{\mathbf{r}}_1 + t\,\vec{\mathbf{r}}_2 + t^2\,\vec{\mathbf{r}}_3$ lies in a plane if the three vectors $\vec{\mathbf{r}}_1, \vec{\mathbf{r}}_2, \vec{\mathbf{r}}_3$ are coplanar, i.e., the determinant consisting of their coordinates vanishes. Any two (linearly independent) vectors from among them define the plane. In our case

```
> r1:=[1, 2, 1]: r2:=[3, -2, 0]: r3:=[2, -4, -1]:
> linalg[det]([r1, r2, r3]); with(plots):
  0
> A:=spacecurve(evalm(r1+t*r2+t^2*r3),t=-2..2,thickness=3):
> B:=plot3d(evalm(u*r1+v*r2), u=-4..2, v=-1..7):
> display([A, B], orientation=[30,70]);  # Fig. 8.1
```

2. Using cycloidal curves (close plane curves) we obtain three-dimensional curves: astroid ($m = -\frac{1}{4}$), deltoid ($m = -\frac{1}{3}$), nephroid ($m = \frac{1}{2}$), and three-dimensional roses.

```
> m:=-1/4: h:=1:  # 3–dimensional astroid, then enter your data
  > r3:=[(1+m)*cos(m*t)-h*m*cos(t+m*t),
  (1+m)*sin(m*t)-h*m*sin(t+m*t),cos(t)]:
  plots[spacecurve](r3,t=0..2*Pi/abs(m),axes=boxed);
```

3. We plot *two engaged circles* (tori).

```
> plots[tubeplot]({[cos(t),sin(t),0],[0,cos(t)+.8,sin(t)]},
  t=0..2*Pi, radius=.25, tubepoints=40, orientation=[0, 60],
  lightmodel=light2, style=patchnogrid);# Fig. 8.6
```

Then we generalize this for a *chain* containing 2*n* circles; Fig. 8.7.

Figs. 8.6–8.8. Two engaged circles. Short chain. Chain armor

```
> n:=3: P:=i -> plots[tubeplot]({[2*cos(t),2*sin(t)+6*i,0],
  [0,2*cos(t)+3+6*i,2*sin(t)]}, t=0..2*Pi, radius=.4,
  orientation=[0,60],style=patchnogrid, lightmodel=light4):
> plots[display]([seq(P(i),i=0..n-1)],scaling=constrained);
```

Finally we generalize it for the *chain armor* with m lines; Fig. 8.8.

```
> with(plots): n:=4: m:=4: P:=(i,j)-> tubeplot({[2*cos(t)+6*j,
  2*sin(t)+6*i,0], [6*j,2*cos(t)+3+6*i,2*sin(t)], [2*cos(t)-
  3+6*i,0+6*j,2*sin(t)]},t=0..2*Pi,radius=.4, orientation=
  [40,50],style=patchnogrid,lightmodel=light4): display([(
  seq(seq(P(i,j), i=0..n), j=0..m))], scaling=constrained);
```

8.1.2 Intuitive Projection

How is a space curve $\vec{\mathbf{r}}(t) = [x(t), y(t), z(t)]$ (or more generally, any space figure) plotted on a planar computer display? Sometimes one creates the image by intuition, as in the following *method of plotting the hyperboloid of one sheet*, using our knowledge of a *star-shaped polygon*.

The coordinates of the sequence of vertices of the star-shaped (n, m) polygon are calculated by the formulas $[R\cos(2\pi i \frac{m}{n}),\ R\sin(2\pi i \frac{m}{n})]$ $(1 \le i \le n)$; see Section 6.1. We transform the circumscribed circle of this polygon to the ellipse and raise and lower it (in the plane) a distance of ± 1 and obtain two star-shaped polygons. Now we connect the ith vertex of one of them with the $(i+1)$th vertex of another, and obtain a part of the hyperboloid of one sheet. We plot it by two methods.

```
> m:=11: n:=50: T:=i -> i*2*m*Pi/n: # first method; Fig. 8.2
> p1:=plot([seq([cos(T(i)),.5*sin(T(i))+(-1)^i],i=1..m*n)]):
  p2:=plot([[cos(t), 0.5*sin(t)+1, t=0..2*Pi],
  [cos(t), 0.5*sin(t)-1, t=0..2*Pi]]):
  plots[display]([p1, p2], scaling=constrained);
```

```
> m:=8: n:=3*m: T:=i-> i*2*Pi/n: # second method; Fig. 8.3
> p1:=plot([seq([[cos(T(i)), 0.5*sin(T(i))-1],
  [cos(T(i+m)), 0.5*sin(T(i+m))+1]], i=1..n)]):
  p2:=plot([[cos(t),.5*sin(t)+1,t=0..2*Pi],
  [cos(t),.5*sin(t)-1,t=0..2*Pi]]):
  plots[display]([p1, p2], scaling=constrained);
```

8.1.3 Standard Coordinate Systems in Space

Other than `rectangular` coordinates, there are two especially popular methods for fixing the place of the point P in the space.

(a) Consider the *height* z as the projection of the segment OP onto the axis OZ; the *distance* $|OP'| = \rho$, where P' is the projection of the point P onto the plane XY; and the *angle* $\varphi \in [-\pi, \pi]$ between the segment OP' and the axis OX. The triple of numbers $(\rho,\ \varphi,\ z)$ is called the *cylindrical coordinates* of the point P. The relation with the rectangular coordinates (x, y, z) is analogous to the case of the polar coordinates:

$$x = \rho\cos\varphi, \quad y = \rho\sin\varphi, \quad z = z.$$

Coordinate surfaces are cylinders $\rho = const$, half-planes $\varphi =$ const through the axis OZ, and also horizontal planes $z =$ const.

(b) Consider the *distance* $|OP| = \rho$, the (*vertical*) *angle* $\phi \in [-\pi, \pi]$ between the segment OP and axis OZ and the (*horizontal*) *angle* $\theta \in [0, \pi]$ between the segment OP' and the axis OX. The triple of numbers $(\rho,\ \theta,\ \phi)$ is called the *spherical coordinates* of the point P. The relation with rectangular coordinates is the following:

$$x = \rho\cos\theta\sin\phi,\ y = \rho\sin\theta\sin\phi,\ z = \rho\cos\phi.$$

Coordinate surfaces are spheres $\rho =$ const with centers at O, half-planes $\theta =$ const through the axis OZ, and circular cones $\phi =$ const with the common axis OZ.

Plotting curves in cylindrical or spherical coordinates is possible by the standard command `spacecurve` with the additional option `coords= cylindrical` or `coords= spherical`.

In addition to the above three, in `MAPLE` there are about thirty systems of curvilinear coordinates in $\mathbb{R}^3$ (see Section 19.3.2), and we can define a number of new coordinate systems using the command `addcoords`.

19

Surfaces in Space

In Sections 19.1 and 19.2 we consider some basic notions of a parametrized surface and a regular surface (analogous definitions for curves were studied in Section 5.1). In Section 19.3 we use a number of `MAPLE` commands to produce surfaces by various methods. In Section 19.4 we calculate and plot tangent planes and normal vectors of a surface. As an application we solve the conditional extremum problems in space (see the two-dimensional case in Section 5.6). In Section 19.5 we use changes in coordinates and linear transformations in space to calculate and plot an osculating paraboloid at the point of a surface. This elementary approach is given only for methodical reasons. In Section 19.6 we consider parametrized and implicitly defined surfaces with singularities.

In Chapter 19 the reader will become acquainted with the commands

```
implicitplot3d, coordplot3d, plot3d, display3d, surfdata,
complexplot3d, listplot3d, matrixplot, PDEplot,
hilbert, toeplitz, multiply, transpose, coeftayl, mtaylor.
```

19.1 What Is a Surface?

Euclid defines a *surface* intuitively, as a two-dimensional figure swept by the path of a moving curve, bounding a solid body.

Planes, some polyhedra, and also some curved surfaces, each defined in some practical way, are studied in school. The mathematically correct definition of a surface is based on notions from *topology*, but it starts from the key notion of an *elementary surface*, which can be imagined as an *elementary do-*

main of the plane after continuous deformation that is stretched in and out in space.

Definition 19.1.1 The set $G \subset \mathbb{R}^n$ ($n = 2, 3$) is called an *open set* if for each point $P \in G$ there exists $\varepsilon > 0$ such that the ball $B(P, \varepsilon)$ of radius ε with center P (the disk, when $n = 2$) lies inside of G.

The complement $F = \mathbb{R}^3 \setminus G$ to the open set G is called a *closed set*.

A *connected* open set (i.e., one that is not the union of two non-empty and non-intersecting open sets) is called a *domain*.

Domains are convenient for working with continuous and differentiable (vector) functions defined on such sets. An arbitrary open set is the union of a finite or countable number of disjoint domains.

Definition 19.1.2 A domain in the plane (in space) that is homeomorphic to a disk (respectively, a ball) is called an *elementary domain*.

The following two elementary domains in the plane with coordinates u, v are often used: the disc $u^2 + v^2 < R^2$ of radius R and the rectangle with sides a, b parallel to the coordinate axes.

As in the definition of an elementary curve, we use the notion of a *topological map* (*homeomorphism*) from one geometric figure to another, i.e., a one-to-one map that is continuous and has a continuous inverse.

Definition 19.1.3 A set M in space is called an *elementary surface* if it is the image of a planar elementary domain G under a topological map $\vec{\mathbf{r}} : G \to \mathbb{R}^3$.

If we fix rectangular coordinates (with the orthonormal base $\{\mathbf{i}, \mathbf{j}, \mathbf{k}\}$) with origin O in space $\mathbb{R}^3$, then the coordinates x, y, z of a point on an elementary surface given by the map $\vec{\mathbf{r}}$ are functions of the coordinates u, v of a point in the domain G:

$$x = x(u, v), \quad y = y(u, v), \quad z = z(u, v). \tag{19.1}$$

In other words, the position vector $\vec{\mathbf{r}} = \vec{OP}$ of the point $P(x, y, z)$ on the surface M is the following vector-valued function:

$$\vec{\mathbf{r}} = \vec{\mathbf{r}}(u, v) = x(u, v)\,\mathbf{i} + y(u, v)\,\mathbf{j} + z(u, v)\,\mathbf{k}, \qquad (u, v) \in G. \tag{19.1 a}$$

We define functions $x(u, v)$, $y(u, v)$, $z(u, v)$ and then use the following command in `MAPLE`:

```
> r:=[x(u,v), y(u,v), z(u,v)];
```

If the initial point of the continuous vector $\vec{\mathbf{r}}(u, v)$ coincides with the origin O, then its endpoint, as a rule, moves along a *surface* in $\mathbb{R}^3$ called the *hodograph* of the vector-valued function. For example, a plane in space is the hodograph of a linear vector-valued function in the variables $u,\ v$:

$$\vec{\mathbf{r}}(u, v) = [a_1u + b_1v + c_1,\ a_2u + b_2v + c_2,\ a_3u + b_3v + c_3].$$

Definition 19.1.4 The system of equalities (19.1) or the vector equation (19.1 a), representing a map $\vec{\mathbf{r}} : G \to \mathbb{R}^3$ from the planar domain G into $\mathbb{R}^3$ is called the *parametric equations of the surface* $M = \vec{\mathbf{r}}\,(G)$: the pair of real numbers (u, v) is called the *curvilinear coordinates* of the point $P(x, y, z)$ on the surface.

Let us first take $v = v_0$ as a constant and $u = t$ as varying. Then we obtain the coordinate *u-curve* on the surface M, which also is the space curve $\vec{\mathbf{r}}(t, v_0)$. Similarly, for a constant $u = u_0$ and $v = t$ varying, we get the *v-curve* on the surface M, that is, the space curve $\vec{\mathbf{r}}(u_0, t)$. These two families of curves, (v-curves and u-curves), form the *coordinate net* of the surface, Fig. 19.1.

An arbitrary *curve* γ *on the surface* M is defined locally by equations for the curvilinear coordinates $u = u(t),\ v = v(t)\ (t \in I)$. The equations for t γ have the following form in space:

$$\tilde{x}(t) = x(u(t), v(t)), \quad \tilde{y}(t) = y(u(t), v(t)), \quad \tilde{z}(t) = z(u(t), v(t)).$$

```
> subs({u=u(t), v=v(t)}, r);
```

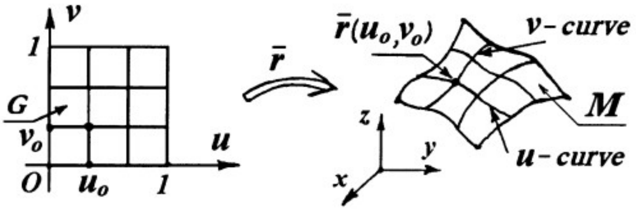

Fig. 19.1. Parametrized (elementary) surface

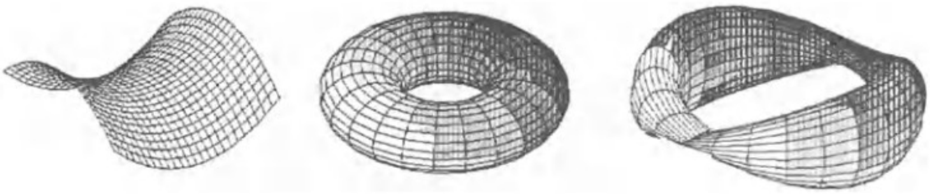
Since we will also be interested in *self-intersecting* surfaces, we give the following definitions:

Definition 19.1.5 A set M in $\mathbb{R}^3$ is called a *surface* if it can be covered by a finite or countable number of elementary surfaces.

Definition 19.1.6 A surface M is called a *simple surface* if it has no points of self-intersection, i.e., for any point $P \in M$ there exists $\varepsilon > 0$ such that the set $U(P, \varepsilon) = B(P, \varepsilon) \cap M$ (the intersection of M with the ball of the radius ε) is an elementary surface.

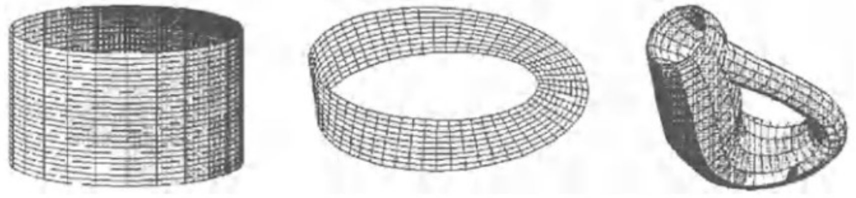
An elementary surface is a simple one. Examples of surfaces that are simple but not elementary are the following: the *sphere*, Fig. 20.7 (which can be covered by two disks); the *circular cylinder*, Fig. 19.5 (which can be covered by two cylindrical strips, each homeomorphic to a rectangle); the *torus*, Fig. 19.3 (which can be covered by four rectangles). The following surfaces are not simple: the *Klein bottle*, Fig. 19.7 (whose points of self-intersection form a circle); the *cone*, Fig. 19.15 (whose vertex is a *singular point*); a *pair of intersecting planes* (the self-intersection points form a straight line); the *pinched torus*, Fig. 19.4 (whose self-intersection points form two line segments). A more complicated example of a surface is the *union of a countable number of cylinders with the common generatrix* OZ: $M = \bigcup_{n\in\mathbb{N}} \{x^2 + (y-n)^2 = n^2\}$. It cannot be covered by a finite number of elementary surfaces. Note that for *local studies* of surfaces (i.e., in a neighborhood of some point) we need only the notion of an elementary surface.



Figs. 19.2–19.4. An elementary surface, the torus, and a pinched torus

Remark 19.1.1 Sometimes we consider surfaces with a *boundary*: in the case of elementary surfaces, a boundary is the image of the boundary of an elementary domain and is homeomorphic to the circle. The boundary of the *half-plane* is a straight line, the boundary of part of a *cylinder* between its parallels is a pair of circles (Fig. 19.5), the boundary of the Möbius band (Fig. 19.6). Recall that a *Möbius band* is obtained when we twist a thin strip of paper through a 180° angle and then glue its lateral sides.

A remarkable property of the Möbius band is that it has only *one side*. Moreover, a surface that "contains" a Möbius band is called *one-sided*. Another example of a one-sided surface is the *Klein bottle*.



Figs. 19.5–19.7. Circular cylinder, the Möbius band, and the Klein bottle

Definition 19.1.7 A simple surface M is called *complete* if the limit point of any sequence of its points which converges in $\mathbb{R}^3$ belongs to M. If a complete surface does not have a *boundary*, it is called *closed*. A closed and bounded surface is called *compact* — recall that a body in $\mathbb{R}^3$ is called *bounded* if it is contained inside some ball of finite radius. This last notion has deep topological generalizations.

The paraboloid, the hyperboloid, and cylinders of the second order are examples of closed surfaces. The sphere, the torus, and the Klein bottle are examples of compact surfaces. If we omit a closed set from a complete surface, then we will obtain an incomplete surface.

Remark 19.1.2 We can derive in `MAPLE` some calculus-types of operations on vector-valued functions $\vec{\mathbf{r}}(u, v) = [x(u, v),\ y(u, v),\ z(u, v)]$ of the class C^k. The key is in using coordinates: the *limit* $\lim\limits_{(u,v)\to(u_0,v_0)} \vec{\mathbf{r}}(u, v)$,

```
> s:={u=u0, v=v0}:
  r0:=[subs(s,x(u,v)), subs(s,y(u,v)), subs(s,z(u,v))];
```

and the *partial derivatives of the first order*

$$\vec{\mathbf{r}}_u = \lim_{\Delta u\to 0} \tfrac{\vec{\mathbf{r}}(u+\Delta u,v)-\vec{\mathbf{r}}(u,v)}{\Delta u}, \quad \vec{\mathbf{r}}_v = \lim_{\Delta v\to 0} \tfrac{\vec{\mathbf{r}}(u,v+\Delta v)-\vec{\mathbf{r}}(u,v)}{\Delta v}.$$

```
> ru:=[Diff(x(u,v),u), Diff(y(u,v),u), Diff(z(u,v),u)];
```

Since $\vec{\mathbf{r}}_u = [x'_u, y'_u, z'_u]$, $\vec{\mathbf{r}}_v = [x'_v, y'_v, z'_v]$ hold, where $x'_u = \frac{\partial x(u,v)}{\partial u}$, then the differential of the vector-valued function $\vec{\mathbf{r}}(u, v)$ has the form $d\vec{\mathbf{r}} = [dx, dy, dz]$, and hence

$$d\vec{\mathbf{r}} = [x'_u\,du + x'_v\,dv,\ y'_u\,du + y'_v\,dv,\ z'_u\,du + z'_v\,dv] = \vec{\mathbf{r}}_u\,du + \vec{\mathbf{r}}_v\,dv.$$

Analogously, we can calculate the second partial derivatives $\vec{\mathbf{r}}_{uu}$, $\vec{\mathbf{r}}_{vv}$, $\vec{\mathbf{r}}_{uv}$, the *Taylor decomposition* (see example in Section 19.5.2), and so on.

19.2 Regular Parametrized Surface

By definition, in a neighborhood of any its points, a simple surface can be defined by a parametric equation:

$$\vec{\mathbf{r}} = \vec{\mathbf{r}}(u, v) \iff x = x(u, v),\ y = y(u, v),\ z = z(u, v).$$

Suppose that the coordinate functions $x(u, v)$, $y(u, v)$, $z(u, v)$ are defined on some planar domain G and are of class C^k in the variables u and v. In this case the u- and v-curves (space curves) are said to be of class C^k, and we can find their velocity vectors:

$$\vec{\mathbf{r}}_u := x'_u(u, v)\,\mathbf{i} + y'_u(u, v)\,\mathbf{j} + z'_u(u, v)\,\mathbf{k} \ \text{(of the } u\text{-curve)},$$
$$\vec{\mathbf{r}}_v := x'_v(u, v)\,\mathbf{i} + y'_v(u, v)\,\mathbf{j} + z'_v(u, v)\,\mathbf{k} \ \text{(of the } v\text{-curve)}.$$

Definition 19.2.1 A surface M is called *regular of class* C^k (resp. C^∞ or C^ω) if each of its points has a neighborhood with a parametrization $\vec{\mathbf{r}}(u, v) = [x(u, v),\ y(u, v),\ z(u, v)]$, where the functions $x(u, v)$, $y(u, v)$, $z(u, v)$, defined on the elementary domain $G \in \mathbb{R}^2$, are of class C^k (resp. C^∞ or C^ω); moreover, we require that the vectors $\vec{\mathbf{r}}_u(u, v)$ and $\vec{\mathbf{r}}_v(u, v)$ be linearly independent at every point $(u, v) \in G$. For $k = 1$, such a surface is called *smooth*.

Each of the following conditions is equivalent to the property of linear independence of vectors $\vec{\mathbf{r}}_u(u, v)$ and $\vec{\mathbf{r}}_v(u, v)$ and is often used for checking this geometrical property:

(a) *The matrix* $\begin{pmatrix} x_u & y_u & z_u \\ x_v & y_v & z_v \end{pmatrix}$ *at the point* (u, v) *has rank* 2.

(b) *The cross product* $\vec{\mathbf{n}} := \vec{\mathbf{r}}_u \times \vec{\mathbf{r}}_v$ *is nonzero at the point* (u, v).

Definition 19.2.2 A point P on a simple surface M is called a *regular (smooth) point* if some neighborhood P admits a C^k-parametrization $\vec{\mathbf{r}}(u, v)$ such that the vectors $\vec{\mathbf{r}}_u$ and $\vec{\mathbf{r}}_v$ are linearly independent at P; otherwise, P is called a *singular point* (for example, the vertex on the top of a circular cone or the bottom fold of such a cone). A curve on a surface, all of whose points are singular, is called a *singular curve* (for example, two line segments on the pinched torus, Fig. 19.4; a singular generatrix on a cylinder over a plane curve with one singular point, Fig. 19.38).

A surface without singular points is smooth; its small open neighborhoods look like plane disks slightly deformed in space.

Although a regular surface admits a number of parametrizations locally, there does not exist a "natural" way to parameterize it, as in the case of curves. We consider the transition from one parametrization to another.

Lemma 19.2.1 *Let* $\mathbf{f} : G \to M$ *be a* C^k*-regular parametrization of the surface* M *and let* $\mathbf{h} : G_1 \to G$ *be an injective map of class* C^k *on the elementary domain* G_1 *into some domain* G *with nonzero Jacobian* J_h. *Then the composition* $\mathbf{f}_1 = \mathbf{f} \circ \mathbf{h} : G_1 \to M$ *is also a* C^k*-regular parametrization of a domain on* M; Fig. 19.8.

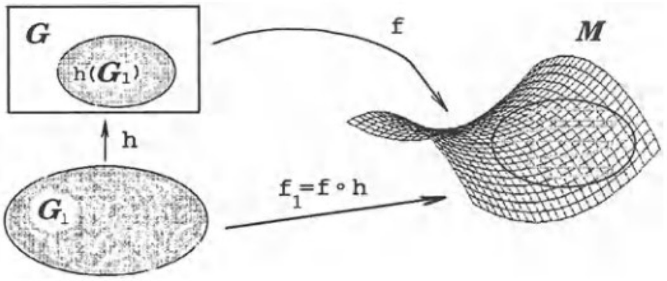
Proof. Let the map $\mathbf{f}$ be defined by the vector-valued function $\vec{\mathbf{r}} = [x(u, v), y(u, v), z(u, v)]$, and let $\mathbf{h}$ be given by the functions $u = \varphi(\alpha, \beta)$, $v = \psi(\alpha, \beta)$. Then the composition $\mathbf{f}_1$ is given by the function

$$\tilde{\mathbf{r}}(\alpha, \beta) = [x(u(\alpha, \beta), v(\alpha, \beta)),\ y(u(\alpha, \beta), v(\alpha, \beta)),\ z(u(\alpha, \beta), v(\alpha, \beta))],$$

and by standard theorems from calculus, the map $\mathbf{f}_1 : \tilde{\mathbf{r}} = \vec{\mathbf{r}}(\varphi(\alpha, \beta),\ \psi(\alpha, \beta))$ is of class C^k. To prove the regularity of the map $\mathbf{f}_1$ we start with $\tilde{\mathbf{r}}_\alpha = \vec{\mathbf{r}}_u \varphi_\alpha +$

$\vec{\mathbf{r}}_v\psi_\alpha$, $\tilde{\mathbf{r}}_\beta = \vec{\mathbf{r}}_u\varphi_\beta + \vec{\mathbf{r}}_v\psi_\beta$. Moreover, $|\vec{\mathbf{r}}_u \times \vec{\mathbf{r}}_v| \neq 0$ holds in view of the regularity of the parametrization **f**. Hence

$$|\tilde{\mathbf{r}}_\alpha \times \tilde{\mathbf{r}}_\beta| = |\vec{\mathbf{r}}_u \times \vec{\mathbf{r}}_v| \cdot |\varphi_\alpha\psi_\beta - \varphi_\beta\psi_\alpha| = |\vec{\mathbf{r}}_u \times \vec{\mathbf{r}}_v| \cdot J_h \neq 0. \square$$



Figs. 19.8. A change of variables on a surface

Exercise 19.2.1

1. Prove that the vector-valued function

(i) $\vec{\mathbf{r}(u, v)} = [u + v, u - v, u^2 + v^2]$ is a C^∞-regular parametrization of the paraboloid $z = \frac{1}{2}(x^2 + y^2)$,

(ii) $\vec{\mathbf{r}(u, v)} = [u^2, uv, v^2]$, where $u > 0,\ v > 0$, defines a C^∞-regular coordinate system on part of the hyperbolic paraboloid $y^2 = xz$;

(iii) $\vec{\mathbf{r}(u, v)} = \left[\frac{a(uv+1)}{u+v},\ \frac{b(u-v)}{u+v},\ \frac{uv-1}{u+v}\right]$ is a C^∞-regular parametrization of part of a hyperboloid of one sheet.

What are the coordinate curves of these parametrizations?

Solution. (i) First check the regularity condition **(ii)**

```
> r:=[u+v, u-v, u^2+v^2]:
> ru:=diff(r,u):rv:=diff(r,v): linalg[crossprod](ru,rv);
```

$[2u + 2v,\ 2u - 2v,\ -2]$ # we obtain a nonzero vector.

Then substitute the vector-valued function in the explicit equation:

```
> r1:=simplify(subs({x=u+v,y=u-v,z=u^2+v^2} , z-(x^2+y^2)/2));
```

0

2. Find which of the following surfaces are compact, and plot them using the command `implicitplot3d` (see Section 19.3.2).

$$(a)\ x^2 - y^4 + z^6 = 1, \qquad (b)\ x^2 - 2x + y^2 + z^4 = 1,$$

$$(c)\quad x^2 + y^2z^2 = 1, \qquad (d)\ x^2 + y^4 + z^6 = 1.$$

```
> plots[implicitplot3d](x^2+y^4+z^6=1,
  x=-2..2, y=-2..2, z=-2..2);   # etc.
```

3. A net of curves on a surface M is said to be *regular* if

- *Every point of the surface belongs to only one curve from each of two families of net curves.*
- *Any curve of one family of the net intersect every curve from another family at exactly one point.*

Check that

(a) The net of straight lines (two families) on the hyperboloid of one sheet is regular locally (i.e., on a neighborhood of an arbitrary point), but it is not regular on the whole surface.

(b) Parallels and meridians on the torus of revolution form a regular net.

Find domains in $\mathbb{R}^2$ where the (polar, parabolic, elliptic, hyperbolic, bipolar) coordinate nets, see Section 6.1, are regular nets.

19.3 Methods of Generating Surfaces

19.3.1 Graphs and Level Sets of Functions

Definition 19.3.1 The *graph* of the function $f : G \subset \mathbb{R}^2 \to \mathbb{R}$ in two real variables (x, y) is the set in space

$$\Gamma_f = \{(x, y, z) \in \mathbb{R}^3 : z = f(x, y), \quad (x, y) \in G\}.$$

Among surfaces of the second order, the elliptic and hyperbolic paraboloids $z = \frac{x^2}{p} \pm \frac{y^2}{q}$ can be expressed as graphs.

Every function in several variables is related to a number of *level sets* (forming the *chart of the function*), which are useful for studying the qualitative properties of the functions.

Definition 19.3.2 Let the function $f(x, y)$ be given on the domain $G \subset \mathbb{R}^2$. The *level curve* with height c of the function f is the set $f^{-1}(c) = \{(x, y) \in G : f(x, y) = c\}$ (the inverse image of c), for example, isobars and isoterms on geographical maps. For every function $F(x, y, z)$ defined on the domain $G \subset \mathbb{R}^3$, the analogous set $F^{-1}(c) = \{(x, y, z) \in G : F(x, y, z) = c\}$ (the inverse image of c) is called the *level surface* of height c of F. In this notation the real number c is called the *height* of the level set.

Note that the level set of height c for the function $f(x)$ consists of roots of the equation $f(x) = c$. In this way, space (or the plane) is fibered by level

1. Introduction

Hyperbolic geometry appeared in the first half of the 19^{th} century as an attempt to understand Euclid's axiomatic basis for geometry. It is also known as a type of non-Euclidean geometry, being in many respects similar to Euclidean geometry. Hyperbolic geometry includes such concepts as: distance, angle and both of them have many theorems in common. There are known many main models for hyperbolic geometry, such as: Poincaré disc model, Poincaré half-plane, Klein model, Einstein relativistic velocity model, etc. The hyperbolic geometry is a non-Euclidian geometry. Here, in this study, we present a proof of Pappus's harmonic theorem in the Einstein relativistic velocity model of hyperbolic geometry. Pappus's harmonic theorem states that if $A'B'C'$ is the cevian triangle of point M with respect to the triangle ABC such that the lines $B'C'$ and BC meet at A'', then $\frac{A''B}{A''C} = \frac{A'B}{A'C}$ [4].

Let D denote the complex unit disc in complex z - plane, i.e.

$$D = \{z \in \mathbb{C} : |z| < 1\}.$$

Chapter 3

Fundamentals of Teleparallel Gravity

The foundations of Teleparallel Gravity, a gauge theory for the translation group, are presented. Gauge transformations are introduced, and the coupling of matter fields to gravitation discussed. The field strength of the theory is shown to be the torsion tensor.

3.1 Geometrical Setting

The geometrical setting of Teleparallel Gravity — a gauge theory for the translation group — is the tangent bundle: at each point p of coordinates x^μ of a general, riemannian spacetime $\mathbf{R}$ — the base space — there is "attached" a Minkowski tangent-space $\mathbf{M} = T_p\mathbf{R} = T_{x^\mu}\mathbf{R}$ — the fiber — on which the gauge transformations take place (see Fig. 3.1, in which the tangent space at $p = \{x^\mu\}$ is indicated normally). A gauge transformation will be a point-dependent translation of the $T_{x^\mu}\mathbf{R}$ coordinates x^a,

$$x'^a = x^a + \epsilon^a, \tag{3.1}$$

with $\epsilon^a \equiv \epsilon^a(x^\mu)$ the transformation parameters.

The generators of infinitesimal translations are here differential operators,

$$P_a = \frac{\partial}{\partial x^a} \equiv \partial_a, \tag{3.2}$$

which satisfy the commutation relations

$$[P_a, P_b] = 0. \tag{3.3}$$

1.3 Affine and Projective Coordinate Systems

From a mathematical point of view it is more satisfactory to proceed in a slightly different manner. In fact, consider a k-vector space V, of finite dimension. We then define the set $\mathbb{P}(V)$ as the set of all 1-dimensional k-subspaces of $U \subset V$. We shall not pursue this *coordinate free* approach very far right now, but postpone it to Part 2 of this book. However, when V is of dimension $n < \infty$, we note that by fixing a k-basis $\{v_1, \ldots, v_n\}$ for V, V is identified with $\mathbb{A}_k^n = k^n$ by letting the element $v = \alpha_1 v_1 + \cdots + \alpha_n v_n$ correspond to the point $(\alpha_1, \ldots, \alpha_n) \in k^n$.

If W is an $n+1$-dimensional k-space, then similarly $\mathbb{P}(W)$ is identified with $\mathbb{P}_k^n$ by fixing a basis $w_0, \ldots, w_n$ for W and letting the point $(\alpha_0 : \ldots : \alpha_n)$ correspond to the subspace spanned by $\alpha_0 w_0 + \cdots + \alpha_n w_n$.

It is clear that switching to a different basis for V, say

$$\begin{aligned}
&\alpha_{1,1} v_1 + \cdots + \alpha_{1,n} v_n \\
&\alpha_{2,1} v_1 + \cdots + \alpha_{2,n} v_n \\
&\vdots \\
&\alpha_{n,1} v_1 + \cdots + \alpha_{n,n} v_n
\end{aligned}$$

For projective n-space we have to work with polynomials in the variables $X_0, X_1, \dots, X_n$, with coefficient from the ground field k, say $\mathbb{R}$ or $\mathbb{C}$ as the case may be. But here we encounter the difficulty that a polynomial $Q(X_0, X_1, \dots, X_n)$ may vanish at the point $(a_0, a_1, \dots, a_n)$, yet have a non-zero value at some $(b_0, b_1, \dots, b_n)$, even though $(a_0, a_1, \dots, a_n) \sim (b_0, b_1, \dots, b_n)$. But if *all the monomials occurring in Q have the same total degree*, then this will not happen. Such a polynomial is called *a homogeneous polynomial.* For a homogeneous polynomial $Q(X_0, X_1, \dots, X_n)$ we therefore are able to make the following definitions:

$$V_+(Q) = \{(a_1 : \dots : a_n) \in \mathbb{P}^n_k \mid Q(a_0, \dots, a_n) = 0\}$$
$$D_+(Q) = \{(a_0 : \dots : a_n) \in \mathbb{P}^n_k \mid Q(a_0, \dots, a_n) \neq 0\}$$

and

$$V_+(Q_1, \dots, Q_m) = \left\{ (a_0, \dots, a_n) \in \mathbb{A}^n_k \,\middle|\, \begin{array}{l} Q_i(a_0, \dots, a_n) = 0 \\ \text{for all } i = 1, \dots, m \end{array} \right\}.$$

Subsets of the last type are referred to as *projective subsets*, and in analogy to the affine case as projective hypersurfaces if there is only one polynomial, and finally, as a projective hyperplane if the polynomial is a linear form, that is, of the type $L = b_0X_0 + \cdots + b_nX_n$, with $b_i \in k$. A common name for affine and projective subsets of $\mathbb{A}^n_k$ and $\mathbb{P}^n_k$, respectively, is *algebraic subsets.*

1.3 Affine and Projective Coordinate Systems

From a mathematical point of view it is more satisfactory to proceed in a slightly different manner. In fact, consider a k-vector space V, of finite dimension. We then define the set $\mathbb{P}(V)$ as the set of all 1-dimensional k-subspaces of $U \subset V$. We shall not pursue this *coordinate free* approach very far right now, but postpone it to Part 2 of this book. However, when V is of dimension $n < \infty$, we note that by fixing a k-basis $\{v_1, \dots, v_n\}$ for V, V is identified with $\mathbb{A}^n_k = k^n$ by letting the element $v = \alpha_1 v_1 + \cdots + \alpha_n v_n$ correspond to the point $(\alpha_1, \dots, \alpha_n) \in k^n$.

If W is an $n+1$-dimensional k-space, then similarly $\mathbb{P}(W)$ is identified with $\mathbb{P}^n_k$ by fixing a basis $w_0, \dots, w_n$ for W and letting the point $(\alpha_0 : \dots : \alpha_n)$ correspond to the subspace spanned by $\alpha_0 w_0 + \cdots + \alpha_n w_n$.

It is clear that switching to a different basis for V, say

$$\begin{array}{l} \alpha_{1,1}v_1 + \cdots + \alpha_{1,n}v_n \\ \alpha_{2,1}v_1 + \cdots + \alpha_{2,n}v_n \\ \vdots \\ \alpha_{n,1}v_1 + \cdots + \alpha_{n,n}v_n \end{array}$$

corresponds to the change of coordinate system in $\mathbb{A}^n_k$ given by

$$\begin{aligned}
&\overline{X}_1 = \alpha_{1,1}X_1 + \cdots + \alpha_{1,n}X_n \\
&\overline{X}_2 = \alpha_{2,1}X_1 + \cdots + \alpha_{2,n}vX_n \\
&\vdots \\
&\overline{X}_n = \alpha_{n,1}X_1 + \cdots + \alpha_{n,n}X_n.
\end{aligned}$$

Similarly, switching to the new basis for W,

$$\begin{aligned}
&\alpha_{0,0}w_0 + \cdots + \alpha_{0,n}w_n \\
&\alpha_{1,0}w_0 + \cdots + \alpha_{1,n}w_n \\
&\vdots \\
&\alpha_{n,0}w_0 + \cdots + \alpha_{n,n}w_n
\end{aligned}$$

corresponds to the change of projective coordinate system in $\mathbb{P}^n_k$ given by

$$\begin{aligned}
&\overline{X}_0 = \alpha_{0,0}X_0 + \cdots + \alpha_{0,n}X_n \\
&\overline{X}_1 = \alpha_{1,0}X_0 + \cdots + \alpha_{1,n}vX_n \\
&\vdots \\
&\overline{X}_n = \alpha_{n,0}X_0 + \cdots + \alpha_{n,n}X_n.
\end{aligned}$$

Now let $L = a_0X_0 + \cdots + X_n$, then by switching to a new projective coordinate system, $D_+(L)$ can be made to correspond to $D_+(\overline{X}_0)$ and thus be identified with $\mathbb{A}^n_k$, while $V_+(L)$ is identified with $V_+(\overline{X}_0)$ and thus with the projective $n-1$-space $\mathbb{P}^{n-1}_k$. In general $V_+(X_0)$ is referred to as the *hyperplane at infinity.*

It is clear that a hypersurface in $\mathbb{A}^n_k$, in particular a curve in $\mathbb{A}^2_k$, given by a polynomial of degree d in the coordinates $x_1, \dots, x_n$ will be given by an equation of the same degree d in the coordinates $\overline{x}_1, \dots, \overline{x}_n$. The same observation holds in the projective case.

Rather than to view this as moving from one coordinate system to a new coordinate system with a new origin in general, it may regarded as a mapping from $\mathbb{A}^n_k$ to itself, a so called affine transformation:

$$\begin{gathered}
\mathbb{A}^n_k \longrightarrow \mathbb{A}^n_k \\
(x_1, \dots, x_n) \mapsto (\overline{x}_1, \dots, \overline{x}_n)
\end{gathered}$$

where

$$\begin{bmatrix} \overline{x}_1 \\ \vdots \\ \overline{x}_n \end{bmatrix} = \begin{bmatrix} \alpha_{1,1} \dots \alpha_{1,n} \\ \vdots \\ \alpha_{n,1} \dots \alpha_{n,n} \end{bmatrix} \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix} + \begin{bmatrix} b_1 \\ \vdots \\ b_n \end{bmatrix}$$

and where $(b_1, \dots, b_n)$ is the new origin. The properties of affine subsets or configurations of affine subsets which are preserved by the affine transformations are referred to as *affine properties.* Affine properties include incidence

Fig. 1.1 Gérard Desargues. Illustration by the author

(that a point lies on a line, or a line passes through a point), collinearity (that several points lie on a common line), concurrency (that several lines pass through a common point). The properties which are not affine include being a circle, while being an ellipse is an affine property. Over $\mathbb{R}$ the property for two lines in $\mathbb{A}^2_{\mathbb{R}}$ forming a right angle is not affine, while the property for a line to bisect in equal parts the angle formed by two given lines, is affine. The property of tangency is affine.

Projective properties are defined analogously: all projective properties are preserved by projective transformations. As for the affine case we may also express this by saying that the projective properties are independent of choice of projective coordinate system. Obviously the points at infinity are not preserved, however.

We now need the following useful observation, the proof of which is of course well known, and is explained in detail when $n = 2$ and $k = \mathbb{R}$ in Chap. 11 of [27], Chap. 12 of [28]. The proof given there carries over to the general case with obvious modifications. We shall not repeat it here.

Proposition 1.1 *Given $n + 2$ points $P_1, P_2, \dots, P_{n+2} \in \mathbb{P}^n_k$ no three of which are collinear, as well as another set of points $P'_1, P'_2, \dots, P'_{n+2} \in \mathbb{P}^n_k$ with the same property. Then there exists a projective transformation G of $\mathbb{P}^n_k$ onto itself, mapping P_i to P'_i, $i = 1, 2, \dots, n$.*

1.4 The Theorem of Desargues

The *Theorem of Desargues* was important in the development of projective geometry. Gérard Desargues came from a wealthy family, and had many influential mathematical friends such as Rene Descartes and the father and son Pascal. He belonged to the famous and influential circle around the secular monk *Marin Mersenne.*

In [27] and [28] the theorem is proved only for $\mathbb{P}^2_k$ and it is assumed that $k = \mathbb{R}$ for this result. But as we shall see below, that assumption is not needed.

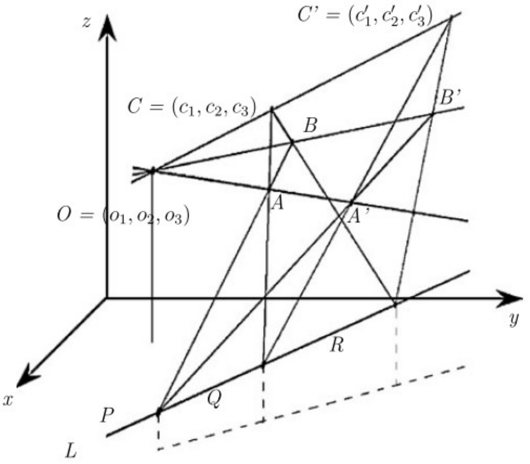

Fig. 1.2 Desargues' theorem, picture with $k = \mathbb{R}$ in the affine piece $D_+(X_0) \subset \mathbb{P}^3_k$

Theorem 1.2 *Let two triangles ABC and $A'B'C'$ be given in $\mathbb{P}^3_k$, such that $A \neq A'$, $B \neq B'$ and $C \neq C'$. Then if the lines through corresponding vertices pass through the same point O, the intersections of the prolongations of corresponding sides will intersect in points lying on the same line L.*

Remark When the triangles have the property that the lines through corresponding vertices pass through O, then O is referred to as the center of perspective, and the triangles are said to be perspective from the point O. If the intersections of the prolongations of corresponding sides intersect in points lying on L, then L is called the *line of perspective*, and the triangles are said to be perspective from the line L.

Proof We introduce notation as in Fig. 1.2. The coordinates of the points are labelled analogously to those of O, C and C'.

Evidently, no three of the points

$$(0:0:1:0), \quad (0:1:0:0), \quad (0:0:0:1) \quad \text{and} \quad (1:0:0:0)$$

are collinear. It is easily seen that the same is true for the points O, P, Q and A. Thus by Proposition 1.1 there is a linear transformations which makes these four points correspond, and hence, after a change of coordinate system, we may assume that

$$O = (0:0:1:0), \quad P = (0:1:0:0),$$
$$Q = (0:0:0:1) \quad \text{and} \quad A = (1:0:0:0:0).$$

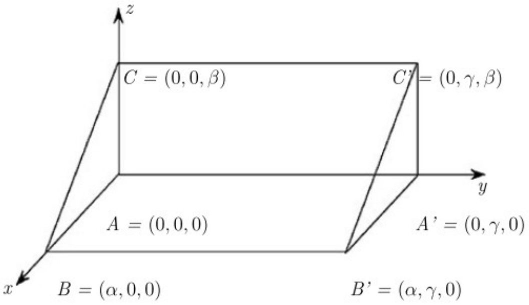

Fig. 1.3 Desargues' theorem, after a good choice of coordinate system in $\mathbb{P}^3_{\mathbb{R}}$

Then a line through O, P and Q, respectively, is given in $D_+(X_0) = \mathbb{A}^2_k$ on parametric form as

$$L_O = \{(x_1, t, z_1) \mid t \in k\}, \qquad L_P = \{(t, y_2, z_2) \mid t \in k\},$$
$$L_Q = \{(x_3, y_3, t) \mid t \in k\}.$$

Since moreover $A = (0,0,0)$, we therefore get in addition that

$$B = (\alpha,0,0), \quad C = (0,\beta,0), \quad A' = (0,\gamma,0),$$
$$B' = (\alpha,\gamma,0) \quad \text{and} \quad C' = (0,\beta,\gamma).$$

The situation is illustrated in Fig. 1.3.

We identify the point $(x,y,z) \in \mathbb{A}^3_{\mathbb{R}}$ with the point $(1:x:y:z) \in D_+(X_0) \subset \mathbb{P}^3_{\mathbb{R}}$ as usual, and get the following parametric forms for the lines BC, $B'C'$ and PQ, where we write $(ua:ub:uc:ud)$ as $u(a:b:c:d)$ to simplify the notation:

$$BC = \{u_1(1:0:0:\beta) + v_1(1:\alpha:0:0) \mid (u_1,v_1) \neq (0,0)\}$$
$$B'C' = \{(u_2(1:0:\gamma:\beta) + v_2(1:\alpha;\gamma:0) \mid (u_2,v_2) \neq (0,0)\}$$
$$PC = \{u_3(0:1:0:0) + v_3(0:0:0:1) \mid (u_3,v_3) \neq (0,0)\}.$$

It is now easily verified that the two lines BC and $B'C'$ intersect in the point $(0:\alpha:0:-\beta)$, which lies on the line PQ. Thus the claim follows. □

This theorem has the following corollary, which is the converse of the theorem in the plane:

Corollary 1.3 *Let two triangles ABC and $A'B'C'$ be given in $\mathbb{P}^2_{\mathbb{R}}$, and assume that $A \neq A'$, $B \neq B'$ and $C \neq C'$. If the triangles are perspective from a line, then they are perspective from a point.*

Proof The proof is immediate by the *Principle of Duality* for $\mathbb{P}^2_{\mathbb{R}}$, which we shall prove in the next section. Here we find that the dual result is actually a *converse* to the assertion of the theorem. The figure in the proof above is actually *self dual.* □

1.5 Duality for $\mathbb{P}^2_k$

We now consider $\mathbb{P}^2_k$, and let P denote some statement involving *points, lines incidence.*

Then the dual statement $P^\vee$ is defined as the statement obtained by interchanging the words "point" and "line", and keeping "incidence", with the adjustments of language which may be necessary to obtain natural geometrical statements.

For example, consider the statement below:

Statement P: Through two distinct points Q_1 and Q_2 there always pass a uniquely determined line ℓ.

Then the dual statement is the following:

Statement $P^\vee$: Two distinct lines q_1 and q_2 always intersect in a uniquely determined point L.

For $\mathbb{P}^2_k$ we have the so called *principle of duality*:

Theorem 1.4 (Duality for $\mathbb{P}^2_k$) *If P denotes a true statement about $\mathbb{P}^2_k$ dealing with points, lines and incidence, then the dual statement $P^\vee$ is also a true statement.*

Proof The statement P may be translated into a possibly infinite set of equations involving the projective coordinates of the points and the coefficients of the equations of the lines occurring in the statement. The equations will all be of the form

$$A_0\alpha_0 + A_1\alpha_1 + A_2\alpha_2 = 0,$$

where $A = (A_0 : A_1 : A_2)$ is a point and α_0, α_1 and α_2 are the coefficients in the equation for a line in $\mathbb{P}^2_k$, so the line is given by

$$\alpha_0X_0 + \alpha_1X_1 + \alpha_2X_2 = 0.$$

If we denote this line by ℓ, then the statement "A lies on ℓ" is equivalent to the relation above. For every point in $\mathbb{P}^2_k$ we now let correspond a *line* in $\mathbb{P}^2_k$ given by the equation whose coefficients are the coordinates of the point, and to every line we let correspond the point whose projective coordinates are the coefficients of the equation giving the line.

Then the set of algebraic equations between the coordinates of points in $\mathbb{P}^2_k$ and coefficients of lines in $\mathbb{P}^2_k$ which expresses the truth of the statement P is the same as the collection of relations which expresses the truth of $P^\vee$.

C4 5 0

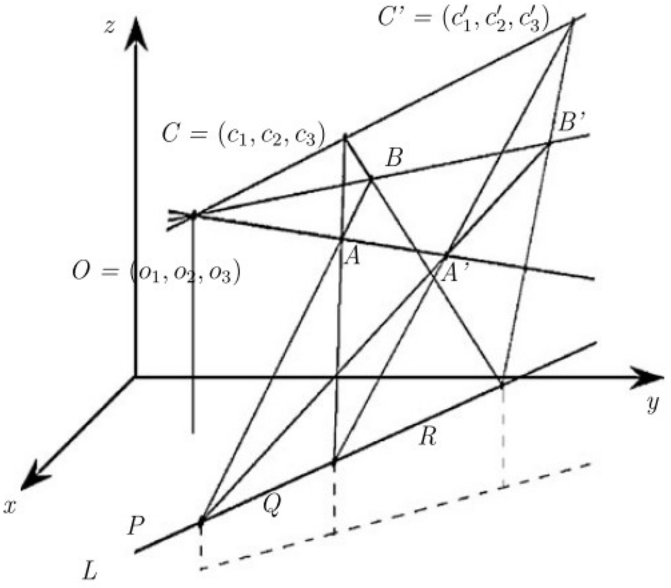

Fig. 1.2 Desargues' theorem, picture with $k = \mathbb{R}$ in the affine piece $D_+(X_0) \subset \mathbb{P}^3_k$

Theorem 1.2 *Let two triangles* ABC *and* $A'B'C'$ *be given in* $\mathbb{P}^3_k$, *such that* $A \neq A'$, $B \neq B'$ *and* $C \neq C'$. *Then if the lines through corresponding vertices pass through the same point* O, *the intersections of the prolongations of corresponding sides will intersect in points lying on the same line* L.

Thirty Essays on Geometric Graph Theory*

Greg Aloupis, Brad Ballinger, Sébastien Collette, Stefan Langerman, Attila Pór, and David R. Wood

Abstract This paper studies problems related to visibility among points in the plane. A point x *blocks* two points v and w if x is in the interior of the line segment $\overline{vw}$. A set of points P is *k-blocked* if each point in P is assigned one of k colors, such that distinct points $v, w \in P$ are assigned the same color if and only if some other point in P blocks v and w. The focus of this paper is the conjecture that each k-blocked set has bounded size (as a function of k). Results in the literature imply that every 2-blocked set has at most 3 points, and every 3-blocked set has at most 6 points. We prove that every 4-blocked set has at most 12 points, and that this

bound is tight. In fact, we characterize all sets $\{n_1,n_2,n_3,n_4\}$ such that some 4-blocked set has exactly n_i points in the ith color class. Among other results, for infinitely many values of k, we construct k-blocked sets with $k^{1.79\cdots}$ points.

1 Introduction

This paper studies problems related to visibility and blocking in sets of colored points in the plane. A point x *blocks* two points v and w if x is in the interior of the line segment $\overline{vw}$. Let P be a finite set of points in the plane. Two points v and w are *visible* with respect to P if no point in P blocks v and w. The *visibility graph* of P has vertex set P, where two distinct points $v,w \in P$ are adjacent if and only if they are visible with respect to P. A point set B *blocks* P if $P \cap B = \emptyset$ and for all distinct $v,w \in P$ there is a point in B that blocks v and w. That is, no two points in P are visible with respect to $P \cup B$, or alternatively, P is an independent set in the visibility graph of $P \cup B$.

A set of points P is *k-blocked* if each point in P is assigned one of k colors, such that each pair of points $v,w \in P$ are visible with respect to P if and only if v and w are colored differently. Thus, v and w are assigned the same color if and only if some other point in P blocks v and w. A *k-set* is a multiset of k positive integers. For a k-set $\{n_1,\ldots,n_k\}$, we say P is $\{n_1,\ldots,n_k\}$-blocked if it is k-blocked, and for some labeling of the colors by the integers $[k] := \{1,2,\ldots,k\}$, the ith color class has exactly n_i points, for each $i \in [k]$. Equivalently, P is $\{n_1,\ldots,n_k\}$-blocked if the visibility graph of P is the complete k-partite graph $K(n_1,\ldots,n_k)$. A k-set $\{n_1,\ldots,n_k\}$ is *representable* if there is an $\{n_1,\ldots,n_k\}$-blocked point set. See Fig. 1 for an example.

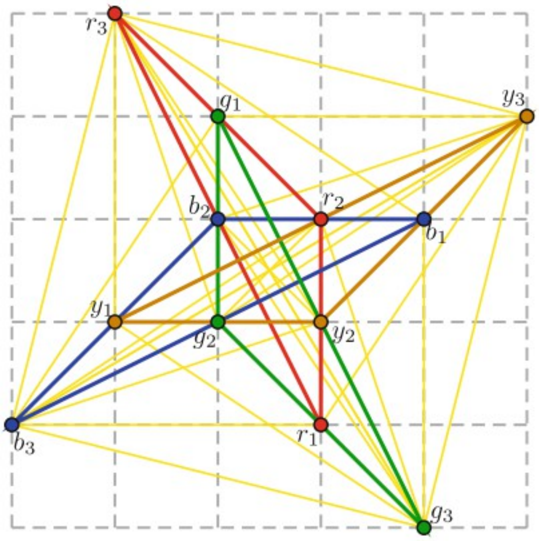

Fig. 1 A $\{3,3,3,3\}$-blocked point set

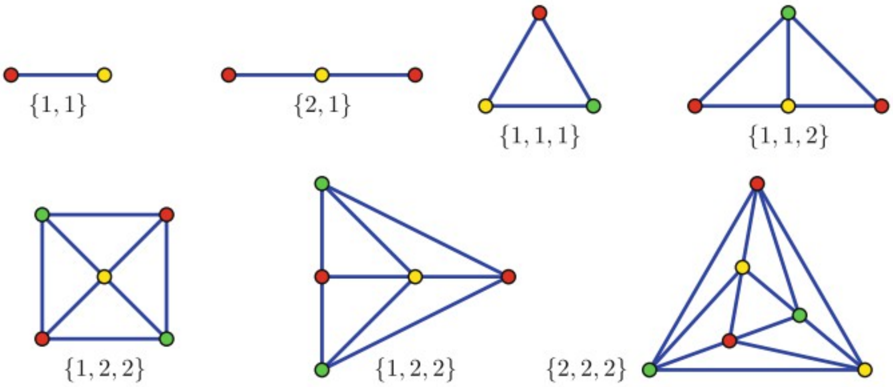

Fig. 2 The 2-blocked and 3-blocked point sets

The following fundamental conjecture regarding k-blocked point sets is the focus of this paper.

Conjecture 1. For each integer k, there is an integer n such that every k-blocked set has at most n points.

As illustrated in Fig. 2, the following theorem is a direct consequence of the characterization of 2- and 3-colorable visibility graphs by Kára et al. [5].

Theorem 2. *$\{1,1\}$ and $\{1,2\}$ are the only representable 2-sets, and $\{1,1,1\}$, $\{1,1,2\}$, $\{1,2,2\}$, and $\{2,2,2\}$ are the only representable 3-sets.*

In particular, every 2-blocked point set has at most three points, and every 3-blocked point set has at most six points. This proves Conjecture 1 for $k \leq 3$.

This paper makes the following contributions. Section 2 introduces some background motivation for the study of k-blocked point sets and observes that results in the literature prove Conjecture 1 for $k = 4$. Section 3 describes methods for constructing k-blocked sets from a given $(k-1)$-blocked set. These methods lead to a characterization of representable k-sets when each color class has at most three points. Section 4 studies the $k = 4$ case in more detail. In particular, we characterize the representable 4-sets, and conclude that the example in Fig. 1 is in fact the largest 4-blocked point set. Section 5 introduces a special class of k-blocked sets (so-called midpoint-blocked sets) that lead to a construction of the largest known k-blocked sets for infinitely many values of k.

Before continuing, we prove some basic properties about k-blocked point sets.

Lemma 3. *At most three points are collinear in every k-blocked point set.*

Proof. Suppose that four points p,q,r,s are collinear in this order. Thus, (p,q,r,s) is an induced path in the visibility graph. Thus, p is not adjacent to r and not adjacent to s. Thus, p, r, and s have the same color. This is a contradiction since r and s are adjacent. Thus, no four points are collinear. □

A set of points P is in *general position* if no three points in P are collinear.

Lemma 4. *Each color class in a k-blocked point set is in general position.*

Proof. Suppose on the contrary that three points from a single color class are collinear. Then no other points are in the same line by Lemma 3. Thus, two of the three points are adjacent, which is a contradiction. ☐

Note that "convex position" in this paper means "strictly convex position."

2 Some Background Motivation

Much recent research on blockers began with the following conjecture by Kára et al. [5].

Conjecture 5 (Big-Line-Big-Clique Conjecture [5]). For all integers t and ℓ, there is an integer n such that for every finite set P of at least n points in the plane:

- P contains ℓ collinear points, or
- P contains t pairwise visible points (that is, the visibility graph of P contains a t-clique).

Conjecture 5 is true for $t \leq 5$ but is open for $t \geq 6$ or $\ell \geq 4$; see [1,9]. Given that, in general, Conjecture 5 is challenging, Jan Kára suggested the following weakening.

Conjecture 6 ([9]). For all integers t and ℓ, there is an integer n such that for every finite set P of at least n points in the plane:

- P contains ℓ collinear points, or
- The chromatic number of the visibility graph of P is at least t.

Conjecture 5 implies Conjecture 6 since every graph that contains a t-clique has chromatic number at least t.

Proposition 7. *Conjecture 6 with $\ell = 4$ and $t = k+1$ implies Conjecture 1.*

Proof. Assume Conjecture 6 holds for $\ell = 4$ and $t = k+1$. Suppose there is a k-blocked set P of at least n points. By Lemma 3, at most three points are collinear in P. Thus, the first conclusion of Conjecture 6 does not hold. By definition, the visibility graph of P is k-colorable. Thus, the second conclusion of Conjecture 6 does not hold. This contradiction proves that every k-blocked set has fewer than n points, and Conjecture 1 holds. ☐

Thus, since Conjecture 5 holds for $t \leq 5$, Conjecture 1 holds for $k \leq 4$. In Sect. 4 we take this result much further, by characterizing all representable 4-sets, thus concluding a tight bound on the size of a 4-blocked set.

Part of our interest in blocked point sets comes from the following.

Proposition 8. *For all $k \geq 3$ and $n \geq 2$, the edge set of the k-partite Turán graph $K(n,n,\ldots,n)$ can be partitioned into a set of "lines," where*

- *Each line is either an edge or an induced path on three vertices;*
- *Every pair of vertices is in exactly one line; and*
- *For every line L, there is a vertex adjacent to each vertex in L.*

Proof. Let (i,p) be the pth vertex in the ith color class for $i \in \mathbb{Z}_k$ and $p \in \mathbb{Z}_n$ (taken as additive cyclic groups). We introduce three types of lines. First, for $i \in \mathbb{Z}_k$ and distinct $p,q \in \mathbb{Z}_n$, let the triple $\{(i,p),(i+1,p+q),(i,q)\}$ be a line. Second, for $i \in \mathbb{Z}_k$ and $p \in \mathbb{Z}_n$, let the pair $\{(i,p),(i+1,p+p)\}$ be a line. Third, for $p,q \in \mathbb{Z}_n$ and distinct nonconsecutive $i,j \in \mathbb{Z}_k$, let the pair $\{(i,p),(j,q)\}$ be a line. By construction, each line is either an edge or an induced path on three vertices.

Every pair of vertices in the same color class are in exactly one line (of the first type). Consider vertices (i,p) and (j,q) in distinct color classes. First, suppose that i and j are consecutive. Without loss of generality, $j = i+1$. If $q \neq p+p$, then (i,p) and (j,q) are in exactly one line (of the first type). If $q = p+p$, then (i,p) and (j,q) are in exactly one line (of the second type). If i and j are not consecutive, then (i,p) and (j,q) are in exactly one line (of the third type). This proves that every pair of vertices is in exactly one line. Moreover, every edge of $K(n,n,\dots,n)$ is in exactly one line, and the lines partition the edges set.

Since every line L is contained in the union of two color classes, each vertex in neither color class intersecting L is adjacent to each vertex in L. □

Proposition 8 is significant for Conjecture 5 because it says that $K(n,\dots,n)$ behaves like a "visibility space" with no four collinear points, but it has no large clique (for fixed k). Conjecture 1, if true, implies that such a visibility space is not "geometrically representable" for large n.

Let $b(n)$ be the minimum integer such that some set of n points in the plane in general position is blocked by some set of $b(n)$ points. Matoušek [6] proved that $b(n) \geq 2n-3$. Dumitrescu et al. [2] improved this bound to $b(n) \geq (\frac{25}{8} - o(1))n$. Many authors have conjectured or stated as an open problem that $b(n)$ is superlinear.

Conjecture 9 ([2, 6, 8, 9]). $\frac{b(n)}{n} \to \infty$ as $n \to \infty$.

Pór and Wood [9] proved that Conjecture 9 implies Conjecture 6, and thus implies Conjecture 1. That Conjecture 1 is implied by a number of other well-known conjectures, yet remains challenging, adds to its interest.

3 *k*-Blocked Sets with Small Color Classes

We now describe some methods for building blocked point sets from smaller blocked point sets.

Lemma 10. *Let G be a visibility graph. Let* $i \in \{1,2,3\}$. *Furthermore, suppose that if* $i \geq 2$, *then* $V(G) \neq \emptyset$, *and if* $i = 3$, *then not all the vertices of G are collinear. Let* G_i *be the graph obtained from G by adding an independent set of i new vertices, each adjacent to every vertex in G. Then* G_1, G_2, *and* G_3 *are visibility graphs.*

Proof. For distinct points p and q, let $\overleftarrow{pq}$ denote the ray that is (1) contained in the line through p and q, (2) starting at p, and (3) not containing q. Let $\mathcal{L}$ be the union of the set of lines containing at least two vertices in G.

$i = 1$: Since $\mathcal{L}$ is the union of finitely many lines, there is a point $p \notin \mathcal{L}$. Thus, p is visible from every vertex of G. By adding a new vertex at p, we obtain a representation of G_1 as a visibility graph.

$i = 2$: Let p be a point not in $\mathcal{L}$. Let v be a vertex of G. Each line in $\mathcal{L}$ intersects $\overleftarrow{vp}$ in at most one point. Thus, $\overleftarrow{vp} \setminus \mathcal{L} \neq \emptyset$. Let q be a point in $\overleftarrow{vp} \setminus \mathcal{L}$. Thus, p and q are visible from every vertex of G, but p and q are blocked by v. By adding new vertices at p and q, we obtain a representation of G_2 as a visibility graph.

$i = 3$: Let u, v, w be noncollinear vertices in G. Let p be a point not in $\mathcal{L}$ and not in the convex hull of $\{u, v, w\}$. Without loss of generality, $\overline{uv} \cap \overline{pw} \neq \emptyset$. There are infinitely many pairs of points $q \in \overleftarrow{up}$ and $r \in \overleftarrow{vp}$ such that w blocks q and r. Thus, there are such q and r both not in $\mathcal{L}$. By construction, u blocks p and q, and v blocks p and r. By adding new vertices at p, q, and r, we obtain a representation of G_3 as a visibility graph. □

Since no (≥ 3)-blocked set is collinear, Lemma 10 implies

Corollary 11. *If $k \geq 4$ and $\{n_1, \dots, n_{k-1}\}$ is representable and $n_k \in \{1, 2, 3\}$, then $\{n_1, \dots, n_{k-1}, n_k\}$ is representable.*

The representable (≤ 3)-sets were characterized in Theorem 2. In each case, each color class has at most three vertices. Now we characterize the representable (≥ 4)-sets, assuming that each color class has at most three vertices.

Proposition 12. *$\{n_1, \dots, n_k\}$ is representable whenever $k \geq 4$ and each $n_i \leq 3$, except for $\{1, 3, 3, 3\}$.*

Proof. Say the k-set $\{n_1, \dots, n_k\}$ *contains* the $(k-1)$-set $\{n_1, \dots, n_{i-1}, n_{i+1}, \dots, n_k\}$ for each $i \in [k]$. We proceed by induction on $k \geq 4$. For the base case, assume that $k = 4$. If $\{n_1, n_2, n_3, n_4\}$ contains $\{1, 1, 1\}$, $\{1, 1, 2\}$, $\{1, 2, 2\}$, or $\{2, 2, 2\}$, then $\{n_1, n_2, n_3, n_4\}$ is representable by Theorem 2 and Corollary 11. In each remaining case, the following table describes a construction, except for $\{1, 3, 3, 3\}$, which is not representable, as proved in Lemma 18.

$\{1, 1, 1, x\}$	Contains $\{1, 1, 1\}$	$\{1, 1, 2, x\}$	Contains $\{1, 1, 2\}$
$\{1, 1, 3, 3\}$	Figure 1 minus $\{r_1, g_3, r_3, g_1\}$	$\{1, 2, 2, x\}$	Contains $\{1, 2, 2\}$
$\{1, 2, 3, 3\}$	Figure 1 minus $\{g_1, g_3, r_3\}$	$\{2, 2, 2, x\}$	Contains $\{2, 2, 2\}$
$\{2, 2, 3, 3\}$	Figure 1 minus $\{g_3, r_3\}$	$\{2, 3, 3, 3\}$	Figure 1 minus g_3
$\{3, 3, 3, 3\}$	Figure 1		

Now assume that $k \geq 5$: Consider a k-tuple $\{n_1, \dots, n_k\}$ with each $n_i \leq 3$. Say $n_1 \leq \cdots \leq n_k$. If $\{n_1, \dots, n_{k-1}\} \neq \{1, 3, 3, 3\}$, then by induction $\{n_1, \dots, n_{k-1}\}$ is representable, which implies that $\{n_1, \dots, n_k\}$ is representable by Corollary 11. Otherwise, $k = 5$ and $\{n_1, \dots, n_5\} = \{1, 3, 3, 3, 3\}$, which contains the representable 4-tuple $\{3, 3, 3, 3\}$, implying $\{n_1, \dots, n_5\}$ is representable by Corollary 11. □

4 4-Blocked Point Sets

As we saw in Sect. 2, Conjecture 1 holds for $k \le 4$. In this section we study 4-blocked point sets in more detail. First, we derive explicit bounds on the size of 4-blocked sets from other results in the literature. Then, following a more detailed approach, we characterize all representable 4-sets, to conclude a tight bound on the size of 4-blocked sets.

Proposition 13. *Every* 4*-blocked set has less than* 2^{790} *points.*

Proof. Abel et al. [1] proved that every set of at least $\mathrm{ES}(\frac{(2\ell-1)^{\ell}-1}{2\ell-2})$ points in the plane contains ℓ collinear points or an empty convex pentagon, where $\mathrm{ES}(k)$ is the minimum integer such that every set of at least $\mathrm{ES}(k)$ points in general position in the plane contains k points in convex position. Let P be a 4-blocked set. The visibility graph of P is 4-colorable, and thus contains no empty convex pentagon. By Lemma 3, at most three points in P are collinear. Thus, $|P| \le \mathrm{ES}(400) - 1$ by the above result with $\ell = 4$. Tóth and Valtr [12] proved that $\mathrm{ES}(k) \le \binom{2k-5}{k-2} + 1$. Hence, $|P| \le \binom{795}{398} < 2^{790}$. □

Lemma 14. *If P is a blocked set of n points with m points in the largest color class, then $n \ge 3m - 3$ and $n \ge (\frac{33}{8} - o(1))m$.*

Proof. If S is the largest color class, then $P - S$ blocks S. By Lemma 4, S is in general position. By the results of Matoušek [6] and Dumitrescu et al. [2] mentioned in Sect. 2, $n - m \ge 2m - 3$ and $n - m \ge (\frac{25}{8} - o(1))m$. □

Proposition 15. *Every* 4*-blocked set has fewer than* 2^{578} *points.*

Proof. Let P be a 4-blocked set of n points. Let S be the largest color class in P. Let $m := |S| \ge \frac{n}{4}$. By Lemma 14, $n \ge (\frac{33}{8} - o(1))m \ge (\frac{33}{32} - o(1))n$. Thus, $o(n) \ge \frac{n}{32}$. Hence, n is bounded. A precise bound is obtained as follows. Dumitrescu et al. [2] proved that S needs at least $\frac{25m}{8} - \frac{25m}{2\ln m} - \frac{25}{8}$ blockers, which come from the other color classes. Thus, $n - m \ge \frac{25m}{8} - \frac{25m}{2\ln m} - \frac{25}{8}$, implying $n \ge \frac{33m}{8} - \frac{25m}{2\ln m} - \frac{25}{8}$. Since $\frac{n}{4} \le m \le n$, we have $\frac{25n}{2\ln n} + \frac{25}{8} \ge \frac{n}{32}$. It follows that $n \le 2^{578}$. □

The next result is the simplest known proof that every 4-blocked point set has bounded size.

Proposition 16. *Every* 4*-blocked set has at most* 36 *points.*

Proof. Let P be a 4-blocked set. Suppose that $|P| \ge 37$. Let S be the largest color class. Thus, $|S| \ge 10$. By Lemma 4, S is in general position. By a theorem of Harborth [4], some 5-point subset $K \subseteq S$ is the vertex-set of an empty convex pentagon $\mathrm{conv}(K)$. Let $T := P \cap (\mathrm{conv}(K) - K)$. Since $\mathrm{conv}(K)$ is empty with respect to S, each point in T is not in S. Thus, T is 3-blocked. K needs at least eight blockers (five blockers for the edges on the boundary of $\mathrm{conv}(K)$, and three blockers for the chords of $\mathrm{conv}(K)$). Thus, $|T| \ge 8$. But every 3-blocked set has at most six points, which is a contradiction. Hence, $|P| \le 36$. □

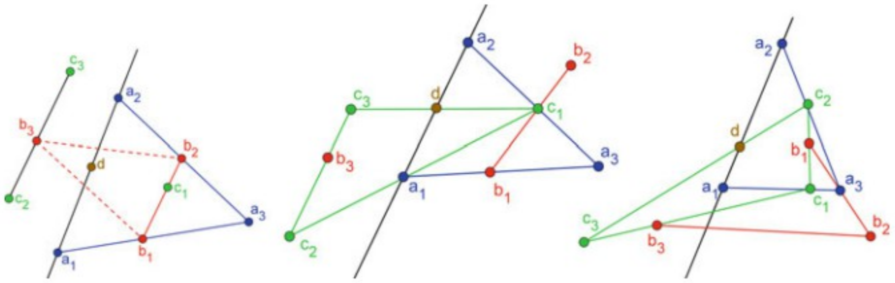

Fig. 3 Cases 1.1, 1.2, and 2 in Lemma 18

We now set out to characterize all representable 4-sets. We need a few technical lemmas.

Lemma 17. *Let A be a set of three monochromatic points in a 4-blocked set P. Then* $P \cap \operatorname{conv}(A)$ *contains a point from each color class.*

Proof. $P \cap \operatorname{conv}(A)$ contains at least three points in A. If $P \cap \operatorname{conv}(A)$ contains no point from one of the three other color classes, then $P \cap \operatorname{conv}(A)$ is a (≤ 3)-blocked set with three points in one color class (A), contradicting Theorem 2. □

Let $a * b * c$ mean that b blocks a and c, and let $a * b * c * d$ mean that $a * b * c$ and $b * c * d$. This allows us to record the order in which points occur on a line. Let $\overleftrightarrow{ab}$ be the line through two points a and b. For three noncollinear points a, b, c, let Δabc be the open triangle with vertices a, b, c.

Lemma 18. $\{3,3,3,1\}$ *is not representable.*

Proof. Suppose that P is a $\{3,3,3,1\}$-blocked set of points, with color classes $A = \{a_1, a_2, a_3\}$, $B = \{b_1, b_2, b_3\}$, $C = \{c_1, c_2, c_3\}$, and $D = \{d\}$.

If d does not block some monochromatic pair, then $P \setminus D$ is a 3-blocked set of nine points, contradicting Theorem 2. Therefore, d blocks some monochromatic pair, which we may call a_1, a_2. Now $\overleftrightarrow{a_1a_2}$ divides the remaining seven points of P into two sets, P_1 and P_2, where without loss of generality, $4 \leq |P_1| \leq 7$ and $0 \leq |P_2| \leq 3$. If $|P_1| \geq 6$, then $P_1 \cup \{a_1\}$ is a 3-blocked set of more than six points, contradicting Theorem 2. Thus, $|P_1| = 4$ and $|P_2| = 3$, or $|P_1| = 5$ and $|P_2| = 2$. Consider the following cases, as illustrated in Fig. 3.

Case 1. $|P_1| = 4$ and $|P_2| = 3$.

By Theorem 2, P_1 is a $\{1,1,2\}$-blocked set. Thus, without loss of generality, $P_1 = \{a_3, b_1, b_2, c_1\}$ and $P_2 = \{b_3, c_2, c_3\}$, where $c_2 * b_3 * c_3$. Some point in P_1 blocks b_1 and b_2. If $b_1 * a_3 * b_2$, then neither b_1 nor b_2 can block $\overline{a_3a_1}$ or $\overline{a_3a_2}$; thus, c_1 blocks a_3 from both a_1 and a_2, a contradiction. Therefore, $b_1 * c_1 * b_2$. Since two of these three points must block $\overline{a_3a_1}$ and $\overline{a_3a_2}$, we may assume that $a_1 * b_1 * a_3$, and either $a_2 * b_2 * a_3$ or $a_2 * c_1 * a_3$.

Case 1.1. $a_2 * b_2 * a_3$: Since $c_2 * b_3 * c_3$, the only possible blockers for $\overline{b_1b_3}$ are on $\overleftrightarrow{a_1a_2}$. We cannot have $b_3 * a_1 * b_1$, for then $b_3 * a_1 * b_1 * a_3$. We cannot have $b_3 * a_2 * b_1$, for then $\overleftrightarrow{b_1b_3}$ separates b_2 from d, implying $d \notin \operatorname{conv}(B)$, contradicting Lemma 17. Therefore, $b_1 * d * b_3$. Similarly, $b_2 * d * b_3$, a contradiction.

Case 1.2. $a_2 * c_1 * a_3$: Thus, a_2 does not block $\overline{c_1c_2}$ or $\overline{c_1c_3}$. Therefore, a_1 and d block $\overline{c_1c_2}$ and $\overline{c_1c_3}$. Without loss of generality, $c_2 * a_1 * c_1$ and $c_3 * d * c_1$. Since $c_2 * b_3 * c_3$, the blocker for $\overline{b_1b_3}$ is on the same side of $\overleftrightarrow{c_1c_3}$ as a_1, and on the same side of $\overleftrightarrow{b_1b_2}$ as a_1. The only such points are a_1, c_2, and b_3. Thus, a_1 or c_2 blocks $\overline{b_1b_3}$. Now, c_2 does not block $\overline{b_1b_3}$, as otherwise $b_1 * c_2 * b_3 * c_3$. Similarly, a_1 does not block $\overline{b_1b_3}$, as otherwise $b_3 * a_1 * b_1 * a_3$. This contradiction concludes this case.

Case 2. $|P_1| = 5$ and $|P_2| = 2$.

We have $a_3 \in P_1$, as otherwise P_1 is 2-blocked, contradicting Theorem 2. Without loss of generality, $P_1 = \{a_3, b_1, b_2, c_1, c_2\}$ and $P_2 = \{b_3, c_3\}$. Note that a_3 must block at least one of $\overline{b_1b_2}$ and $\overline{c_1c_2}$, because $P_1 \setminus \{a_3\}$ is too large to be 2-blocked; however, it cannot block both, for then there would be no valid blockers left for a_3. Thus, without loss of generality, $b_1 * a_3 * b_2$ and $c_1 * b_1 * c_2$. Since $a_3 \in \overline{b_1b_2}$, neither b_1 nor b_2 blocks $\overline{a_3a_1}$ or $\overline{a_3a_2}$. Thus, without loss of generality, $a_1 * c_1 * a_3$ and $a_2 * c_2 * a_3$.

By Lemma 17, $P \cap \operatorname{conv}\{c_1, c_2, c_3\}$ contains some member of A, say a_1. We cannot have $a_1 \in \overline{c_1c_3}$, for then $c_3 * a_1 * c_1 * a_3$. Therefore, a_1 is on the same side of $\overleftrightarrow{c_1c_3}$ as c_2; consequently, d and a_2 are, as well. It follows that $c_1 * b_3 * c_3$, and so b_3 sees b_2. □

Lemma 19. *Let P be a 4-blocked set. Suppose that some color class S of P contains a subset K, such that $|K| = 4$ and K is the vertex-set of a convex quadrilateral* $\operatorname{conv}(K)$ *that is empty with respect to S. Then P is $\{4,2,2,1\}$-blocked.*

Proof. Let $T := P \cap (\operatorname{conv}(K) - K)$. Since $\operatorname{conv}(K)$ is empty with respect to S, each point in T is not in S. Thus, T is 3-blocked. K needs at least five blockers (four blockers for the edges on the boundary of $\operatorname{conv}(K)$, and at least one blocker for the chords of $\operatorname{conv}(K)$). The only representable 3-sets with at least five points are $\{2,2,1\}$ and $\{2,2,2\}$. At least four points in T are on the boundary of $\operatorname{conv}(T)$. Every $\{2,2,2\}$-blocked set contains three points on the boundary of the convex hull. Thus, T is $\{2,2,1\}$-blocked. Hence, as illustrated in Fig. 4, one point c in T is at the intersection of the two chords of $\operatorname{conv}(K)$, and exactly one point in T is on each edge of the boundary of $\operatorname{conv}(K)$, such that the points on opposite edges of $\operatorname{conv}(K)$ are collinear with c.

We claim that no other point is in P. Suppose otherwise, and let p be a point in P outside $\operatorname{conv}(K)$ at a minimum distance from $\operatorname{conv}(K)$. Let x be a point in $\operatorname{conv}(K)$ receiving the same color as p. Thus, p and x are blocked by some point b in $\operatorname{conv}(K)$. Hence, b and x are collinear with no other point in $P \cap \operatorname{conv}(K)$, so $x \neq c$. Since p sees the nearest vertex in $\operatorname{conv}(K)$, we also have $x \notin K$. Thus, x is in the interior of one of the edges of the boundary of $\operatorname{conv}(K)$. Let y be the point in $\operatorname{conv}(K)$ receiving the same color as x. Thus, x and y are on opposite edges of the boundary of $\operatorname{conv}(K)$. Hence, p and y receive the same color, implying p and y are blocked. Since p is at a

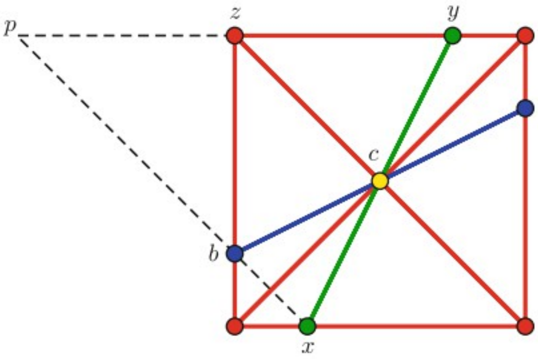

Fig. 4 A $\{4,2,2,1\}$-blocked point set

minimum distance from $\text{conv}(K)$, this blocker must be a point z of $\text{conv}(K)$. Having both $p*b*x$ and $p*z*y$ implies that p,z,y and one other point of $\text{conv}(K)$ are four collinear points, which contradicts Lemma 3. Hence, no other point is in P, and P is $\{4,2,2,1\}$-blocked. □

Lemma 19 has the following corollary (let $K := S$).

Corollary 20. *Let P be a 4-blocked set. Suppose that some color class S consists of exactly four points in convex position. Then P is $\{4,2,2,1\}$-blocked.*

The next lemma is a key step in our characterization of representable 4-sets.

Lemma 21. *Each color class in a 4-blocked point set has at most four points.*

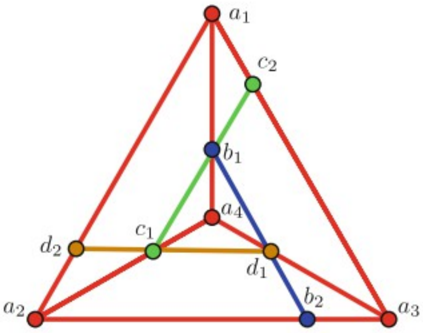
Proof. Suppose that some 4-blocked point set P has a color class S with at least five points. Esther Klein [3] proved that every set of at least five points in general position in the plane contains an empty quadrilateral. By Lemma 4, S is in general position. Thus, S contains a subset K, such that $|K| = 4$ and K is the vertex set of a convex quadrilateral $\text{conv}(K)$ that is empty with respect to S. By Lemma 19, P is $\{4,2,2,1\}$-blocked, which is the desired contradiction. □

Lemma 22. *Let P be a 4-blocked point set with color classes A,B,C,D. Suppose that no color class consists of exactly four points in convex position (that is, Corollary 20 is not applicable). Furthermore, suppose that some color class A consists of exactly four points in nonconvex position. Then P is $\{4,2,2,2\}$-blocked, as in Fig. 5 for example.*

Proof. By Lemma 21, each color class has at most four points. By assumption, every 4-point color class is in nonconvex position. We may assume that A is minimal in the sense that no other 4-point color class is within $\text{conv}(A)$.

Let $Q := P \cap \text{conv}(A)$. Thus, Q is 4-blocked, and one color class is A. By the minimality of A, each other color class in Q has at most three points. We first prove that Q is $\{4,2,2,2\}$-blocked, and then show that this implies that $P = Q$.

Fig. 5 A $\{4,2,2,2\}$-blocked point set



Let $A = \{a_1, a_2, a_3, a_4\}$, where a_4 is the interior point of $\operatorname{conv}(A)$. Note that the edges with endpoints in A divide $\operatorname{conv}(A)$ into three triangles with disjoint interiors. By Lemma 17, each color class of Q is represented in each of these triangles; this requires at least two points of each color (one of which could sit on the edge shared by two triangles).

We name a point with reference to its color class, such as $b_1 \in B$; or we name a point with reference to its position.

Let $Q' := Q \setminus A$. Let x_{ij} be the unique member of Q' that blocks $\overline{a_i a_j}$, for $1 \leq i < j \leq 4$. This accounts for exactly six points of Q'. For each case below we prove that Q' contains four mutually visible points (with respect to Q), which is a contradiction since Q' is 3-colored.

Q is not $\{4,3,3,3\}$-blocked, as otherwise we could delete the three outer members of A to represent $\{3,3,3,1\}$, which contradicts Lemma 18. Thus, Q is $\{4,3,2,2\}$-blocked, $\{4,3,3,2\}$-blocked, or $\{4,2,2,2\}$-blocked.

First, suppose that Q is $\{4,3,2,2\}$-blocked. Then Q' consists of six points x_{ij} and one additional point, y. The following three cases arise, as illustrated in Fig. 6.

Case 1. y blocks two points x_{i4} and x_{j4}: Without loss of generality, $x_{24} * y * x_{34}$. Now y is on one side or the other of $\overleftrightarrow{x_{14}a_4}$, and therefore y sees x_{12} or x_{13}. Without loss of generality, y sees x_{12}. Thus, x_{12}, x_{14}, x_{24}, and y are mutually visible points in Q'.

Case 2. y is collinear with, but does not block, two points x_{i4} and x_{j4}. Without loss of generality, $y * x_{24} * x_{34}$. Now x_{12} is on one side or the other of $\overleftrightarrow{yx_{24}}$; thus, x_{12} sees some $p \in \{x_{14}, x_{23}\}$, which is mutually visible with x_{12}, x_{24} and y; thus, we have four mutually visible points in Q'.

Case 3. y is not collinear with two points x_{i4} and x_{j4}: Then y sees all such points; thus, x_{14}, x_{24}, x_{34}, and y are mutually visible in Q'.

Now suppose that Q is $\{4,3,3,2\}$-blocked. Then Q' consists of the six points x_{ij} and two additional points, y_1 and y_2. Let $\delta = \{x_{14}, x_{24}, x_{34}\}$ and let δ_2 be the set of segments with both endpoints in δ. How many of the points y_i block members of δ_2? The following cases arise.

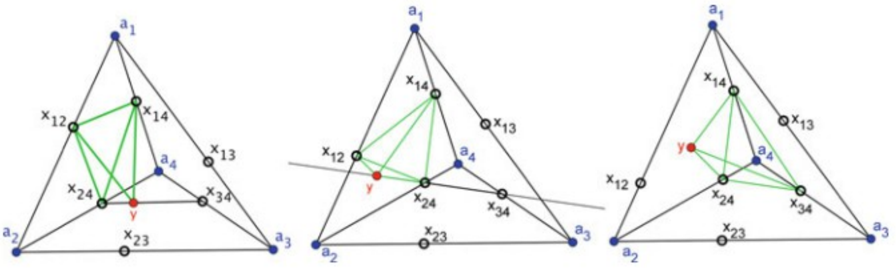


Fig. 6 Cases 1–3 when Q is $\{4,3,2,2\}$-blocked

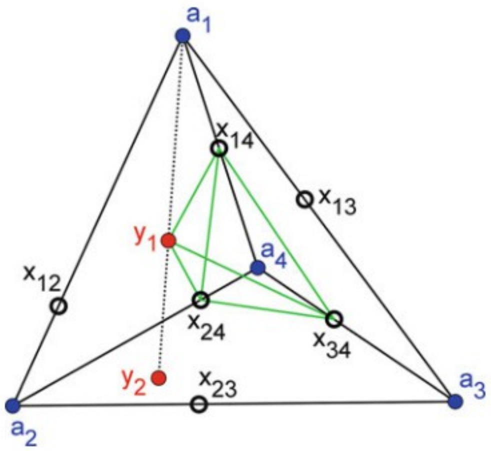

Fig. 7 Case 1 when Q is $\{4,3,3,2\}$-blocked

Case 1. Neither y_1 nor y_2 blocks a segment in δ_2 (see Fig. 7).

Since y_1 and y_2 cannot block each other, without loss of generality, y_2 does not block y_1. Thus, δ and y_1 give four mutually visible points in Q'.

Case 2. At least one of y_1 and y_2 blocks a segment in δ_2.

Without loss of generality, y_1 blocks a segment in δ_2 and $x_{24} * y_1 * x_{34}$. Neither a_1 nor a_4 belongs to $\overleftrightarrow{x_{14}y_1}$, because otherwise *both* do (since $a_1 * x_{14} * a_4$), yielding four collinear points. Since $y_1 \in \Delta a_2a_3a_4 \subset \Delta a_2a_3x_{14}$, we know that a_2 and a_3 are on opposite sides of $\overleftrightarrow{x_{14}y_1}$ by the Crossbar Theorem. Thus, without loss of generality, a_4 is on the same side of $\overleftrightarrow{x_{14}y_1}$ as x_{24}—call this side "west" and the other side "east."

We now show that $\{x_{13}, x_{14}, x_{34}, y_1\}$ is a set of four points in general position. If not, then three of these points are collinear. Observe that x_{13}, x_{14}, and x_{34} are noncollinear. Thus, y_1 is one of the three collinear points. Since $\overleftrightarrow{x_{34}y_1}$ already contains a third point, namely x_{24}, it contains neither x_{13} nor x_{14} by Lemma 3. Thus, our three collinear points are $\{x_{13}, x_{14}, y_1\}$. Since $x_{24} * y_1 * x_{34}$, the point x_{34} is east of $\overleftrightarrow{x_{14}y_1}$. Thus, a_1 and a_3 are also east of $\overleftrightarrow{x_{14}y_1}$, so x_{13} must be as well. Therefore, x_{13} is not collinear with x_{14} and y_1. Thus, $\{x_{13}, x_{14}, x_{34}, y_1\}$ is a set of four points in general position.

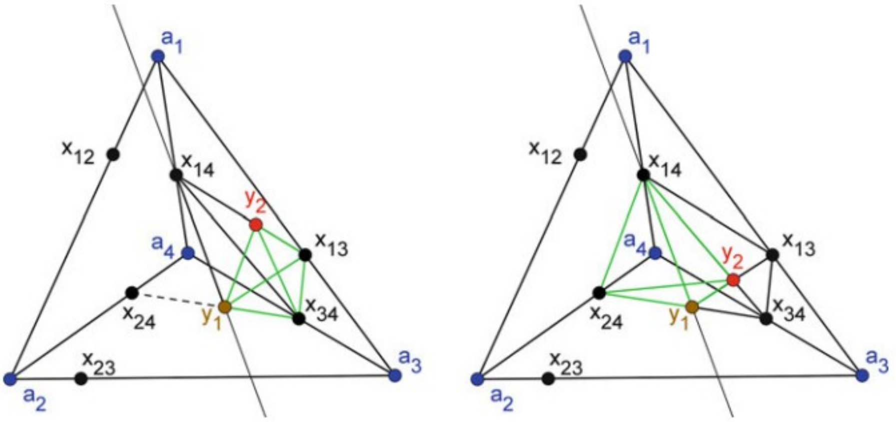

Fig. 8 Case 2a when Q is $\{4,3,3,2\}$-blocked

Since Q' does not contain four mutually visible points, there is some blocker in the midst of $\{x_{13}, x_{14}, x_{34}, y_1\}$. Because a_4 and x_{24} are west of $\overleftrightarrow{x_{14}y_1}$, the only possible blocker—which must be an interior point of $\mathrm{conv}(Q)$—is y_2, which must therefore belong to $\mathrm{conv}(x_{13}, x_{14}, x_{34}, y_1)$.

Case 2a. $\{x_{13}, x_{14}, x_{34}, y_1\}$ is in convex position (see Fig. 8).

If y_1 and x_{13} are on the same side of $\overleftrightarrow{x_{14}x_{34}}$, then y_1 and x_{24} would be on opposite sides of $\overleftrightarrow{x_{14}x_{34}}$, implying y_1 would not block $\overline{x_{24}x_{34}}$, which is a contradiction. Thus, y_1 and x_{13} are on opposite sides of $\overleftrightarrow{x_{14}x_{34}}$. It follows that $\mathrm{conv}(x_{13}, x_{14}, x_{34}, y_1)$ has chords $\overline{x_{14}x_{34}}$ and $\overline{x_{13}y_1}$. If y_2 blocks just one edge between $\{x_{13}, x_{14}, x_{34}, y_1\}$ (as in Fig. 8, left), then we may substitute y_2 for one endpoint of that edge to build a set of four mutually visible points in Q'. Thus, y_2 must block two edges between $\{x_{13}, x_{14}, x_{34}, y_1\}$ (as in Fig. 8, right). Hence, $x_{14} * y_2 * x_{34}$ and $y_1 * y_2 * x_{13}$. Now (1) a_4 is blocked by both x_{14} and x_{24}, and therefore blocks neither of them; (2) a_4 cannot block $\overline{y_1y_2}$, which is on the other side of $\overleftrightarrow{x_{14}y_1}$; (3) x_{34} is blocked by both y_1 and y_2, and therefore cannot block either of them; (4) x_{34} cannot block $\overline{x_{14}x_{24}}$, which is on the other side of $\overleftrightarrow{x_{14}y_1}$. Thus, $\{x_{14}, x_{24}, y_1, y_2\}$ is a set of four mutually visible points in Q'.

Case 2b. $\{x_{13}, x_{14}, x_{34}, y_1\}$ is not in convex position (see Fig. 9).

One of these four points lies inside the triangle formed by the other three. This interior point cannot be x_{13}, since it is on the boundary of $\mathrm{conv}(A)$. Nor can it be x_{14} or y_1, as we previously showed that x_{13} and x_{34} are on the same side (east) of $\overleftrightarrow{x_{14}y_1}$. Thus, x_{34} is in $\Delta x_{13}x_{14}y_1$. Hence, x_{13} and x_{14} are on opposite sides of $\overleftrightarrow{x_{34}y_1}$. That is, x_{13} and x_{23} are on the same side of $\overleftrightarrow{x_{34}y_1}$. This implies that x_{24} and y_1 are boundary points of $\mathrm{conv}(x_{23}, x_{24}, y_1, x_{13})$. Moreover, x_{13} and x_{23} must also be boundary points of $\mathrm{conv}(x_{23}, x_{24}, y_1, x_{13})$, as they are boundary points of $\mathrm{conv}(A)$.

Now $\{x_{23}, x_{24}, y_1, x_{13}\}$ is a set of four points in convex position. Note that $\mathrm{conv}(x_{13}, x_{14}, x_{34}, y_1)$ meets $\mathrm{conv}(x_{23}, x_{24}, y_1, x_{13})$ along only a single edge, $\overline{y_1x_{13}}$.

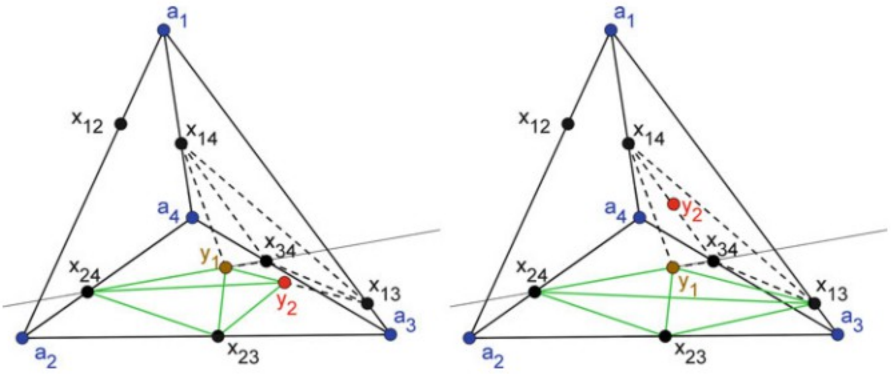

Fig. 9 Case 2b when Q is $\{4,3,3,2\}$-blocked

If y_2 blocks $\overline{y_1x_{13}}$, then $\{x_{23},x_{24},y_1,y_2\}$ is a set of four mutually visible points in Q' (as in Fig. 9, left). If y_2 does not block $\overline{y_1x_{13}}$, then $\{x_{23},x_{24},y_1,x_{13}\}$ is a set of four mutually visible points in Q' (as in Fig. 9, right).

The only remaining case is that Q is $\{4,2,2,2\}$-blocked. This is possible, as illustrated in Fig. 5. We now show that this point set is essentially the only $\{4,2,2,2\}$-blocked set, up to betweenness-preserving deformations. There are exactly enough points in color classes B, C, and D to block all edges between points in A. As each of the three A-triangles with point a_4 must contain a representative from each of the other three color classes, it follows that of the six A-edges, B blocks one interior edge and the opposite boundary edge, and likewise for C and D. Without loss of generality $b_1 = x_{14}$, $b_2 = x_{23}$, $c_1 = x_{24}$, $c_2 = x_{13}$, $d_1 = x_{34}$, and $d_2 = x_{12}$. Since b_1 blocks a_4, a_4 cannot block b_1. Since $\overline{b_1b_2}$ can be blocked only by an interior point of conv(A), it follows that either c_1 or d_1 blocks $\overline{b_1b_2}$. As these cases are symmetric, we may choose $c_1 \in \overline{b_1b_2}$. Now b_1 cannot block c_1, so c_1 must be blocked by d_1, which must in turn be blocked by b_1.

Now we show that $P = Q$. (This basically says that the point set in Fig. 5 cannot be extended without introducing a new color.) Suppose to the contrary that $P \setminus \text{conv}(A) \neq \emptyset$. Let x be a point in $P \setminus \text{conv}(A)$ closest to conv(A). Thus, x sees a vertex of conv(A), and $x \notin A$. Without loss of generality, $x \in B$. Recall that b_2 is on the line $\overleftrightarrow{a_2a_3}$. Thus, x is in the same half-plane determined by $\overleftrightarrow{a_2a_3}$ as the rest of Q, as otherwise b_2 would see $x \in B$. Which point blocks $\overline{b_1x}$? Not a_2 or a_3, for this would put x in the wrong half-plane. Not a_1, a_4, c_1, or c_2, since b_1 blocks each of these. Not d_1, which is on $\overline{b_1b_2}$. Therefore, $\overline{b_1x}$ can be blocked only by d_2. Since $d_1 \in \overline{b_1b_2}$ and $d_2 \in \overline{b_1x}$, it follows that b_2 and x (and any blocker between them) are on the same side of $\overleftrightarrow{d_1d_2}$. But the only other points of Q in that open half-plane are a_2 and a_3, which cannot block b_2. Thus, x sees b_2, which is a contradiction. Thus, $P = Q$ and P is $\{4,2,2,2\}$-blocked. □

We now prove the main theorem of this section.

Theorem 23. *A 4-set $\{a,b,c,d\}$ is representable if and only if*

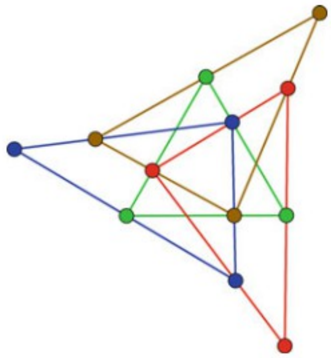

Fig. 10 Another $\{3,3,3,3\}$-blocked point set

- *$\{a,b,c,d\} = \{4,2,2,1\}$, or*
- *$\{a,b,c,d\} = \{4,2,2,2\}$, or*
- *All of $a,b,c,d \leq 3$ except for $\{3,3,3,1\}$.*

Proof. Figures 4 and 5 respectively show $\{4,2,2,1\}$-blocked and $\{4,2,2,2\}$-blocked point sets. When $a,b,c,d \leq 3$, the required constructions are described in Proposition 12. Now we prove that these are the only representable 4-sets. Let P be a 4-blocked point set. By Lemma 21, each color class has at most four points. Let S be the largest color class. If $|S| \leq 3$, then we are done by Proposition 12. Now assume that $|S| = 4$. If S is in nonconvex position, then P is $\{4,2,2,2\}$-blocked by Lemma 22. If S is in convex position, then P is $\{4,2,2,1\}$-blocked by Corollary 20. □

Corollary 24. *Every 4-blocked set has at most 12 points, and there is a 4-blocked set with 12 points.*

Note that in addition to the $\{3,3,3,3\}$-blocked set shown in Fig. 1, there is a different $\{3,3,3,3\}$-blocked point set, as illustrated in Fig. 10.

5 Midpoint-Blocked Point Sets

A k-blocked point set P is *k-midpoint-blocked* if for each monochromatic pair of distinct points $v,w \in P$ the midpoint of $\overline{vw}$ is in P. Of course, the midpoint of $\overline{vw}$ blocks v and w. A point set P is *$\{n_1,\dots,n_k\}$-midpoint-blocked* if it is $\{n_1,\dots,n_k\}$-blocked and k-midpoint-blocked. For example, the point set in Fig. 1 is $\{3,3,3,3\}$-midpoint-blocked.

Another interesting example is the projection[1] of $[3]^d$. With $d = 1$ this point set is $\{2,1\}$-blocked, with $d = 2$ it is $\{4,2,2,1\}$-blocked, and with $d = 3$ it is

---

[1] If G is the visibility graph of some point set $P \subseteq \mathbb{R}^d$, then G is the visibility graph of some projection of P to $\mathbb{R}^2$ (since a random projection of P to $\mathbb{R}^2$ is occlusion-free with probability 1).

$\{8,4,4,4,2,2,2,1\}$-blocked. In general, each set of points with exactly the same set of coordinates equal to 2 is a color class. Each color class of points with exactly i coordinates equal to 2 has size 2^{d-i}, and there are $\binom{d}{i}$ such color classes. Hence, $[3]^d$ is $\{\binom{d}{i} \times 2^{d-i} : i \in [0,d]\}$-midpoint-blocked and 2^d-midpoint-blocked.

We now prove Conjecture 1 when restricted to k-midpoint-blocked point sets. (Finally, we have weakened Conjecture 5 to something provable!)

A. Hernández-Barrera, F. Hurtado, J. Urrutia, and C. Zamora (On the midpoints of a plane point set, 2001, unpublished manuscript) introduced the following definition. Let $m(n)$ be the minimum number of midpoints determined by some set of n points in general position in the plane. Since the midpoint of $\overline{vw}$ blocks v and w, we have $b(n) \leq m(n)$. A. Hernández-Barrera, F. Hurtado, J. Urrutia, and C. Zamora (On the midpoints of a plane point set, 2001, unpublished manuscript) constructed a set of n points in general position in the plane that determine at most $cn^{\log 3}$ midpoints for some constant c. (All logarithms here are binary.) Thus, $b(n) \leq m(n) \leq cn^{\log 3} = cn^{1.585\cdots}$. This upper bound was improved independently by Pach [7] and Stanchescu [11] (and later by Matoušek [6]) to

$$b(n) \leq m(n) \leq nc^{\sqrt{\log n}}.$$

A. Hernández-Barrera, F. Hurtado, J. Urrutia, and C. Zamora (On the midpoints of a plane point set, 2001, unpublished manuscript) conjectured that $m(n)$ is superlinear (that is, $\frac{m(n)}{n} \to \infty$ as $n \to \infty$), which was verified by Pach [7]. More precise bounds were obtained by Stanchescu [11] and Sanders [10]. Applying the latest results on Freiman's Theorem, Pór and Wood [9] observed that for all $\varepsilon > 0$ there is an integer $N(\varepsilon)$ such that $m(n) \geq n(\log n)^{4/11-\varepsilon}$ for all $n \geq N(\varepsilon)$.

Theorem 25. *For each k, there is an integer n such that every k-midpoint-blocked set has at most n points. More precisely, for all $\varepsilon > 0$ and for all k, every k-midpoint-blocked set has at most $k\max\{N(\varepsilon), 2^{(k-1)^{11/(4-11\varepsilon)}}\}$ points.*

Proof. Let P be a k-midpoint-blocked set of n points. If $n \leq kN(\varepsilon)$, then we are done. Now assume that $\frac{n}{k} > N(\varepsilon)$. Let S be a set of exactly $s := \lceil \frac{n}{k} \rceil$ monochromatic points in P. Thus, S is in general position by Lemma 4. And for every pair of distinct points $v, w \in S$, the midpoint of $\overline{vw}$ is in $P - S$. Thus,

$$\tfrac{n}{k}(\log \tfrac{n}{k})^{4/11-\varepsilon} \leq m(s) \leq n - s \leq n(1 - \tfrac{1}{k}).$$

Hence, $(\log \frac{n}{k})^{4/11-\varepsilon} \leq k-1$, implying $n \leq k2^{(k-1)^{11/(4-11\varepsilon)}}$. The result follows. $\square$

We now construct k-midpoint-blocked point sets with a "large" number of points. The method is based on the following product of point sets P and Q. For each point $v \in P \cup Q$, let (x_v, y_v) be the coordinates of v. Let $P \times Q$ be the point set $\{(v,w) : v \in P, w \in Q\}$, where (v,w) is at (x_v, y_v, x_w, y_w) in 4-dimensional space. For brevity we do not distinguish between a point in $\mathbb{R}^4$ and its image in an occlusion-free projection of the visibility graph of $P \times Q$ into $\mathbb{R}^2$.

Lemma 26. *If P is a $\{n_1,\dots,n_k\}$-midpoint-blocked point set and Q is a $\{m_1,\dots,m_\ell\}$-midpoint-blocked point set, then $P \times Q$ is $\{n_i m_j : i \in [k], j \in [\ell]\}$-midpoint-blocked.*

Proof. Color each point (v,w) in $P \times Q$ by the pair $(\mathrm{col}(v),\mathrm{col}(w))$. Thus, there are $n_i m_j$ points for the (i,j)th color class. Consider distinct points (v,w) and (a,b) in $P \times Q$.

Suppose that $\mathrm{col}(v,w) = \mathrm{col}(a,b)$. Thus, $\mathrm{col}(v) = \mathrm{col}(a)$ and $\mathrm{col}(w) = \mathrm{col}(b)$. Since P and Q are midpoint-blocked, $\frac{1}{2}(v+a) \in P$ and $\frac{1}{2}(w+b) \in Q$. Thus, $(\frac{1}{2}(v+a), \frac{1}{2}(w+b))$, which is positioned at $(\frac{1}{2}(x_v+x_a), \frac{1}{2}(y_v+y_a), \frac{1}{2}(x_w+x_b), \frac{1}{2}(y_w+y_b))$, is in $P \times Q$. This point is the midpoint of $\overline{(v,w)(a,b)}$. Thus, (v,w) and (a,b) are blocked by their midpoint in $P \times Q$.

Conversely, suppose that some point $(r,s) \in P \times Q$ blocks (v,w) and (a,b). Thus, $x_r = \alpha x_v + (1-\alpha)x_a$ for some $\alpha \in (0,1)$, $y_r = \beta y_v + (1-\beta)y_a$ for some $\beta \in (0,1)$, $x_s = \delta x_w + (1-\delta)x_b$ for some $\delta \in (0,1)$, and $y_s = \gamma y_w + (1-\gamma)y_b$ for some $\gamma \in (0,1)$. Hence, r blocks v and a in P, and s blocks w and b in Q. Thus, $\mathrm{col}(v) = \mathrm{col}(a) \neq \mathrm{col}(r)$ in P, and $\mathrm{col}(w) = \mathrm{col}(b) \neq \mathrm{col}(s)$ in Q, implying $(\mathrm{col}(v),\mathrm{col}(w)) = (\mathrm{col}(a),\mathrm{col}(b))$.

We have shown that two points in $P \times Q$ are blocked if and only if they have the same color. Thus, $P \times Q$ is blocked. Since every blocker is a midpoint, $P \times Q$ is midpoint-blocked. □

Say P is a k-midpoint blocked set of n points. By Lemma 26, the i-fold product $P^i := P \times \cdots \times P$ is a k^i-blocked set of $n^i = (k^i)^{\log_k n}$ points. Taking P to be the $\{3,3,3,3\}$-midpoint-blocked point set in Fig. 1, we obtain the following result:

Theorem 27. *For all k a power of 4, there is a k-blocked set of $k^{\log_4 12} = k^{1.79\dots}$ points.*

This result describes the largest known construction of k-blocked or k-midpoint-blocked point sets. To promote further research, we make the following strong conjectures:

Conjecture 28. Every k-blocked point set has $O(k^2)$ points.

Conjecture 29. In every k-blocked point set there are at most k points in each color class.

Conjecture 29 would be tight for the projection of $[3]^d$ with $k = 2^d$. Of course, Conjecture 29 implies Conjecture 28, which implies Conjecture 1.

Acknowledgements This research was initiated at The 24th Bellairs Winter Workshop on Computational Geometry, held in February 2009 at the Bellairs Research Institute of McGill University in Barbados. The authors are grateful to Godfried Toussaint and Erik Demaine for organizing the workshop, and to the other participants for providing a stimulating working environment. Thanks to the reviewer for many helpful suggestions. David R. Wood was supported by a QEII Research Fellowship from the Australian Research Council.

Chapter 1
The Minimal Geometric Deformation

General Relativity (GR) in its century of existence represents, without a doubt, one of the most important achievements of human knowledge. The predictions made by this theory, like the perihelion shift of Mercury, light deflection and gravitational lensing, the gravitational redshift and time delay, black holes and gravitational waves—just to mention some of the most remarkable ones, have given it the honours which deserves as one of the fundamental theories of Physics (for a recent review on experimental tests of GR see [1] and references therein). On the other hand, the great technological advances during the past decades have provided us with increasingly powerful instruments which allow for accurate measurements of the evolution of compact systems, which represent the best candidate laboratories for the study of gravity in the strong regime (see for instance [2]). This progress not only serves to test the theory like never before, but also appears to leave GR as the most reliable gravitational theory to be used in the analysis of phenomena occurring in the strong field regime. Likewise, the ability of observing increasingly distant objects deep in the universe, thus with a larger and larger cosmological redshift, leads to the conclusion that we can obtain an excellent modelling of these phenomena within GR [3, 4]. Additionally, due to the results obtained by the PLANCK collaboration [5], which improved greatly on the previous findings by WMAP [6], the cosmological models based on GR are enjoying a well-deserved and well-earned recognition. Furthermore, the recent direct observation of black holes shadows by the EHT collaboration [7, 8], as well as the detection of gravitational waves by the LIGO and Virgo collaborations [9–11], allows us to ensure that GR is one of the most successful scientific theories in the history of science. Why would we want to find new gravitational theories beyond GR then?

Despite the above success, there are fundamental questions about the gravitational interaction which GR cannot answer satisfactorily. These can be broadly grouped in the following fundamental issues, which could likely be closely related:

J. Ovalle and R. Casadio, *Beyond Einstein Gravity*, SpringerBriefs in Physics,
https://doi.org/10.1007/978-3-030-39493-6_1

(1) The inability of GR to explain satisfactorily the phenomenology of dark matter [12, 13] and dark energy, without introducing some kind of unknown matter-energy to reconcile its predictions with the observed galactic rotation curves and accelerated expansion of the universe; (2) The general GR prediction of the existence of space-time singularities, most notably in the gravitational collapse of regular matter distributions, which are both mathematically and physically hard to accept; (3) The impossibility, so far, to reconcile GR with the Standard Model of particle physics, or equivalently, the difficulties met when one tries and quantize GR by the same schemes used successfully for the other fundamental interactions. All of these have strongly motivated searches for a gravitational theory beyond GR. If the new theory is a consistent quantum theory, this could lead to a modification of GR at low energy which accounts for the dark matter and dark energy. If the new theory is not a consistent quantum theory for gravity, this should also contain GR in a suitable limit, and somehow show greater tolerance to its quantum description.

Indeed, there are many alternative theories, as for instance, high curvature gravity theories, Galileon theories, $f(R)$ theories, scalar-tensor theories, massive gravity, new massive gravity, topologically massive gravity, Chern-Simons theories, higher spin gravity theories, Horava-Lifshitz gravity, extra-dimensional theories, etc. All of these proposals entail a modification of the original Einstein equations

$$G_{\mu\nu} \equiv R_{\mu\nu} - \frac{1}{2}\, R\, g_{\mu\nu} = k^2\, T_{\mu\nu}\ , \tag{1.1}$$

where Greek indices run from 0 to 3, $R_{\mu\nu}$ and R are, respectively, the Ricci tensor and its trace determined by the space-time metric $g_{\mu\nu}$, $T_{\mu\nu}$ is the energy-momentum tensor of the matter which sources gravity, and $k^2 = 8\,\pi\, G_{\rm N}/c^2$ with $G_{\rm N}$ the Newton constant (we shall also mostly set the speed of light $c = 1$ and use the metric signature $+ - - -$, unless otherwise specified).

1.1 The Simplest Extension

Any extension of GR will eventually give rise to new terms in the effective four-dimensional Einstein equations (1.1). These "corrections" can usually be cast in the form of an effective energy-momentum tensor and appear in such a way that they should vanish or be negligible in an appropriate limit, as for instance, at solar system scale, where GR has been successfully tested. This limit represents not only a critical point when a consistent extension to GR is studied, but also a non-trivial problem that must be treated carefully.

The simplest way to produce an extension to GR is by considering a modification of the Hilbert-Einstein action as

$$S = \int \left(\frac{R}{2\,k^2} + \mathcal{L}_M \right) \sqrt{-g}\, d^4x + \alpha\, (correction)\ , \tag{1.2}$$

where α is a free parameter associated with the new gravitational sector not described by GR. The explicit form corresponding to the generic correction shown in Eq. (1.2) should be, of course, a well justified and physically motivated expression. At this stage, the GR limit obtained by setting $\alpha = 0$, is just a trivial issue, and everything looks consistent so far. Indeed, we may go further and calculate the equations of motion corresponding to this new theory. Upon demanding as usual that the variation $\delta S = 0$, one obtains

$$R_{\mu\nu} - \frac{1}{2}\, R\, g_{\mu\nu} = k^2\, T_{\mu\nu} + \alpha\, (new\ term)_{\mu\nu}\ , \tag{1.3}$$

where the new term in Eq. (1.3) may be consolidated as part of an effective energy-momentum tensor. The explicit form of this tensor may contain some new degrees of freedom, as for instance scalar, vector and tensor fields, all of them coming from the new gravitational sector not described by Einstein's original theory. The GR limit is still a trivial issue, since $\alpha = 0$ leads to the standard Einstein equations (1.1).

The above arguments seem to tell us that the consistency with the GR predictions—more formally, the GR limit—is a trivial problem. However, when the system of Eq. (1.3) is solved, the result may show a completely different story. In fact, it is very common that a general solution of Eq. (1.3) does not reproduce any GR space-time metric by simply setting $\alpha = 0$. The origin of this problem is in the non-linearity of the system (1.3), and it should not come as a surprise. To clarify this point, let us consider a static and spherically symmetric perfect fluid. The most general spherically symmetric space-time metric can be written as

$$\begin{aligned} ds^2 &= g_{\mu\nu}\, dx^\mu\, dx^\nu \\ &= e^{\nu(r)}\, dt^2 - e^{\lambda(r)}\, dr^2 - r^2 \left(d\theta^2 + \sin^2\theta\, d\phi^2\right)\ , \end{aligned} \tag{1.4}$$

where ν and λ are functions of the areal radius r only. The Einstein equations (1.1) then yield the metric component

$$e^{-\lambda} = 1 - \frac{2\, m(r)}{r}\ , \tag{1.5}$$

where

$$m = \frac{k^2}{2} \int_0^r \rho(x)\, x^2\, dx \tag{1.6}$$

is the (Misner-Sharp) mass function of the self-gravitating system. Now let us consider the same perfect fluid under the "new" gravitational theory defined in Eq. (1.2). When the Eq. (1.3) are solved we obtain an expression which may generically be written as

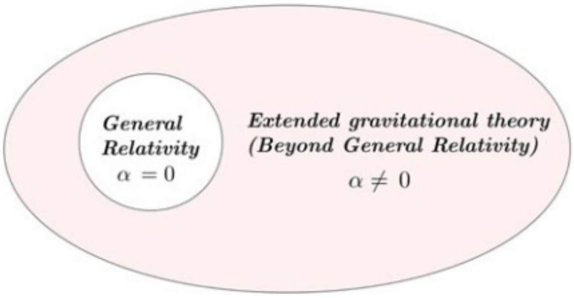

Fig. 1.1 MGD: the new gravitational sector not described by GR is fully controlled by the deformation parameter α. GR represents a "sub-space" in this extended version of gravity and is recovered for $\alpha = 0$

$$e^{-\lambda} = 1 - \frac{2\,m(r)}{r} + (\textit{geometric deformation})\ , \tag{1.7}$$

where the term *geometric deformation* should be understood as denoting the modification undergone by the metric component in Eq. (1.5) due to the generic extension of GR shown in Eq. (1.2). Therefore "deformation" means the difference with respect to a specific GR solution. Now, and this is very important, the deformation shown in the expression (1.7) always induces an *effective anisotropy* on the perfect isotropic fluid. Hence, the self-gravitating system does not behave like a perfect fluid anymore. Indeed, and this is a critical point in our analysis, the anisotropy $\mathcal{P}$ produced by the geometric deformation always appears to be of the form

$$\mathcal{P} = A + \alpha\, B\ . \tag{1.8}$$

This expression shows that the GR limit cannot be recovered simply by setting $\alpha = 0$, since the α-independent contribution A in the anisotropy (1.8) will survive in this limit. Consequently, the perfect fluid GR solution (1.5) is not contained in this extension and we could say that we have an extension to GR which does not contain GR. This seems a contradiction, but it is in fact mathematically correct and appears more properly as a problem of physical consistency. The source of this problem is the *geometric deformation* shown in Eq. (1.7), which always appears as

$$\textit{geometric deformation} = X + \alpha\, Y\ . \tag{1.9}$$

That is, there is a "sector" of the geometric deformation, generically called X, which is α-independent. Obviously this is physically problematic, since we expect to be able to control the deformation undergone by GR by varying the parameter α. It is important to remark once more that the source of this problem is solely given by the high non-linearity of the effective Einstein equations (1.3), and has nothing to do with any specific extensions of GR.

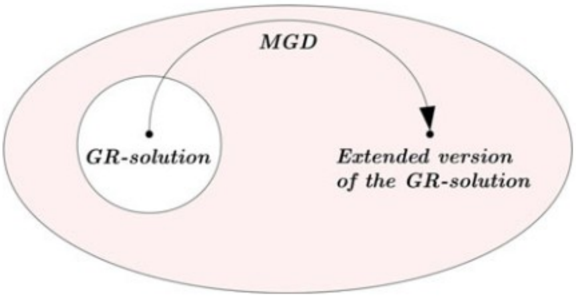

Fig. 1.2 MGD: when a GR solution is kept as a solution in the new gravitational theory, the α-independent new terms in the extended solution vanish, and the GR limit can be recovered

A method devised to solve precisely the non-trivial issue of consistency described above is the so-called *Minimal Geometric Deformation approach* (MGD) [14, 15]. The key idea is to keep under control the anisotropy induced by the extension to the Einstein theory. In particular, if we demand that the α-independent sector X in the geometric deformation (1.9) vanishes identically, the α-independent contribution to the anisotropy A in Eq. (1.8) will also vanish as a consequence. This procedure ensures that the extended theory will recover GR in the limit $\alpha = 0$. In this approach the generic expression Y in Eq. (1.9) represents the *minimal geometric deformation* undergone by the radial metric component, being the generic expression B in Eq. (1.8) the *minimal anysotropy* added to GR by the correction terms in the action (1.2) (see Figs. 1.1, 1.2).

Now, the question is how to implement the approach described above in practice. Or, more clearly, how to impose $X = 0$ in Eq. (1.9) in order to obtain a consistent extension to GR? This is accomplished when a GR solution is forced to remain a solution in the extended theory. Roughly speaking, we need to introduce the GR solution into the new theory, as far as possible. This provides the practical foundation for the MGD approach [16–24]. We want to emphasise that the GR solution used to make $X = 0$ in Eq. (1.9) will eventually be modified by using, for instance, the matching conditions at the surface of compact astrophysical object. This will in general allow us to express physical variables as functions of the deformation parameter of the theory, here generically named α. The first application of the MGD was to so called Brane-World (BW) models, and the parameter α was therefore given by the (inverse of the) brane tension. For this reason, most of this book will consider BW models of stars and other compact objects, such as black holes, although the MGD can be applied to any modification of GR of the form described above.

1.2 Extra-Dimensional Gravity: The Brane-World

Superstring/M-theory has been long considered one of the most promising candidates of quantum gravity. It describes gravity as a higher-dimensional interaction which becomes effectively four-dimensional at low enough energies. Extra-dimensional

3.7 PAPPUS' THEOREM AND FURTHER PROPERTIES

Multiplication in a Desarguesian affine plane is not necessarily commutative. To present an example of a plane with noncommutative multiplication, some algebraic results are necessary, so the example is deferred until Chapter 4. However, the geometric counterpart of commutativity of multiplication is *Pappus' Theorem*, which was stated as a *Euclidean* theorem in Chapter 1, Theorem 12.

■ **PAPPUS' THEOREM.** Let $\ell \cap m = O$, with P, Q, and R in ℓ; S, T, U in m; $\ell(P,T) \parallel \ell(Q,U)$, and $\ell(Q,S) \parallel \ell(R,T)$. Then $\ell(P,S) \parallel \ell(R,U)$.

■ **THEOREM 17.** Pappus' Theorem is true in a Desarguesian affine plane if and only if multiplication on the points of its lines is commutative.

Proof: Choosing I in ℓ so that $\ell(I,S) \parallel \ell(P,T)$, then $PQ = R$ (multiplied using S (and T)). If Pappus' Theorem is true, then $QP = R$ as well (multiplied using S (and U)). (See Fig. 3.19) Conversely, if Pappus' Theorem fails, then, relative to O and I, $PQ = R$ but $QP \neq R$, so multiplication is not commutative. ■

Pappus and Desargues

In all the examples of Desarguesian affine planes presented so far, Pappus' Theorem holds. In fact algebraic methods can be used to show that Pappus' Theorem is true in any *finite* Desarguesian affine plane, but there are (infinite) Desarguesian affine planes in which Pappus' Theorem fails. On the other hand, it has been shown that Pappus' Theorem implies that of Desargues (Hessenberg 1905).

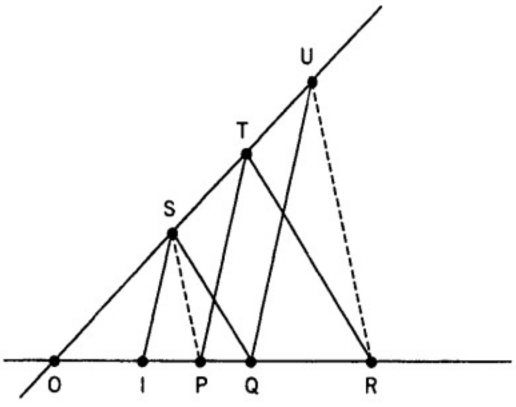

Figure 3.19

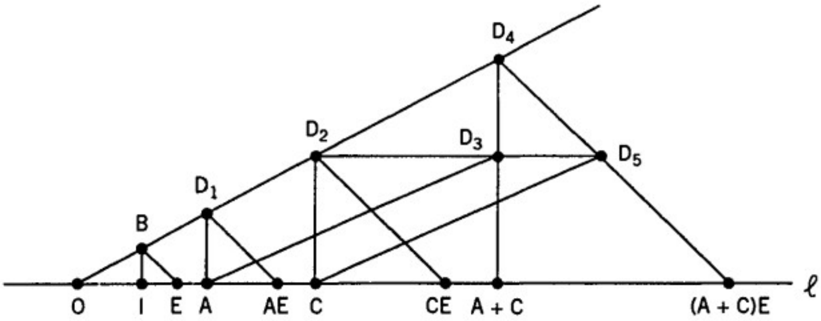

Figure 3.20

The Distributive Laws

Besides their individual properties, addition and multiplication are related by the *distributive laws*. Because multiplication is not necessarily commutative, two distributive laws are needed. Furthermore, after laws $(A + C)E = AE + CE$ and $E(I + C) = E + EC$ are proved *geometrically*, an algebraic proof shows that, for an arbitrary A, $E(A + C) = EA + EC$.

■ **THEOREM 18.** For A, C, and E in ℓ, $(A + C)E = AE + CE$.

Proof: Select $B \notin \ell$. (See Fig. 3.20.)
Compute:

AE using B (and D_1).
CE using B (and D_2).
$A + C$ using D_2 (and D_3).
$(A + C)E$ using B (and D_4).

Let D_5 be in $\ell(D_4, (A + C)E)$, so that $\ell(A, D_3) \| \ell(AE, D_5)$. Use Desargues' Theorem on D_4, D_3, D_5 and D_1, A, AE to get $\ell(D_3, D_5) \| \ell(A, AE)$, which shows that $D_5 \in \ell(D_2, D_3)$. Now add $AE + CE$ using D_2 (and D_5), and note that $\ell(D_2, CE) \| \ell(D_5, AE + CE)$. But this means that $AE + CE = (A + C)E$. ■

■ **THEOREM 19.** For C and E in ℓ, $E(I + C) = E + EC$.

Proof: Select $B \notin \ell$. (See Fig. 3.21.)
Compute:

EC using B (and D).
$I + C$ using B (and D_1).
$E + EC$ using D_1 (and D_2).

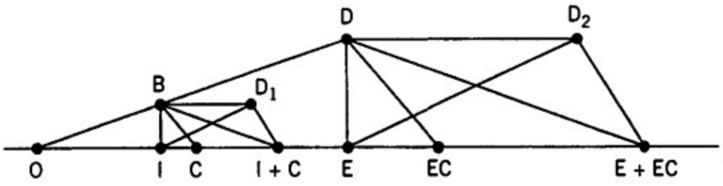

Figure 3.21

Use the converse of Desargues' Theorem on D_1, B, I and D_2, D, E which implies that $O \in \ell(D_1, D_2)$. Now use Desargues' Theorem on D_1, D_2, E + EC, and B, D_1, I + C, which gives $\ell(D, E + EC) \| \ell(B, I + C)$, whence E + EC = E(I + C). ■

Corollary. For A, C, and E in ℓ, E(A + C) = EA + EC.

Proof: If A = O, the result is immediate. If A ≠ O, then

$$\begin{aligned}(E(A + C) - EA - EC)A^{-1} &= E((A + C)A^{-1} - E - ECA^{-1} \\ &= E\left(I + CA^{-1}\right) - E - ECA^{-1} \\ &= E + ECA^{-1} - E - ECA^{-1} \\ &= O.\end{aligned}$$

Thus E(A + C) − EA − EC = O, and

$$E(A + C) = EA + EC.$$ ■

The fundamental theorem of synthetic affine geometry, stated as Theorem 1 of this chapter and repeated below, has now been proved.

■ **THEOREM 20. The fundamental theorem of synthetic affine geometry.** Relative to fixed coordinates O and I, any line in a Desarguesian affine plane is a *division ring* in that its addition and multiplication are associative, and have identites, every element has an additive inverse, and every nonzero element has a multiplicative inverse. Addition is commutative, and multiplication distributes over addition.

In the next chapter we will prove that for any division ring $\mathbb{D}$, the elements of $\mathbb{D} \times \mathbb{D}$ are the points of a Desarguesian affine plane whose lines satisfy linear equations of the form $xa + yb = c$. Conversely, any Desarguesian affine plane can be so represented over (or *coordinatized by*) a division ring.

This chapter concludes with another example of an affine plane of order 5. It will be shown in Chapter 4 that this plane can be coordinatized by the field $\mathbb{Z}_5$.

□**EXAMPLE 1: An affine plane of order 5.** $\mathscr{P} = \{A, B, C, \ldots, Y\}$, and the lines are

□

EXERCISES

The following exercises pertain to the plane of order 5 given above.

1. Make addition and multiplication tables for {OIABC}.
2. Make addition and multiplication tables for $\mathbb{Z}_5$. Show that {OIABC} is *isomorphic* to $\mathbb{Z}_5$ by finding a bijection from {OIABC} to $\mathbb{Z}_5$ that preserves addition and multiplication. [*Hint:* Map O to 0 and I to 1.]
3. Find a parallelogram in $(\mathscr{P}, \mathscr{L})$ and find the point of intersection of its diagonals.
4. Find an instance of the configurations for Desargues' Theorem in $(\mathscr{P}, \mathscr{L})$.
5. Find an instance of the configuration for Pappus' Theorem in $(\mathscr{P}, \mathscr{L})$.
6. Use $(\mathscr{P}, \mathscr{L})$ to define a projective plane of order 5.

*7. Let $(\mathscr{P}', \mathscr{L}')$ be a projective plane in which Pappus' Theorem holds, and prove Desargues' Theorem as follows: Let $\ell(A, A') \cap \ell(B, B') \cap \ell(C, C') = O$, and let $A'' = \ell(B, C) \cap \ell(B', C')$, $B'' = \ell(A, C) \cap \ell(A', C')$, and $C'' = \ell(A, B) \cap \ell(A', B')$. Define $E = \ell(A, C) \cap \ell(B', C')$, $F = \ell(A, B') \cap \ell(O, C)$, $G = \ell(A, B) \cap \ell(O, E)$, and $H = \ell(A', B') \cap \ell(O, E)$. Prove that A'', B'', and C'' are collinear by using Pappus' Theorem on O, B, B' and A, E, C; then on O, A, A' and B', C', E, and finally, on A, B', F and H, G, E. [*Hint:* In the first use of Pappus' Theorem, since $\ell(B, C) \cap \ell(B', E) = A''$, $\ell(A, B') \cap \ell(O, C) = F$ and $\ell(O, E) \cap \ell(A, B) = G$, we obtain A'', F, and G collinear.]

8. Find six orthogonal partitions of the set $\{1, 2, \ldots, 25\}$.

9. Find four orthogonal Latin squares of order 5.

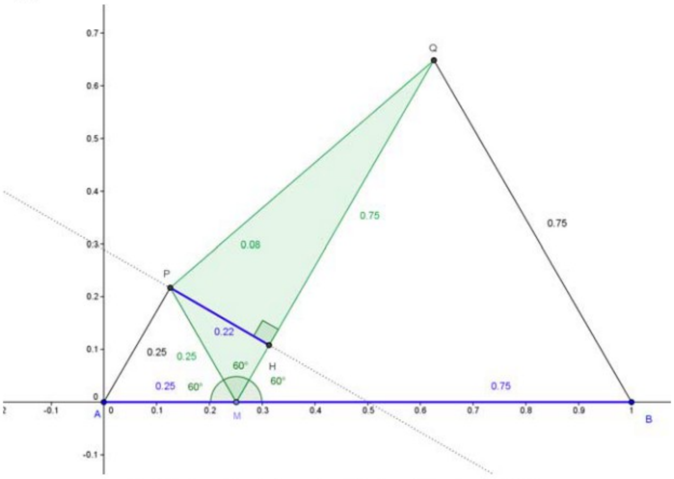
- Compléter la copie d'écran de Youssra par une légende associant courbes et aires.
- Retrouver le « texte caché » de la rédaction de Youssra.

Pour aller plus loin, j'ai pensé utiliser une fonction polynôme de degré 2 pour modéliser la courbe verte qui ressemble à un morceau de parabole. J'ai tâtonné avec trois curseurs, je suis certaine que w=0, et que u et v sont opposés. Mais ça ne marche pas, je n'ai pas réussi à superposer les courbes !

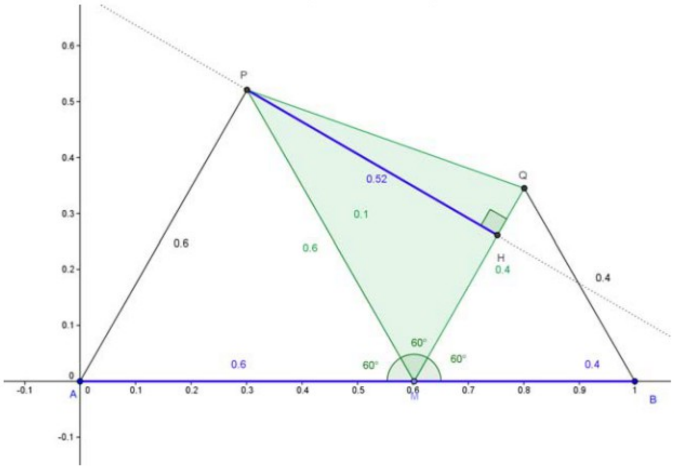
- Expliquer pourquoi w=0.
- Expliquer pourquoi u et v sont opposés.

Séance 2 : analyse de la production de Mylène

Pour comprendre le problème qui me semblait compliqué, j'ai d'abord utilisé GéoGébra pour faire une figure.



Ici l'aire du triangle MPQ est égale à 0,08.



Ici l'aire du triangle MPQ est égale à 0,1.

Première question du sujet.

J'ai calculé, dans le cas général, la hauteur PH en posant x=AM.

Puis j'ai obtenu l'aire du triangle MPQ : $0,4x \times (1 - x) = 0,4x - 0,4x^2$

- Critiquer le résultat énoncé par Mylène :
  « l'aire du triangle MPQ est égale à $0,4x \times (1 - x) = 0,4x - 0,4x^2$ ».

(f) The following manifolds are homogeneous spaces for the unitary group $U(n)$:

(i) The odd-dimensional sphere S^{2n-1}, defined in n-dimensional complex space $\mathbb{C}^n$ by the equation

$$|z^1|^2 + \cdots + |z^n|^2 = 1.$$

It is not difficult to show that in this case

$$S^{2n-1} \cong U(n)/U(n-1) \cong SU(n)/SU(n-1).$$

(ii) The complex projective space $\mathbb{C}P^{n-1}$. In this case we have

$$\mathbb{C}P^{n-1} \cong U(n)/(U(1) \times U(n-1)).$$

(iii) The complex Grassmannian manifold $G_{n,k}^{\mathbb{C}}$ consisting of the k-dimensional complex planes in $\mathbb{C}^n$ passing through the origin. Here

$$G_{n,k}^{\mathbb{C}} \cong U(n)/(U(k) \times U(n-k)).$$

5.3. Exercises

1. Let M be a homogeneous space of a Lie group G, and let H be the isotropy group. Prove that the dimension of the manifold M is the difference in the dimensions of G and H:

$$\dim M = \dim G - \dim H.$$

Compute the dimension of the Grassmannian manifold $G_{n,k}$.

2. Prove the compactness of the manifolds $V_{n,k}$ and $G_{n,k}$.

3. Let $m = (m_1, \ldots, m_k)$ be a partition of the integer n, i.e.

$$n = m_1 + \cdots + m_k, \qquad m_i \geq 0.$$

A collection of linear subspaces $\pi_0, \pi_1, \ldots, \pi_k$ of the space $\mathbb{R}^n$ is called an *m-flag* if:

(i) $\dim \pi_i - \dim \pi_{i-1} = m_i$;
(ii) $\pi_0 = 0$, $\pi_k = \mathbb{R}^n$;
(iii) $\pi_{i-1} \subset \pi_i$.

Show how the totality of all *m-flags* $F(n, m)$ can be made to serve as a homogeneous space for the group $O(n)$, and calculate its isotropy group.

§6. Spaces of Constant Curvature (Symmetric Spaces)

6.1. The Concept of a Symmetric Space

Of great interest are those manifolds endowed with a metric g_{ab} whose curvature tensor (defined in §30.1 of Part I in terms of the connexion compatible with the metric) has identically zero covariant derivative (see §§28, 29 of Part I):

$$\nabla_s(R_{abcd}) = 0. \tag{1}$$

In any metrized space the components of the covariant derivative of the curvature tensor satisfy certain relations (namely Bianchi's identities—see Exercise 7, §30.5, Part I). However condition (1) places further severe restrictions on those components; thus, in particular, it follows from (1) that the scalar characteristics of the curvature are constant:

$$R = R_a^a = \text{const.}; \qquad R_{abcd}R^{abcd} = \text{const.}$$

It turns out also that under certain global conditions on a manifold, condition (1) implies the homogeneity of the metric g_{ab}; this is the case if the manifold is "simply connected" (see §17 below). Any manifold satisfying (1) is obtainable from some simply connected such manifold M as the quotient space (i.e. by identification) under some discrete group of motions. In this construction it can happen that the discrete group Γ in question is not central in the full isometry group of M, in which case the space M/Γ will not be homogeneous; such spaces are sometimes called "locally homogeneous" or "locally symmetric".

However our approach to symmetric spaces will be via the following definition.

6.1.1. Definition. A simply connected manifold M with a metric g_{ab} defined on it, is called a *symmetric space* (or *symmetric manifold*) if for every point x of M there exists an isometry (motion) $s_x: M \to M$ with the properties that x is an isolated fixed point of it, and that the induced map on the tangent space at x reflects (i.e. reverses) every tangent vector at x, i.e. $\xi \mapsto -\xi$. Such an isometry is called a *symmetry of M at the point x*.

The significance of the requirement in this definition that the manifold be simply connected will appear below (in §§17, 18). In the present section we shall not make use of the properties of simply connected manifolds; the reader not familiar with these properties may wish to attempt the appropriate exercises in §6.6 below, after he has studied the relevant sections of Chapter 4.

6.1.2. Lemma. *Every symmetric space satisfies condition* (1).

PROOF. Let x be any particular point of the symmetric space M and let s_x be a symmetry of M at the point x. We can choose co-ordinates in some neighbourhood of x such that at x itself we have (see §29.3 of Part I)

$$x^a = 0, \qquad g_{ab} = \delta_{ab}, \qquad \frac{\partial g_{ab}}{\partial x^a} = 0.$$

(Here we are making the (inessential) assumption that the metric is Riemannian.)

Under the symmetry s_x, at the point x the tensor $\nabla_s R_{abcd}$ goes into its negative (and the tensors g_{ab} and R_{abcd} go into themselves) simply by virtue of the symmetry property of s_x and the transformation rule for tensors. On the other hand, since s_x is actually an isometry it is clear that $\nabla_s R_{abcd}$ must go into itself at x. The only way out is for $\nabla_s R_{abcd}$ to vanish at x, as required. □

Remark. The converse of this statement (under the assumption of simple-connectedness) is also true; however, in view of the greater technical complexity of its proof, we shall not prove it here. The following discussion may, however, be illuminating. In some neighbourhood of each point x of a Riemannian manifold we can define a *local symmetry* s_x as follows: Consider the pencil of geodesics on M passing through the point x (and assumed parametrized so that for each geodesic γ we have $\gamma(0)=x$); then for sufficiently small τ set

$$s_x(\gamma(\tau))=\gamma(-\tau).$$

(Recall (e.g. from §29.2 of Part I) that in a sufficiently small neighbourhood of x the geodesics through x will intersect nowhere else.)

Exercise

Prove that such local transformations s_x are for all x isometries of the manifold precisely if condition (1) holds on the manifold. (*Hint*. The simplest case is $n=2$, when the curvature tensor is determined by a single scalar R. For the general case it is easiest to deduce the preservation of the curvature tensor by the transformations s_x, from the preservation of Jacobi's equation along a geodesic.)

The existence of the "symmetries" s_x for all points x of a manifold M guarantees a sufficiently large supply of isometries for M to be (locally at least) homogeneous.

6.1.3. Lemma. *A symmetric space M is locally homogeneous; i.e. around each point $x\in M$, there is a neighbourhood such that for each point $\bar{x}$ in that neighbourhood (i.e. for each $\bar{x}$ sufficiently close to x) there exists an isometry of M sending x to $\bar{x}$. For each pair of points $x,\ y\in M$ which can be joined by a geodesic, there exists an isometry g of M such that $g(x)=y$.*

Proof. The first statement of the lemma follows from the second since around every point x there is a neighbourhood with the property that every point $\bar{x}$ in that neighbourhood is joined to x by a geodesic, i.e. the geodesics through x sweep out the whole neighbourhood.

For the second statement, let γ be a geodesic arc joining the points x and y, and parametrized by the natural (length) parameter τ, with $0\le\tau\le T$, $\gamma(0)=x$, $\gamma(T)=y$. Let s_z be a symmetry of the manifold M at the point $z=\gamma(T/2)$. It follows from its symmetry property, together with the fact that it is an isometry of M, that s_z must send γ to γ, and therefore interchange x and y. (If the metric is pseudo-Riemannian of type $(1,\ n-1)$, and γ is an isotropic geodesic, then we may take as τ the "affine" (called also "natural" in Chapter 5 of Part I) parameter yielded in solving the equation for the geodesics (see §29.2 of Part I). □

Remark. Since any two points of a (connected) Riemannian manifold can be joined by a broken geodesic, it follows almost immediately that a symmetric Riemannian manifold is always homogeneous.

6.2. The Isometry Group of a Manifold. Properties of Its Lie Algebra

Henceforth in this section we shall consider only homogeneous, symmetric manifolds M (hence satisfying (1)), with metric g_{ab}. The Lie group of all isometries of M will be denoted by G, and the isotropy group by H, so that we may identify M with the set of left cosets of H in G (i.e. $M = G/H$, in the notation of the preceding section).

Let $\gamma = \gamma(\tau)$ be a geodesic on M parametrized by a natural parameter τ, and write $x_0 = \gamma(0)$. For each appropriate real T we define a map $f_{T,\gamma}\colon M \to M$ by setting

$$f_{T,\gamma} = s_{x_0}^{-1} s_x,$$

where $x = \gamma(-T/2)$ (see Figure 11). This map has the following three important properties:

(i) $f_{T,\gamma}$ moves each point of γ through a time-interval T along the geodesic (as indicated in Figure 11):

$$\gamma(T) \mapsto \gamma(\tau + T);$$

(ii) $f_{T,\gamma}$ parallel transports vectors along the geodesic;

(iii) for any fixed geodesic γ, the transformations $f_{T,\gamma}$ with T variable, form a one-parameter subgroup of the isometry group G:

$$f_{T_1+T_2,\gamma} = f_{T_1,\gamma} f_{T_2,\gamma},$$

$$f_{-T,\gamma} = (f_{T,\gamma})^{-1}.$$

From the last of these properties and §3.1 above, it follows that for each geodesic γ the one-parameter subgroup $f_{T,\gamma}$ of G has the form

$$f_{T,\gamma} = \exp(TB_\gamma),$$

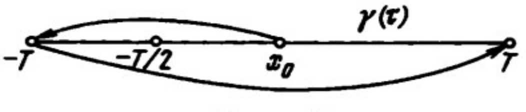

Figure 11

where B_γ is a certain vector in the Lie algebra $\mathfrak{g}$ of G (namely the tangent vector to the curve $f_{T,\gamma}$ at $T=0$). We denote by L^1 the linear subspace of the algebra $\mathfrak{g}$ spanned by the vectors $B_\gamma \in \mathfrak{g}$, where γ ranges over all geodesics through x_0, and by L^0 the Lie algebra of the isotropy group H_{x_0} of the point x_0. It follows (essentially from the fact that corresponding to each direction on the tangent plane to M at x_0 there is a geodesic through x_0 with that direction (see §29.2 of Part I)) that

$$\mathfrak{g} = L^0 + L^1 \quad \text{(direct sum of subspaces).} \tag{2}$$

If γ_1, γ_2 are two geodesics through the point x_0 then it can be shown that for small ε the product

$$f_{\varepsilon,\gamma_1} f_{\varepsilon,\gamma_2} f_{-\varepsilon,\gamma_1} f_{-\varepsilon,\gamma_2}$$

sends x_0 to a point whose distance from x_0 is of order ε^3. (This follows without difficulty from the properties of the Riemann curvature tensor. Verify!) We deduce from this (e.g. using formula (7) of §3.1) that we must have $[B_{\gamma_1}, B_{\gamma_2}] \in L_0$, whence $[L^1, L^1] \subset L^0$.

Suppose now that $g_T = \exp(TA)$ is a one-parameter subgroup of G leaving x_0 fixed (so that $A \in L_0$). Let γ be any geodesic through x_0, and denote by $\tilde{\gamma}$ the image of γ under the map g_ε. It then follows, again from the isometric property of the maps involved, that for small enough ε the map $g_\varepsilon f_{T,\gamma} g_{-\varepsilon}$ translates the points of the geodesic $\tilde{\gamma}$ along that geodesic (which of course also passes through x_0). Hence the tangent vector to the one-parameter subgroup $g_\varepsilon f_{T,\gamma} g_{-\varepsilon}$ (with parameter T), is in L_1. We now look for this tangent vector. From the basic facts about Lie algebras described in §3.1 it follows that for any two elements X, Y of the Lie algebra of a Lie group we have

$$\exp(tX)\exp(tY) = \exp\left(t(X+Y) + \frac{t^2}{2}[X, Y] + \text{higher-order terms}\right).$$

(This is a weak form of the "Campbell–Baker–Hausdorff formula".) It is an easy consequence of this that

$$\exp(tX)\exp(tY)\exp(-tX) = \exp(tY + t^2[X, Y] + \text{higher-order terms}).$$

Putting $t=1$, $X=\varepsilon A$, $Y=TB_\gamma$, we deduce that the desired tangent vector is $B_\gamma + \varepsilon[A, B_\gamma]$. Since $B_\gamma \in L^1$, it follows that $[A, B_\gamma] \in L^1$, whence $[L^0, L^1] \subset L^1$.

We include these facts in the following

6.2.1. Lemma. *With G and $\mathfrak{g} = L^0 + L^1$ as above, we have*

$$[L^0, L^0] \subset L^0, \qquad [L^1, L^0] \subset L^1, \qquad [L^1, L^1] \subset L^0. \tag{3}$$

A Lie algebra which decomposes as the direct sum of two subspaces satisfying (3) is called a *$\mathbb{Z}_2$-graded Lie algebra*, since (3) can be rewritten as

$$[L^i, L^j] \subset L^{(i+j) \bmod 2}. \tag{4}$$

6.2.2. Corollary. *With G as above, and* $\mathfrak{g} = L^0 + L^1$ *(direct) its Lie algebra, the linear operator*

$$\sigma: \mathfrak{g} \to \mathfrak{g}$$

whose restriction to L^0 *is the identity map* 1, *and whose restriction to* L^1 *is the reflection* -1, *is a Lie algebra automorphism (i.e. also preserves commutators). (The map* σ *is an "involution", i.e.* $\sigma^2 = 1$.)

(The converse is also true. To each involuntary automorphism σ of a Lie algebra $\mathfrak{g}$, there corresponds a $\mathbb{Z}_2$-grading $\mathfrak{g} = L^0 + L^1$ (direct sum of spaces) of the Lie algebra, where L^0 is the set of elements fixed by σ and L^1 the set of elements which σ negates.)

In view of the homogeneity of the manifold M, the local geometry around any point x_0 is determined by a scalar product on the tangent space $\mathbb{R}^n_{x_0}$ at the point. (Here $n = \dim M$.) We now elicit a certain property (familiar from Part I) which this scalar product must have.

Note first that the tangent space $\mathbb{R}^n_{x_0}$ can be identified naturally with the space $L^1 \subset \mathfrak{g}$. Let A be any element of L^0, and consider the one-parameter subgroup $g_T = \exp(TA)$. For each T we have the map

$$\operatorname{Ad}(g_T): \xi \mapsto \xi_T, \qquad \xi \in L^1.$$

As was shown in the course of proving part (i) of Theorem 3.1.4, we have

$$\xi_T = \operatorname{Ad}(g_T)(\xi) = \xi + T[A, \xi] + O(T^2),$$

whence

$$\left.\frac{d\xi_T}{dT}\right|_{T=0} = [A, \xi] = (\operatorname{ad} A)(\xi). \tag{5}$$

In view of the fact that g_T is an isometry of M the inner product on L^1 should be invariant under $\operatorname{Ad}(g_T)$, i.e.

$$\langle \xi_T, \eta_T \rangle = \langle \xi, \eta \rangle,$$

whence on differentiating with respect to T at $T = 0$, and using (5), we obtain

$$\langle [A, \xi], \eta \rangle + \langle \xi, [A, \eta] \rangle = 0. \tag{6}$$

This is the condition on the metric (i.e. scalar product) on $L^1 = \mathbb{R}^n_{x_0}$, that we were seeking. (Cf. the definition of a Killing metric in §24.4 of Part I.)

6.3. Symmetric Spaces of the First and Second Types

In the preceding subsection we obtained what might be called the algebraic model of a symmetric space. In principle all symmetric spaces can be classified (in the framework of the classification of compact Lie groups). In the present subsection we consider the most important examples of such spaces.

The simplest examples of (simply-connected) symmetric spaces are provided of course by the Euclidean spaces $\mathbb{R}^n$ and pseudo-Euclidean spaces $\mathbb{R}^n_{p,q}$ (where the curvature is zero). Here the group G is the full isometry group of $\mathbb{R}^n$ (or $\mathbb{R}^n_{p,q}$). (For the structure of some of these groups see §4 of Part I.) The isotropy group H is $O(n)$ (or $O(p, q)$), and the space $L^1 = \mathbb{R}^n$ consists of the translations. We have, as in the general case, $\mathfrak{g} = L^0 + L^1$, with the usual commutator relations between L^0 and L^1 (as in Lemma 6.2.1), and with the additional relation $[L^1, L^1] = 0$. Non-simply-connected symmetric spaces (earlier called "locally symmetric") can be obtained from these simply-connected ones by identification under various discrete groups Γ consisting of translations (and possibly also involving certain reflections, as for instance in the case of the Klein bottle—see §18 below).

In the remainder of our examples the group G will be semisimple. Recall from §3.1 that semisimplicity is equivalent to non-degeneracy of the Killing form on the Lie algebra $\mathfrak{g}$. Recall also that the Killing form $\langle\ ,\ \rangle$ on $\mathfrak{g}$ is defined by:

$$\langle A, B\rangle = -\operatorname{tr}(\operatorname{ad} A \operatorname{ad} B),$$

where $(\operatorname{ad} X)(\xi) = [X, \xi]$. (We shall also restrict G to being the connected component of the identity of the full isometry group.)

There are two distinct important types of simply-connected symmetric spaces with such G (even assuming the metric positive definite, i.e. Riemannian), namely:

Type I: the group G is compact and the Killing form on $\mathfrak{g}$ is positive definite. (We note here the result that a Lie group is compact if and only if it is a closed subgroup of some $O(m)$.)

Type II: the group G is non-compact and the Killing form on the Lie algebra $\mathfrak{g}$ is indefinite.

We consider the simplest (non-trivial) example of each type.

(a) The sphere S^2 is of type I. Here $G = SO(3)$, which is compact, and $H = SO(2)$.

(b) The Lobachevskian plane L^2 is of type II. Here G is the connected component of the identity of $SO(1, 2)$ (shown in §13.2 of Part I to be isomorphic to $SL(2, \mathbb{R})$), and $H = SO(2)$. The Lie algebra $\mathfrak{g}$ consists of all 2×2 matrices with zero trace, and the Killing form is given by

$$\langle A, B\rangle = -\operatorname{tr}(AB).$$

As a basis for the Lie algebra we may take

$$A_1 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad A_2 = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \qquad A_3 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}.$$

We then have

$$A_1^2 = A_2^2 = 0, \qquad A_3^2 = 1,$$

and

$$\langle A_1, A_2\rangle = -1, \qquad \langle A_1, A_3\rangle = \langle A_2, A_3\rangle = 0,$$
$$\langle A_3, A_3\rangle = -2, \qquad \langle A_1, A_1\rangle = \langle A_2, A_2\rangle = 0.$$

It follows essentially from the fact that the matrices in $H = SO(2)$ have the form

$$\begin{pmatrix} \cos\varphi & \sin\varphi \\ -\sin\varphi & \cos\varphi \end{pmatrix},$$

that the subalgebra $L^0 \subset \mathfrak{g}$ is comprised of the matrices of the form $\lambda(A_1 - A_2)$. The subspace L^1 of $\mathfrak{g}$ is spanned by the vectors $A_1 + A_2, A_3$. It is easy to check that the inclusions (3) hold.

The restriction of the Killing form to the subspace L^1 is positive definite; this reflects the positive definiteness of the metric on the Lobachevskian plane.

Exercise

Investigate the general cases S^n and L^n.

6.4. Lie Groups as Symmetric Spaces

A Lie group Q endowed with a Riemannian metric invariant under left and right multiplications by group elements, can itself be regarded as a symmetric space. The isometry group of Q has a subgroup isomorphic to $Q \times Q$, whose action on Q is defined by

$$(g_1, g_2)\colon q \mapsto g_1 q g_2^{-1}.$$

The isotropy group of this action is clearly the diagonal subgroup $H = \{(q, q) | q \in Q\}$, which is isomorphic to Q: clearly $H(1) = 1$. For each q in Q the corresponding symmetry is defined by

$$s_q\colon x \mapsto q x^{-1} q.$$

(Verify that this does indeed define a symmetry.) In particular, $s_1(x) = x^{-1}$.

We shall examine in detail the case where Q is a compact connected subgroup of $SO(m)$, with the Euclidean metric

$$\langle A, B\rangle = \operatorname{tr}(AB^{\mathrm{T}}), \tag{7}$$

where B^{T} denotes the transpose of the matrix B. (Recall that it can be shown that a Lie group is compact if and only if it is a closed subgroup of some $O(m)$.)

Exercise

Show that the scalar product (7) is the Killing metric on $SO(m)$ determined by the Killing form on its Lie algebra (cf. §24.4 of Part I).

(The formula for the curvature of the Killing metric was derived in §30.3 of Part I. It follows from that formula that the Ricci tensor R_{ab} is positive definite. In the same subsection it was shown that the geodesics through the identity are precisely the one-parameter subgroups of Q.)

As noted in §24.4 of Part I, the group $SO(m)$ lies on the sphere of radius $\sqrt{m}$ (in the Euclidean space $\mathbb{R}^{m^2}$ of all $m \times n$ matrices with the metric (7)), since for $A \in SO(m)$, we have $AA^{\mathrm{T}} = 1$, whence $\langle A, A \rangle = m$; thus

$$SO(m) \subset S^{m^2-1}$$

6.4.1. Lemma. *The (Euclidean) scalar product (7) is invariant under right and left translations (i.e. multiplications) by elements of $SO(m)$.*

Proof. Let $g \in SO(m)$, and let A, B be any $m \times m$ matrices. Then

$$\langle gA, gB \rangle = \operatorname{tr}(gAB^{\mathrm{T}}g^{\mathrm{T}}) = \operatorname{tr}(gAB^{\mathrm{T}}g^{-1}) = \operatorname{tr}(AB^{\mathrm{T}}) = \langle A, B \rangle,$$

and

$$\langle Ag, Bg \rangle = \operatorname{tr}(Agg^{\mathrm{T}}B^{\mathrm{T}}) = \operatorname{tr}(AB^{\mathrm{T}}) = \langle A, B \rangle,$$

whence the desired conclusion. □

6.4.2. Corollary. *The metric (7) restricted to any subgroup Q of $SO(m)$ is invariant under right and left multiplications $q \mapsto q_1 q q_2$.*

We call such a metric *bi-invariant* or *two-sided invariant.*

6.4.3. Lemma. *Every bi-invariant metric on a simple Lie group is proportional (with constant proportionality factor) to the Killing metric.*

Proof. Let Q be a simple Lie group with bi-invariant metric $\langle\ ,\ \rangle$. The bi-invariance implies that for all elements A, B, C of the Lie algebra L of Q, and all $g_T = \exp(AT)$, we have

$$\langle \operatorname{Ad}(g_T)(B), \operatorname{Ad}(g_T)(C) \rangle = \langle B, C \rangle, \tag{8}$$

whence it follows, just as in the derivation of (6) above, that

$$\langle [A, B], C \rangle + \langle B, [A, C] \rangle = 0. \tag{9}$$

Now let $g_{ab}, \bar{g}_{ab}$ be two metrics on Q satisfying (8), (9). Then any linear combination $g_{ab} - \lambda \bar{g}_{ab}$ will also be Ad-invariant (or equivalently skew ad-invariant). Let λ_1 be any eigenvalue of the pair of quadratic forms $g_{ab}, \bar{g}_{ab}$, i.e. $\det(g_{ab} - \lambda_1 \bar{g}_{ab}) = 0$. (The symmetry of $g_{ab}, \bar{g}_{ab}$ implies that λ_1 is real.) The subspace R_{λ_1} of all eigenvectors corresponding to the eigenvalue λ_1 is easily seen (from (9)) to be a (non-zero) ideal of L, whence by the assumed simplicity of L, we must have $R_{\lambda_1} = L$. Hence $g_{ab} = \lambda_1 \bar{g}_{ab}$. Since the Killing metric satisfies (9), the desired result follows. □

6.4.4. Corollary. *Every simple subgroup Q of the group $SO(m)$ endowed with the Killing metric, can be isometrically embedded in the sphere S^{m^2-1} endowed with a metric proportional to the usual metric on the sphere.*

6.4.5. Corollary. *Since the Ricci tensor R_{ab} (determined by the Killing metric g_{ab} on a group) also satisfies* (8), (9), *it follows that for simple groups, $R_{ab} = \lambda g_{ab}$ where $\lambda =$ const.*

Note finally that, as remarked above, it follows essentially from §30.3 of Part I that R_{ab} is positive definite for compact connected Lie groups. This is true also for semisimple groups, since each such group is (locally) a direct product $G_1 \times \cdots \times G_k$ of simples, and the sign of λ_i is easily determined for each of the simple factors G_i.

6.5. Constructing Symmetric Spaces. Examples

We now return to general symmetric spaces. In the notation of §6.2 above write

$$M = G/H, \qquad \mathfrak{g} = L^0 + L^1 \quad \text{(direct sum of subspaces)},$$

where M is a given symmetric space, G is its isometry group, L^0 is the Lie algebra of the isotropy group H, and L^1 is identifiable with the tangent space $\mathbb{R}^n_{x_0}$ to M at the point x_0 (fixed by H, i.e. $H = Hx_0$). Recall also that by virtue of the homogeneity of M, its metric is determined locally by a metric on L^1 satisfying (6); in what follows we shall assume the metric on M to be obtained from the Killing form on $\mathfrak{g}$ (see below).

6.5.1. Lemma. *The subspaces L^0 and L^1 of the Lie algebra $\mathfrak{g}$ are orthogonal with respect to the Killing form.*

Proof. From Lemma 6.2.1, it is immediate that for all $A \in L^0$, $B \in L^1$ we have

$$\begin{aligned} &\operatorname{ad} A(L^0) \subset L^0, \qquad &\operatorname{ad} A(L^1) \subset L^1,\\ &\operatorname{ad} B(L^1) \subset L^0, \qquad &\operatorname{ad} B(L^0) \subset L^1. \end{aligned}$$

It follows readily (using a basis of $\mathfrak{g}$ which is the union of bases for L^0 and L^1) that $\operatorname{tr}(\operatorname{ad} A \operatorname{ad} B) = 0$, as required. □

We deduce at once from this that in terms of a basis for $\mathfrak{g}$ of the kind just mentioned, the Killing form on $\mathfrak{g}$ has the form

$$(g_{ab}) = \begin{pmatrix} g^{(0)}_{\alpha\beta} & 0 \\ 0 & g^{(1)}_{\gamma\delta} \end{pmatrix}, \tag{10}$$

where α, β range over the indices of the basis for L^0, and γ, δ over the indices of the basis for L^1. (The form $g^{(1)}_{\gamma\delta}$ is often called the *Killing form of the symmetric space M*.)

Since the Killing form (10) on $\mathfrak{g}$ satisfies (9), so also does the form $g^{(0)}_{\alpha\beta}$ on L^0. Hence by the proof of Lemma 6.4.3, if L^0 is simple then the form $g^{(0)}_{\alpha\beta}$ will be a constant multiple of the Killing form on the algebra L^0. However, in the important examples the algebra L^0 is not simple, but rather semisimple of the form $L^0 = L^0_1 \oplus L^0_2$ where L^0_1 and L^0_2 are simple. From Lemma 6.5.1 (with now L^0 in the role of $\mathfrak{g}$), we see that in this situation the restrictions of the form $g^{(0)}_{\alpha\beta}$ to the factors L^0_1, L^0_2 will be constant multiples (by λ_1, λ_2 say) of the Killing forms on those factors.

It can be seen that if H is compact and the metric $g^{(1)}_{\gamma\delta}$ is positive definite, then with respect to suitable bases for L^0 and L^1 the matrices ad A, $A \in L^0$, are skew-symmetric. Hence $\langle A, A\rangle = -\operatorname{tr}(\operatorname{ad} A)^2$ is positive, and therefore in view of

$$-\operatorname{tr}(\operatorname{ad} A)^2 = -[\operatorname{tr}(\operatorname{ad} A)^2_{L^0} + \operatorname{tr}(\operatorname{ad} A)^2_{L^1}],$$

it follows that

$$\langle A, A\rangle_{\mathfrak{g}} > \langle A, A\rangle_{L^0}. \tag{11}$$

Hence for compact H (and positive-definite metric on the symmetric space M) the restriction to L^0 (namely $g^0_{\alpha\beta}$) of the Killing form on the Lie algebra $\mathfrak{g}$, is positive definite. (Cf. the fact that the Killing form on the Lie algebra of a compact Lie group (e.g. on the Lie algebra L^0 of H) is non-negative.)

We see that in order to construct a symmetric space it essentially suffices to choose a suitable subalgebra L^0 of $\mathfrak{g}$ on which the restriction of the Killing form of the enveloping algebra $\mathfrak{g}$ is non-degenerate; then L^1 is defined as the orthogonal complement of L^0 in $\mathfrak{g}$. However the inequality (11) greatly restricts the choice of L^0: If the Killing form on $\mathfrak{g}$ is indefinite (type II) then for symmetric spaces with Riemannian metric the subalgebra $L^0 \subset \mathfrak{g}$ must be such that the restriction of the Killing form to its orthogonal complement is either positive or negative definite, and at the same time L^0 must be the Lie algebra of a compact group, and therefore of a subgroup of $SO(m)$.

Remark. A given symmetric space can be realized as a submanifold of the group G in such a way that the geodesics of M are geodesics also in the manifold G. This embedding can be obtained in any one of the following three (equivalent) ways:

(i) by considering all one-parameter subgroups of G emanating from the identity in the direction of vectors $B \in L^1$ (show that these geodesics sweep out a submanifold of G diffeomorphic to M);
(ii) via the map $\varphi: M \to G$, defined by $\varphi(x) = s_{x_0}^{-1} s_x$ (where s_{x_0}, s_x are the appropriate symmetries);
(iii) by means of an "involution" $\bar{\sigma}: G \to G$ (by which we mean an anti-automorphism of the group $(\bar{\sigma}(g_1 g_2) = \bar{\sigma}(g_2)\bar{\sigma}(g_1))$ such that the map

induced on $\mathfrak{g}$ is the identity map on L^0 and the negative of the identity map on L^1); $M \subset G$ is then the image under the map $g \mapsto g\bar{\sigma}(g^{-1})$.

EXERCISE
Show the equivalence of these embeddings.

What follows is a list of the basic examples of connected symmetric spaces of type I. (As an exercise, find in each case the corresponding direct decomposition $\mathfrak{g} = L^0 + L^1$.)

(1) $SO(2n)/U(n)$.
(2) $SU(n)/SO(n)$.
(3) $SU(2n)/Sp(n)$.
(4) $Sp(n)/U(n)$.
(5) $SO(p+q)/(SO(p) \times SO(q))$.
(6) $SU(p+q)/(SU(p) \times U(q))$.
(7) $Sp(p+q)/(Sp(p) \times Sp(q))$.

(5)–(7): Grassmannian manifolds (including the projective spaces and spheres).

The following are examples of symmetric spaces of type II (with positive-definite metric). (The simply-connected ones among such spaces turn out to have the topology of Euclidean space $\mathbb{R}^n$.)

(1) $SO(p, q)/(SO(p) \times SO(q))$. (For $q = 1$ this is the Lobachevsky space L^p.)
(2) $SU(p, q)/(U(p) \times SU(q))$. (For $q = 1$ this is the unit ball in $\mathbb{C}^p$, as a complex manifold; if also $p = 1$, this manifold is identifiable with $L^2 \cong SU(1, 1)/U(1)$.)
(3) $Sp(p, q)/(Sp(p) \times Sp(q))$.
(4) $SL(n, \mathbb{R})/SO(n)$.
(5) $SL(n, \mathbb{C})/SU(n)$.
(6) $SO(n, \mathbb{C})/SO(n, \mathbb{R})$.

We conclude with a list of symmetric spaces of dimension 4 with metric of signature $(+ - - -)$. (These spaces are of potential importance for the general theory of relativity since (by Corollary 6.4.5) the metric g_{ab} satisfies the equation $R_{ab} - \lambda g_{ab} = 0$ (see §37.4 of Part I).

I. Spaces of constant curvature with isotropy group $H = SO(1, 3)$:

(1) Minkowski space $\mathbb{R}^4_{1,3}$.
(2) The de Sitter space $S_+ = SO(1, 4)/SO(1, 3)$; note that S_+ is homeomorphic to $\mathbb{R} \times S^3$. Here the curvature tensor R is the identity operator on the space of bivectors $\Lambda^2(\mathbb{R}^4)$: $R = 1$.
(3) The de Sitter space $S_- = SO(2, 3)/SO(1, 3)$; this space is homeomorphic to $S^1 \times \mathbb{R}^3$, and its "universal covering space" $\tilde{S}_- = \widetilde{SO}(2, 3)/\widetilde{SO}(1, 3)$ (see §18) is homeomorphic to $\mathbb{R}^4$. Here the curvature tensor $R = -1$.

II. Reducible spaces (products of spaces of constant curvature):

(1) $H = SO(3)$; $M = \mathbb{R}_+ \times M^3_{---}$, where M^3_{---} is a space of constant curvature, with signature $(- - -)$.
(2) $H = SO(1, 2)$; $M = \mathbb{R}_- \times M^3_{+--}$, where M^3_{+--} is a space of constant curvature with signature $(+ - -)$.
(3) $H = SO(2) \times SO(1, 1)$; $M = M^2_{--} \times M^2_{+-}$, the product of two 2-dimensional spaces of constant curvatures.

III. The symmetric spaces M_t of plane waves. (For these the isotropy group is abelian, and the isometry group is soluble.) In terms of a certain system of global co-ordinates the metric has the form

$$dl^2 = 2\, dx_1\, dx_4 + \underbrace{[(\cos t)x_2^2 + (\sin t)x_3^2]}_{K}\, dx_4^2 + dx_2^2 + dx_3^2,$$

$$\cos t \geq \sin t.$$

In terms of the tetrad (see §30.1 of Part I) given by the 1-forms

$$p = dx_1, \qquad q = dx_1 + K\, dx_4, \qquad x = dx_3, \qquad y = dx_4,$$

the curvature tensor is constant, of the form

$$R = -4[\cos t(p \wedge x) \otimes (p \wedge x) + \sin t(p \wedge y) \otimes (p \wedge y)].$$

Remarks. 1. A simply connected symmetric space is uniquely determined by its curvature tensor at a point. To see this let $R: \Lambda^2(V) \to \Lambda^2(V)$ be the curvature tensor, and denote by $\mathfrak{h}$ the Lie algebra of skew-symmetric linear operators on the space V generated by those operators of the form $R(x, y)$, $x, y \in V$. (Then $\mathfrak{h}$ is the Lie algebra of the isotropy group (previously denoted by L^0).) Let $\mathfrak{g}$ denote the Lie algebra $V + \mathfrak{h}$, where the commutator operation on this direct sum of spaces is defined by

$$[(u, a), (v, b)] = (av - bu, [a, b] + R(u, v)).$$

Then in terms of the pair $\mathfrak{g}$, $\mathfrak{h}$ the structure of the original symmetric space is naturally reproduced on the symmetric space $M = G/H$.

2. The problem of classifying all curvature tensors of symmetric spaces with a given isotropy group H reduces to that of finding the H-invariant tensors R of the type of the curvature tensor, for which $R(x, y)$ belongs to the Lie algebra of H for all x, y in V.

6.6. Exercises

1. Show that for symmetric spaces of type II with positive-definite metric, the dimension of the subalgebra L^0 of $\mathfrak{g}$ is equal to the number of positive squares in the Killing form on $\mathfrak{g}$.

2. Show that in the complex case (e.g. where $G = SL(n, \mathbb{C})$ or $SO(n, \mathbb{C})$) the numbers of negative and positive square terms in the complex Lie algebra $\mathfrak{g}$ are equal, and $\dim L^0 = \frac{1}{2} \dim \mathfrak{g}$. Find the subalgebra L^0 of the Lie algebra $\mathfrak{g}$ of the group $G = SL(n, \mathbb{C})$.

3. Show that for symmetric spaces of type II with positive-definite metric one always has $M \cong G/H$, where H is a maximal compact subgroup of G. Investigate the particular cases $SL(n, \mathbb{R})/SO(n)$, $SL(n, \mathbb{C})/SU(n)$.

4. Show that a simply-connected, symmetric space of type II always has the topology of Euclidean $\mathbb{R}^n$.

For the next few exercises, note that, as for Lie groups (see §30.3 of Part I), so also for symmetric spaces do we have

$$\langle R(\xi, \eta)\zeta, \tau\rangle|_{x_0} = \tfrac{1}{4}\langle[\xi, \eta], [\zeta, \tau]\rangle_{L^0}, \qquad \xi, \eta, \zeta, \tau \in \mathbb{R}^n_{x_0} = L^1.$$

5. Show that for spaces of type I, the Ricci tensor R_{ab} is positive definite, and the "sectional curvature" $\langle R(\xi, \eta)\xi, \eta\rangle$ (where ξ, η span a parallelogram of unit area) is non-negative.

6. Show that for spaces of type II the sectional curvature is non-positive. Deduce from this that a simply-connected, symmetric space of type II is topologically the same as $\mathbb{R}^n$ (assuming the metric Riemannian).

7. Decide which of the 7 symmetric spaces of type I and 6 spaces of type II listed above have non-vanishing sectional curvature. Investigate the spaces S^n, $\mathbb{C}P^n$, $\mathbb{H}P^n$ of type I, and the spaces L^n, $SU(n, 1)/U(n)$, $SL(n, \mathbb{R})/SO(n)$, $SL(n, \mathbb{C})/SU(n)$ of type II.

8. Prove that in dimensions $n = 2, 3$ the only simply-connected, symmetric spaces with positive-definite metric are L^n, S^n, $\mathbb{R}^n$. (*Hint.* Show that the isotropy group $H \subset G$ must be $SO(n)$ $(n = 2, 3)$, and thence deduce (for $n = 3$) the constancy of all sectional curvatures.)

9. Prove that a simply-connected symmetric space M with semisimple $G = G_1 \times \cdots \times G_k$ (where the G_i are simple) has the form

$$M = (G_1/H_1) \times \cdots \times (G_k/H_k),$$

with the metric decomposing as a direct product of metrics on the factors $M_i = G_i/H_i$, each of which is proportional to the Killing metric on the subspace L_i^1 of the corresponding Lie algebra $\mathfrak{g}_i = L_i^0 + L_i^1$.

§7. Vector Bundles on a Manifold

7.1. Constructions Involving Tangent Vectors

From any n-dimensional manifold M we can construct a $2n$-dimensional manifold, called the *tangent bundle* $L(M)$ of M as follows. The points of the manifold $L(M)$ are defined to be the pairs (x, ξ) where x ranges over the points

Preface vii

1 **The geometry of world-vectors and spin-vectors** 1
1.1 Minkowski vector space 1
1.2 Null directions and spin transformations 8
1.3 Some properties of Lorentz transformations 24
1.4 Null flags and spin-vectors 32
1.5 Spinorial objects and spin structure 41
1.6 The geometry of spinor operations 56

2 **Abstract indices and spinor algebra** 68
2.1 Motivation for abstract-index approach 68
2.2 The abstract-index formalism for tensor algebra 76
2.3 Bases 91
2.4 The total reflexivity of $\mathfrak{S}^{\cdot}$ on a manifold 98
2.5 Spinor algebra 103

3 **Spinors and world-tensors** 116
3.1 World-tensors as spinors 116
3.2 Null flags and complex null vectors 125
3.3 Symmetry operations 132
3.4 Tensor representation of spinor operations 147
3.5 Simple propositions about tensors and spinors at a point 159
3.6 Lorentz transformations 167

4 **Differentiation and curvature** 179
4.1 Manifolds 179
4.2 Covariant derivative 190
4.3 Connection-independent derivatives 201
4.4 Differentiation of spinors 210
4.5 Differentiation of spinor components 223
4.6 The curvature spinors 231
4.7 Spinor formulation of the Einstein–Cartan–Sciama–Kibble theory 237

4.8 The Weyl tensor and the Bel–Robinson tensor 240
4.9 Spinor form of commutators 242
4.10 Spinor form of the Bianchi identity 245
4.11 Curvature spinors and spin-coefficients 246
4.12 Compacted spin-coefficient formalism 250
4.13 Cartan's method 262
4.14 Applications to 2-surfaces 267
4.15 Spin-weighted spherical harmonics 285

5 Fields in space–time 312
5.1 The electromagnetic field and its derivative operator 312
5.2 Einstein–Maxwell equations in spinor form 325
5.3 The Rainich conditions 328
5.4 Vector bundles 332
5.5 Yang–Mills fields 342
5.6 Conformal rescalings 352
5.7 Massless fields 362
5.8 Consistency conditions 366
5.9 Conformal invariance of various field quantities 371
5.10 Exact sets of fields 373
5.11 Initial data on a light cone 385
5.12 Explicit field integrals 393
Appendix: diagrammatic notation 424
References 435
Subject and author index 445
Index of symbols 457

Contents

Preface vii
Summary of Volume 1 1

6 Twistors 43
6.1 The twistor equation and its solution space 43
6.2 Some geometrical aspects of twistor algebra 58
6.3 Twistors and angular momentum 68
6.4 Symmetric twistors and massless fields 75
6.5 Conformal Killing vectors, conserved quantities and exact sequences 82
6.6 Lie derivatives of spinors 101
6.7 Particle constants; conformally invariant operators 104
6.8 Curvature and conformal rescaling 120
6.9 Local twistors 127
6.10 Massless fields and twistor cohomology 139

7 Null congruences 169
7.1 Null congruences and spin-coefficients 169
7.2 Null congruences and space–time curvature 182
7.3 Shear-free ray congruences 189
7.4 SFRs, twistors and ray geometry 199

8 Classification of curvature tensors 223
8.1 The null structure of the Weyl spinor 223
8.2 Representation of the Weyl spinor on S^+ 226
8.3 Eigenspinors of the Weyl spinor 233
8.4 The eigenbivectors of the Weyl tensor and its Petrov classification 242
8.5 Geometry and symmetry of the Weyl curvature 246
8.6 Curvature covariants 258
8.7 A classification scheme for general spinors 265
8.8 Classification of the Ricci spinor 275

9 Conformal infinity 291
9.1 Infinity for Minkowski space 291
9.2 Compactified Minkowski space 297
9.3 Complexified compactified Minkowski space and twistor geometry 305
9.4 Twistor four-valuedness and the Grgin index 316
9.5 Cosmological models and their twistors 332
9.6 Asymptotically simple space–times 347
9.7 Peeling properties 358
9.8 The BMS group and the structure of $\mathscr{I}^+$ 366
9.9 Energy–momentum and angular momentum 395
9.10 Bondi–Sachs mass loss and positivity 423

Appendix: spinors in *n* dimensions 440
References 465
Subject and author index 481
Index of symbols 499

Contents

1 Sets, Functions, and Cardinality 1
1.1 Naive Set Theory 2
1.2 Relation and Ordering 9
1.3 Functions 17
1.4 Cardinality 26
1.5 Development of Function Concept—A Historical Note 37
References 51

2 The Real Numbers 53
2.1 Ordered Field $\mathbb{Q}$ 54
2.2 The Complete Ordered Field 65
2.3 Modulus Metric 78
2.4 Countable and Uncountable Sets in $\mathbb{R}$ 81
References 87

3 Sequences and Series of Numbers 89
3.1 The Limit of a Sequence 91
3.2 Algebra of Convergent Sequences 103
3.3 Convergence Theorems 107
3.3.1 Cauchy Sequences 113
3.3.2 The Existence of the Set $\mathbb{R}$ 118
3.4 Infinite Series 120
3.4.1 Tests of Convergence 124
3.4.2 Arbitrary Terms Series 129
3.4.3 Decimal Expansion of Real Numbers 133
Reference 140

4 Analysis on $\mathbb{R}$ 141
4.1 Limit and Continuity 142
4.2 Differentiability 153
4.3 Riemann Integration 159
4.3.1 Darboux Integral 161

4.3.2 Examples and Important Theorems 167
4.3.3 Properties of Riemann Integral 179
Reference 188

5 Topology of the Real Line 189
5.1 Open and Closed Set 190
5.2 Compactness 198
5.3 Connectedness 205

6 Metric Spaces 211
6.1 Some Important Metric Spaces 212
6.1.1 The Euclidean Space $\mathbb{R}^n$ 216
6.1.2 Function Spaces 225
6.1.3 Metric Subspace 230
6.2 Topology of Metric Spaces 231
6.2.1 Open Sets 234
6.2.2 Limit Points and Closed Sets 240
6.3 Convergence and Completeness 243
6.4 Compactness 252
6.5 Connectedness 258
6.5.1 Path-Connectedness 265
6.5.2 Components 267
Reference 272

7 Multivariable Analysis 273
7.1 Limit of Functions 274
7.2 Continuity of a Function 277
7.3 Differentiability 287
7.3.1 Partial Derivatives 288
7.3.2 Directional Derivatives 291
7.3.3 The Differential 292
7.4 Geometry of Curves and Surfaces 307
7.5 Two Fundamental Theorems 320
References 331

8 Sequences and Series of Functions 333
8.1 Pointwise Convergence 334
8.2 Uniform Convergence 338
8.3 Power Series 343

9 Measure and Integration 349
9.1 Measure Space 350
9.1.1 Outer Measure 361
9.1.2 Null Sets and Completion 366
9.2 Lebesgue Measure 368
9.2.1 Regularity Property 375
9.3 Lebesgue Integration 377

9.3.1 Measurable Functions 378
9.3.2 Lebesgue Integral 385
9.4 Fundamental Convergence Theorems 396
9.5 L^p Spaces 399
References 403

10 Fourier Series 405
10.1 Evolution of Modern Mathematics 407
10.2 Definitions and Examples 412
10.2.1 Sine and Cosine Fouries Series 422
10.2.2 Half-Range Fourier Series 426
10.3 Convergence Issues 430
10.3.1 Dirichlet Theorem 432
10.3.2 Gibbs Phenomenon 437
10.3.3 Convergence in Mean 439
10.3.4 Uniform Convergence 442
10.4 An Application to Infinite Series 446
References 449

Appendix: Mathematical Logic 451

Contents

1 Metric Spaces 1
- 1.1 Metrics 1
  - 1.1.1 Rationale for Metrics 1
  - 1.1.2 Defining Metric Space 2
  - 1.1.3 Exercises 5
- 1.2 Examples of Metric Spaces 6
  - 1.2.1 Normed Spaces 6
  - 1.2.2 Subspaces 8
  - 1.2.3 Examples; Not Subspaces of Normed Spaces 9
  - 1.2.4 Pseudometrics 9
  - 1.2.5 Cauchy-Schwarz, Hölder, Minkowski 11
  - 1.2.6 Exercises 14
- 1.3 Cantor's Middle Thirds Set 16
  - 1.3.1 Exercises 19
- 1.4 The Normed Spaces of Functional Analysis 20
  - 1.4.1 Sequence Spaces 20
  - 1.4.2 Function Spaces 22
  - 1.4.3 Spaces of Continuous Functions 23
  - 1.4.4 Spaces of Integrable Functions 23
  - 1.4.5 Hölder's and Minkowski's Inequalities for Integrals 24
  - 1.4.6 Exercises 25

2 Basic Theory of Metric Spaces 29
- 2.1 Balls in a Metric Space 29
  - 2.1.1 Limit of a Convergent Sequence 30
  - 2.1.2 Uniqueness of the Limit 31
  - 2.1.3 Neighbourhoods 32
  - 2.1.4 Bounded Sets 32
  - 2.1.5 Completeness; a Key Concept 32
  - 2.1.6 Exercises 35

2.2 Open Sets, and Closed 37
  2.2.1 Open Sets 38
  2.2.2 Union and Intersection of Open Sets 39
  2.2.3 Closed Sets 39
  2.2.4 Union and Intersection of Closed Sets 40
  2.2.5 Characterisation of Open and Closed Sets by Sequences ... 41
  2.2.6 Interior, Closure and Boundary 42
  2.2.7 Limit Points of Sets 43
  2.2.8 Characterisation of Closure by Limit Points 43
  2.2.9 Subspaces 45
  2.2.10 Open and Closed Sets in a Subspace 45
  2.2.11 Exercises 47
2.3 Continuous Mappings 52
  2.3.1 Defining Continuity 52
  2.3.2 New Views of Continuity 53
  2.3.3 Limits of Functions 55
  2.3.4 Characterising Continuity by Sequences 57
  2.3.5 Lipschitz Mappings 57
  2.3.6 Examples of Continuous Functions 58
  2.3.7 Exercises 59
2.4 Continuity of Linear Mappings 63
  2.4.1 Continuity Criterion 64
  2.4.2 Operator Norms 66
  2.4.3 Exercises 68
2.5 Homeomorphisms and Topological Properties 70
  2.5.1 Equivalent Metrics 72
  2.5.2 Exercises 73
2.6 Topologies and σ-Algebras 74
  2.6.1 Order Topologies 77
  2.6.2 Exercises 79
  2.6.3 Pointers to Further Study 82
2.7 (◊) Mazur-Ulam 82
  2.7.1 Exercises 84

3 Completeness of the Classical Spaces 87
3.1 Coordinate Spaces and Normed Sequence Spaces 87
  3.1.1 Completeness of $\mathbb{R}^n$ 87
  3.1.2 Completeness of ℓ^p 88
  3.1.3 Exercises 90
3.2 Product Spaces 90
  3.2.1 Finitely Many Factors 91
  3.2.2 Infinitely Many Factors 91
  3.2.3 The Space $2^{\mathbb{N}_+}$ and the Cantor Set 93
  3.2.4 Subspaces of Complete Spaces 95
  3.2.5 Exercises 96

3.3 Spaces of Continuous Functions 99
 3.3.1 Uniform Convergence 99
 3.3.2 Series in Normed Spaces 101
 3.3.3 The Weierstrass M-Test 103
 3.3.4 The Spaces $C(\mathbb{R})$ and $C^p(\mathbb{R})$ 103
 3.3.5 Exercises 105
3.4 (◊) Rearrangements 108
 3.4.1 Vector Series 108
 3.4.2 Exercises 111
 3.4.3 Pointers to Further Study 111
3.5 (◊) Invertible Operators 112
 3.5.1 Fredholm Integral Equation 115
 3.5.2 Exercises 116
 3.5.3 Pointers to Further Study 118
3.6 (◊) Tietze 118
 3.6.1 Formulas for an Extension 121
 3.6.2 Exercises 121
 3.6.3 Pointers to Further Study 123

4 Compact Spaces 125
4.1 Sequentially Compact Spaces 125
 4.1.1 Continuous Functions on Sequentially Compact Spaces 126
 4.1.2 Bolzano-Weierstrass in $\mathbb{R}^n$ 126
 4.1.3 Sequentially Compact Sets in $\mathbb{R}^n$ 127
 4.1.4 Sequentially Compact Sets in Other Spaces 127
 4.1.5 The Space $C(M)$ 128
 4.1.6 Exercises 129
4.2 The Correct Definition of Compactness 130
 4.2.1 Thoughts About the Definition 131
 4.2.2 Compact Spaces and Compact Sets 132
 4.2.3 Continuous Functions on Compact Spaces 134
 4.2.4 Uniform Continuity 135
 4.2.5 Exercises 136
4.3 Equivalence of Compactness and Sequential Compactness 137
 4.3.1 Relative Compactness 141
 4.3.2 Local Compactness 142
 4.3.3 Exercises 143
4.4 Finite Dimensional Normed Vector Spaces 150
 4.4.1 Exercises 153
4.5 (◊) Ascoli 154
 4.5.1 Peano's Existence Theorem 157
 4.5.2 Exercises 160
 4.5.3 Pointers to Further Study 162

5 Separable Spaces 163
- 5.1 Dense Subsets of a Metric Space 163
  - 5.1.1 Defining a Vector-Valued Integral 165
  - 5.1.2 Exercises 168
- 5.2 Separability 171
  - 5.2.1 Second Countability 172
  - 5.2.2 Exercises 173
- 5.3 (◊) Weierstrass 176
  - 5.3.1 Exercises 180
  - 5.3.2 Pointers to Further Study 182
- 5.4 (◊) Stone-Weierstrass 182
  - 5.4.1 Exercises 185
  - 5.4.2 Pointers to Further Study 186

6 Properties of Complete Spaces 187
- 6.1 Cantor's Nested Intersection Theorem 187
  - 6.1.1 Categories 188
  - 6.1.2 Exercises 190
- 6.2 (◊) Genericity 193
  - 6.2.1 Exercises 196
  - 6.2.2 Pointers to Further Study 199
- 6.3 (◊) Nowhere Differentiability 199
  - 6.3.1 Exercises 202
  - 6.3.2 Pointers to Further Study 203
- 6.4 Fixed Points 203
  - 6.4.1 Exercises 204
- 6.5 (◊) Picard 206
  - 6.5.1 Exercises 209
- 6.6 (◊) Zeros 209
  - 6.6.1 Exercises 213
  - 6.6.2 Pointers to Further Study 216
- 6.7 Completion of a Metric Space 216
  - 6.7.1 Other Ways to Complete a Metric Space 218
  - 6.7.2 Exercises 218

7 Connected Spaces 219
- 7.1 Connectedness 219
  - 7.1.1 Connected Sets 221
  - 7.1.2 Rules for Connected Sets 221
  - 7.1.3 Connected Subsets of $\mathbb{R}$ 223
  - 7.1.4 Exercises 223
- 7.2 Continuous Mappings and Connectedness 224
  - 7.2.1 Continuous Curves 224
  - 7.2.2 Arcwise Connectedness 225
  - 7.2.3 Exiting a Set 226
  - 7.2.4 Exercises 227

7.3 Connected Components 229
  7.3.1 Examples of Connected Components 229
  7.3.2 Arcwise Connected Components 232
  7.3.3 Exercises 232
7.4 (◊) Peano 236
  7.4.1 Exercises 236
  7.4.2 Pointers to Further Study 237

$$= M_{s1} P_1(u_1, v_1)$$

$$M_{s\_p2} = M_{s2} P_2(u_2, v_2)$$

$$M_{p1} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos(\varphi_1) & \sin(\varphi_1) & 0 \\ 0 & -\sin(\varphi_1) & \cos(\varphi_1) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$M_{qp} = \begin{bmatrix} 1 & 0 & 0 & H_1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$M_{rq} = \begin{bmatrix} \cos(\Sigma) & 0 & -\sin(\Sigma) & 0 \\ 0 & 1 & 0 & 0 \\ \sin(\Sigma) & 0 & \cos(\Sigma) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$M_{sr} = \begin{bmatrix} 1 & 0 & 0 & H_2 \\ 0 & 1 & 0 & -V \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$M_{s2} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos(\varphi_2) & \sin(\varphi_2) & 0 \\ 0 & -\sin(\varphi_2) & \cos(\varphi_2) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

φ_1 and φ_2 are the rotary angles of pinion and gear. M_{s1} and M_{s2} are the transformation matrices from measuring coordinate system S_1 and S_2 to the meshing coordinate system S_s for the pinion and gear. S_p, S_q, and S_r are auxiliary coordinate systems. H_1 and H_2 are the axial settings of pinion and gear. Σ is the shaft angle. V is the pinion offset distance.

outro assunto!

This curve will be best discussed when we come to deal with the problem of squaring the circle (Chapter VII);

here we need only remark that it implies the proportion that the lengths of arcs in a circle are proportional to the angles subtended by them at the centre

(Eucl. VI. 33)

---

trisecting any rectilineal angle ...

and these problems are not what the Greeks called 'plane' problems, i.e,

they cannot be solved by means of the ruler and compasses.

Hippasus — Pág. 65 (85)

Chapter III

Pythagorean Arithmetic

Hippasus → ... for making known the discovery of the irrational or incommensurable.

Pág. 160 (180) -

Hippasus

who was a Pythagorean but,
owing to his being the first
to publish and write down the
(construction of the) sphere
with (ἐκ, from)
the twelve pentagons, perished
by shipwreck for his (impiety),
but received credit for the
discovery...

$1^3 = 3$ ou 4

$\underbrace{1}_{(01)} \times \underbrace{1}_{(02)} \times \underbrace{1}_{(03)} = \boxed{3}$ (3 unidades)

3 unidades

Usando da mesma lógica:

$2^3 = 8$

$\underbrace{2 \times 2 \times 2}_{3 \text{ elementos}} = 8$ (valor em unidades)

O número 2 é o dobro de 1, portanto, se $2^3 = 8$ e o número 1 é a metade de 2^3, portanto, $1^3 = \boxed{4}$

Prosseguindo (com base na razão no número real (exponenciando)

~~2~~ $3^3 = 27$

$3 \times 3 \times 3 = 27 \Rightarrow 1 = \frac{1}{3}$ de 27

$\frac{27}{3} = \boxed{9}$

$4^3 = 64 \Rightarrow 1 \Rightarrow \frac{1}{4}$ de $64 = \frac{64}{4} = \boxed{16}$

$5^3 = 75 \Rightarrow 1 = \frac{1}{5}$ de $125 = \frac{125}{5} = \boxed{25}$

$6^3 = 216 \Rightarrow 1 = \frac{1}{6}$ de $216 = \frac{216}{6} = \boxed{36}$

$7^3 = 343' \Rightarrow 1 = \frac{1}{7}$ de $343 = \frac{343}{7} = \boxed{49}$

$8^3 = 512 \Rightarrow 1 = \frac{1}{8}$ de $512 = \frac{512}{8} = \boxed{64}$

$9^3 = 729 \Rightarrow 1 = \frac{1}{9}$ de $729 = \frac{729}{8} = \boxed{81}$

$10^3 = 1000 \Rightarrow 1 = \frac{1}{10}$ de $1000 = \frac{1000}{10} = \boxed{100}$

Divisão por 4:

$1 \times 1 \times 1 = 4$

$2 \times 2 \times 2 = 8 \; > \frac{8}{4} = 2$ (dobro)

$3 \times 3 \times 3 = 27 \; > \frac{27}{8} = 3,375$

$4 \times 4 \times 4 = 64 \; > \frac{64}{27} = 2,\overline{370}$

$5 \times 5 \times 5 = 125 \; > \frac{125}{64} = 1,953125$ (1,953125)

$6 \times 6 \times 6 = 216 \; > \frac{216}{75} = 2,88$

$7 \times 7 \times 7 = 343 \; > \frac{343}{216} = 1,58796296$

$8 \times 8 \times 8 = 512 \; > \frac{512}{343} = 1,49271137$

$9 \times 9 \times 9 = 729 \; > \frac{729}{512} = 1,42382812$

$10 \times 10 \times 10 = 1000 \; > \frac{1000}{729} = 1,37174211$

entre os números reais

$\cong \sqrt{2} = 1,414217$..

Relação direta entre os números.

$1 \rightarrow 2 \Rightarrow 8 \div 4 = 2$
$1 \rightarrow 3 \Rightarrow 27 \div 4 = 6,75$
$1 \rightarrow 4 \Rightarrow 64 \div 4 = 16$
$1 \rightarrow 5 \Rightarrow 125 \div 4 = 31,25$
$1 \rightarrow 6 \Rightarrow 216 \div 4 = 54$
$1 \rightarrow 7 \Rightarrow 343 \div 4 = 85,75$
$1 \rightarrow 8 \Rightarrow 512 \div 4 = 128$
$1 \rightarrow 9 \Rightarrow 729 \div 4 = 182,25$
$1 \rightarrow 10 \Rightarrow 1000 \div 4 = 250$

Se em vez de $4 \rightarrow 3$

$1 \times 1 \times 1 = 3$

$8 \div 3 = 2,\overline{6}$
$27 \div 3 = 9$
$64 \div 3 = 21,\overline{3}$
$125 \div 3 = 41,\overline{6}$ (41,6)
$216 \div 3 = 72$
$343 \div 3 = 114,\overline{3}$
$512 \div 3 = 170,6$
$729 \div 3 = 243$
$1000 \div 3 = 333,\overline{3}$

Voltando:

$1^3 = 4 \leftarrow \left(\frac{8}{2} = 4\right)$

$2^3 = 8 \rightarrow$ 2 é o dobro de ①

$6,75 - 2 = 4,75$
$16 - 6,75 = 9,25$
$31,25 - 16 = 15,25$
$54 - 31,25 = 22,75$
$85,75 - 54 = 31,75$
$128 - 85,75 = 42,25$
$182,25 - 128 = 54,25$
$250 - 182,25 = 67,75$

$\Downarrow$

4,75 > 4,5
9,25 > 6
15,25 > 7,5
22,75 > 9
31,75 > 10,5
42,25 > 12
54,25 > 13,5
67,75

diferenças de 1,5 em ⑴,5 N

data

$1^3=4$

$2^3=8 \rightarrow 2$ é o dobro 1 $= 8 \div 4 = 2$

$3^3=27 \rightarrow 3$ é o triplo 1 $= 27 \div 4 = 6,75$

$4^3=64 \rightarrow 4 \times 1 = 64 \div 4 =$

$5^3=175 \rightarrow 5 \times 1 = 175 \div 4 =$

$6^3=216 \rightarrow 6 \times 1 = 216 \div 4 =$

$7^3=343 \rightarrow 7 \times 1 = 343 \div 4 =$

$8^3=512 \rightarrow 8 \times 1 = 512 \div 4 =$

$9^3=729 \rightarrow 9 \times 1 = 729 \div 4 =$

$10^3=1000 \rightarrow 10 \times 1 = 1000 \div 4 =$

corrigindo

$8 \div 4$ = erro

$8 \div 2 = 4 \leftarrow (1^3)$ > 5
$27 \div 3 = 9$ > 7
$64 \div 4 = 16$ > 9
$125 \div 5 = 25$ > 11
$216 \div 6 = 36$ > 13
$343 \div 7 = 49$ > 15
$512 \div 8 = 64$ > 17
$729 \div 9 = 81$ > 19
$1000 \div 10 = 100$

outro erro!!!

Correto

O valor aumenta de 2 em 2

conjunto:

Uzando a multiplicação partindo-se do número $1^3=4$,

depois faremos $1^3=3$

2x

$1^3 = \boxed{4}$

$2^3 = \boxed{4} \times 2 = 8$

×3

$3^3 = \boxed{4} \times 3 = 12$

$4^3 = \boxed{4} \times 4 = 16$

$5^3 = \boxed{4} \times 5 = 20$

$6^3 = \boxed{4} \times 6 = 24$

$7^3 = \boxed{4} \times 7 = 28$

$8^3 = \boxed{4} \times 8 = 32$

$9^3 = \boxed{4} \times 9 = 36$

$10^3 = \boxed{4} \times 10 = 40$

mantendo-se
a proporção,
(pensamento
equivocado com
potenciação
↓
estudar!!!

mas numericamente
está correto.
(?)
checar!!!

Valores reais:

4 $8 \div 4 = 2$
8
27 $27 \div 4 = 6{,}75$
64 $64 \div 4 = 16$
125 $125 \div 4 = 31{,}25$
216 $216 \div 4 = 54$
343 $343 \div 4 = 85{,}75$
512 $512 \div 4 = 128$
729 $729 \div 4 = 182{,}25$
1000 $1000 \div 4 = 250$

discrepância.

Simulações:

$1^3 = 1 \times 1 \times 1 = 3$

$2^3 = 2 \times 2 \times 2 = 8$ $\Big\} \; 8 \div 3 = 2,\overline{6}$

$3^3 = 27 \rightarrow 27 \div 3 = 9$

$4^3 = 64 \rightarrow 64 \div 3 = 21,\overline{3}$

$5^3 = 125 \rightarrow 125 \div 3 = 41,\overline{6}$

$6^3 = 216 \rightarrow 216 \div 3 = 72$

$7^3 = 343 \rightarrow 343 \div 3 = 114,\overline{3}$

$8^3 = 512 \rightarrow 512 \div 3 = 170,\overline{6}$

$9^3 = 729 \rightarrow 729 \div 3 = 243$

$10^3 = 1000 \rightarrow 1000 \div 3 = 333,\overline{3}$

Aprofundando:

começando desde o número

$1^3 = \overset{1}{4}$

$1^3 = 4 \Rightarrow 4 \div 1 = 4$

$2^3 = 8 \Rightarrow 8 \div 2 = 4$ > $\boxed{4-4 = 0}$

$3^3 = 27 \Rightarrow 27 \div 3 = 9$ > 5

$4^3 = 64 \Rightarrow 64 \div 4 = 16$ > 7

$5^3 = 125 \Rightarrow 125 \div 5 = 25$ > 9

$6^3 = 216 \Rightarrow 216 \div 6 = 36$ > 11

$7^3 = 343 \Rightarrow 343 \div 7 = 49$ > 13

$8^3 = 512 \Rightarrow 512 \div 8 = 64$ > 15

$9^3 = 729 \Rightarrow 729 \div 9 = 81$ > 17

$10^3 = 1000 \Rightarrow 1000 \div 10 = 100$ > 19

relação direta perfeita!!! (em relação direta)

aumento de 2 em 2"

Obs:

Mantendo-se esta constante e retroagindo até o número 1,

$1^3 = 1$, pois $2^3 = 8 \div 2 = 4$

$4 - 3 = 1$

e não $1^3 = 3$ ou 4"

data

$1^3 = 3$ ou 4

$1 \times 1 \times 1 = \boxed{3}$ (3 unidades)

$\underset{(01)}{1} \quad \underbrace{\underset{(02)}{1} \quad \underset{(03)}{1}}_{3 \text{ unidades}}$

Usando da mesma lógica.

$2^3 = 8$

$\underbrace{2 \times 2 \times 2}_{3 \text{ elementos}} = 8$ (valor em unidades)

O número 2 é o dobro de 1, portanto, se $2^3 = 8$ e o número 1 é a metade de 2^3, portanto, $1^3 = \boxed{4}$

Prosseguindo (com base na razão no número real (exponenciando)

~~2~~ $3^3 = 27$

$3 \times 3 \times 3 = 27 \Rightarrow 1 = \frac{1}{3}$ de 27

$\frac{27}{3} = \boxed{9}$

$4^3 = 64 \Rightarrow 1 \Rightarrow \frac{1}{4}$ de $64 = \frac{64}{4} = \boxed{16}$

$5^3 = 75 \Rightarrow 1 = \frac{1}{5}$ de $125 = \frac{125}{5} = \boxed{25}$

$6^3 = 216 \Rightarrow 1 = \frac{1}{6}$ de $216 = \frac{216}{6} = \boxed{36}$

$7^3 = 343 \Rightarrow 1 = \frac{1}{7}$ de $343 = \frac{343}{7} = \boxed{49}$

$8^3 = 512 \Rightarrow 1 = \frac{1}{8}$ de $512 = \frac{512}{8} = \boxed{64}$

$9^3 = 729 \Rightarrow 1 = \frac{1}{9}$ de $729 = \frac{729}{8} = \boxed{81}$

$10^3 = 1000 \Rightarrow 1 = \frac{1}{10}$ de $1000 = \frac{1000}{10} = \boxed{100}$

Divisão por 4:

$1 \times 1 \times 1 = 4$

$2 \times 2 \times 2 = 8 \quad \rangle \ \frac{8}{4} = 2$ (dobro)

$3 \times 3 \times 3 = 27 \quad \rangle \ \frac{27}{8} = 3,375$

$4 \times 4 \times 4 = 64 \quad \rangle \ \frac{64}{27} = 2,\overline{370}$

$5 \times 5 \times 5 = 125 \quad \rangle \ \frac{125}{64} = 1,953125$ (1,953125)

$6 \times 6 \times 6 = 216 \quad \rangle \ \frac{216}{75} = 2,88$

$7 \times 7 \times 7 = 343 \quad \rangle \ \frac{343}{216} = 1,58796296$

$8 \times 8 \times 8 = 512 \quad \rangle \ \frac{512}{343} = 1,49271137$

$9 \times 9 \times 9 = 729 \quad \rangle \ \frac{729}{512} = 1,42382812$

$10 \times 10 \times 10 = 1000 \quad \rangle \ \frac{1000}{729} = 1,37174211$

entre os números reais

$\cong \sqrt{2} = 1,414217$..

Relação direta entre os números.

$1 \rightarrow 2 \Rightarrow 8 \div 4 = 2$
$1 \rightarrow 3 \Rightarrow 27 \div 4 = 6,75$
$1 \rightarrow 4 \Rightarrow 64 \div 4 = 16$
$1 \rightarrow 5 \Rightarrow 125 \div 4 = 31,25$
$1 \rightarrow 6 \Rightarrow 216 \div 4 = 54$
$1 \rightarrow 7 \Rightarrow 343 \div 4 = 85,75$
$1 \rightarrow 8 \Rightarrow 512 \div 4 = 128$
$1 \rightarrow 9 \Rightarrow 729 \div 4 = 182,25$
$1 \rightarrow 10 \Rightarrow 1000 \div 4 = 250$

$6,75 - 2 = 4,75$
$16 - 6,75 = 9,25$
$31,25 - 16 = 15,25$
$54 - 31,25 = 22,75$
$85,75 - 54 = 31,75$
$128 - 85,75 = 42,25$
$182,25 - 128 = 54,25$
$250 - 182,25 = 67,75$

$\Downarrow$

$4,75 > 4,5$
$9,25 > 6$
$15,25 > 7,5$
$22,75 > 9$
$31,75 > 10,5$
$42,25 > 12$
$54,25 > 13,5$
$67,75$

diferenças de 1,5 em ⓵,⓹ N

Se em vez de 4 → 3

$1 \times 1 \times 1 = 3$

$8 \div 3 = 2,\overline{6}$
$27 \div 3 = 9$
$64 \div 3 = 21,\overline{3}$
$125 \div 3 = 41,6 \quad (41,\overline{6})$
$216 \div 3 = 72$
$343 \div 3 = 114,\overline{3}$
$512 \div 3 = 170,\overline{6}$
$729 \div 3 = 243$
$1000 \div 3 = 333,\overline{3}$

Voltando:

$1^3 = 4 \leftarrow \left(\frac{8}{2} = 4\right)$

$2^3 = 8 \rightarrow 2$ é o dobro de ①

$1^3 = 4$

$2^3 = 8$ → 2 é o dobro 1 = 8 ÷ 4 = 2
$3^3 = 27$ → 3 é o triplo 1 = 27 ÷ 4 = 6,75
$4^3 = 64$ → 4 x 1 = 64 ÷ 4 =
$5^3 = 125$ → 5 x 1 = 125 ÷ 4 =
$6^3 = 216$ → 6 x 1 = 216 ÷ 4 =
$7^3 = 343$ → 7 x 1 = 343 ÷ 4 =
$8^3 = 512$ → 8 x 1 = 512 ÷ 4 =
$9^3 = 729$ → 9 x 1 = 729 ÷ 4 =
$10^3 = 1000$ → 10 x 1 = 1000 ÷ 4 =

corrigindo

8 ÷ 4 = erro

✡

8 ÷ 2 = 4 ← (1^3) > 5
27 ÷ 3 = 9 > 7
64 ÷ 4 = 16 > 9
125 ÷ 5 = 25 > 11
216 ÷ 6 = 36 > 13
343 ÷ 7 = 49 > 15
512 ÷ 8 = 64 > 17
729 ÷ 9 = 81 > 19
1000 ÷ 10 = 100

outro erro!!!

Correto

O valor aumenta de 2 em 2 ///

conjunto:

Usando a multiplicação partindo-se do número $1^3 = 4$,
depois faremos $1^3 = 3$ //

2x

$1^3 = \boxed{4}$

$2^3 = \boxed{4} \times 2 = 8$

x3

$3^3 = \boxed{4} \times 3 = 12$

$4^3 = \boxed{4} \times 4 = 16$

$5^3 = \boxed{4} \times 5 = 20$

$6^3 = \boxed{4} \times 6 = 24$

$7^3 = \boxed{4} \times 7 = 28$

$8^3 = \boxed{4} \times 8 = 32$

$9^3 = \boxed{4} \times 9 = 36$

$10^3 = \boxed{4} \times 10 = 40$

mantendo-se
a proporção,
(o pensamento
equivocado com
potenciação
estudar!!!

mas numericamente
está correto.
(?)
Checar!!!

Valores reais:

4 $8 \div 4 = 2$
8
27 $27 \div 4 = 675$
64 $64 \div 4 = 16$
125 $125 \div 4 = 31,25$
216 $216 \div 4 = 54$
343 $343 \div 4 = 85,75$
512 $512 \div 4 = 128$
729 $729 \div 4 = 182,25$
1000 $1000 \div 4 = 250$

discrepância.

Simulações:

$1^3 = 1 \times 1 \times 1 = 3$ $\rangle$ $8 \div 3 = 2,\overline{6}$

$2^3 = 2 \times 2 \times 2 = 8$

$3^3 = 27 \rightarrow 27 \div 3 = 9$

$4^3 = 64 \rightarrow 64 \div 3 = 21,\overline{3}$

$5^3 = 125 \rightarrow 125 \div 3 = 41,\overline{6}$

$6^3 = 216 \rightarrow 216 \div 3 = 72$

$7^3 = 343 \rightarrow 343 \div 3 = 114,\overline{3}$

$8^3 = 512 \rightarrow 512 \div 3 = 170,\overline{6}$

$9^3 = 729 \rightarrow 729 \div 3 = 243$

$10^3 = 1000 \rightarrow 1000 \div 3 = 333,\overline{3}$

Aprofundando:

começando desde o
número

1

$1^3 = 4$

$1^3 = 4 \Rightarrow 4 \div 1 = 4$

$4 - 4 = 0$

relação direta perfeita!!! (em relação direta)

$2^3 = 8 \Rightarrow 8 \div 2 = 4$ > 5

$3^3 = 27 \Rightarrow 27 \div 3 = 9$ > 7

$4^3 = 64 \Rightarrow 64 \div 4 = 16$ > 9

$5^3 = 125 \Rightarrow 125 \div 5 = 25$ > 11

$6^3 = 216 \Rightarrow 216 \div 6 = 36$ > 13

$7^3 = 343 \Rightarrow 343 \div 7 = 49$ > 15

$8^3 = 512 \Rightarrow 512 \div 8 = 64$ > 17

$9^3 = 729 \Rightarrow 729 \div 9 = 81$ > 19

$10^3 = 1000 \Rightarrow 1000 \div 10 = 100$

aumento de 2 em 2

Obs:

Mantendo-se esta constante e retroagindo até o número 1,

$1^3 = 1$, pois $2^3 = 8 \div 2 = 4$

$4 - 3 = 1$

e NÃO $1^3 = 3$ ou 4.

Comparando → 3 e 4

Pág. 58 (74) - between $\sqrt{8}$ and $\sqrt{10}$ for which there will be one more crossing of lines in the cross position, producing a total of eleven pieces.'

d) d) cont.

Pág. 86(102) - Figure F1.2 illustrates the method on a sheet of metal that is 3 x 4.

In this case, $x = \frac{(7-\sqrt{13})}{6} \approx 0.5657$.

The Volume is $\frac{(35+13\sqrt{13})}{27} \approx 3.0323$.

e) Recreational problems in geometric dissections how to solve...(1972).pdf

Obs.: 212 pages.

6) Geometry and Symmetry Kinsey/

a) Kinsey - Symmetry, Shape and Space...pdf

514 pages / Obs.: Livro todo!!

20220617

b) Kinsey - Topology of Surfaces (1993).pdf

Pág. 184(190) - Chapter 9 - Homotopy

"The essence of mathematics is not to make simple things complicated, but to make complicated things simple"

Gudder.

9.1. Homotopy and homology.

The euler characteristics and the homology groups cannot tell the difference between the cylinder and the Möbius band.

We are not going to try to change that situation, but rather (em vez disso) investigat what they have in common that makes them algebraically indistinguishable.

Pág. 199(205) - Chapter 10 - Miscellany.

Pág. 201(207) - (10.3) Corollary ⇙

Trace a map or picture. Crumple the copy, being careful not to tear it, and place it so that (de modo a) the crumpled copy lies on the original (encontra-se no original)
There is some point on the copy which lies directly on top of the same point of the original.

Fig. 10.2 - Crumpling a map.

This is a composition of the two continuous functions: the crumpling and projecting straight downwards.
(para baixo)

Obs.: Proof: taking a point x on the original to the point immediately below the image of x on the crumpled copy.

⇒

Pág. 206 (212) - (10.11) - Corollary.

If S^2 is divided into three closed subsets, then at least one of these subsets contains a pair of antipodal points.

(10.12) - Corollary.

At any time, there are two points directly opposite each other on the earth with exacty the same temperature and barometric pressure (or any other two continuous functions).

(10.13) - ~~Corollary.~~ Ham Sandwich Theorem.

Let A, B, and C be compact subsets of R^3. There is a plane which divides each region exactly in half (by volume).

Pág. 207 (213) - Fig. 10.8.

The diameter D_x and the plane P_t.

Pág. 208 (214) - 10.2 The Jordan Curve Theorem

We will prove the theorem for polygonal curves only. A polygonal curve is a 1-complex made up of straight edges and vertices. The following proof is adapted from Moise's Geometric Topology in Dimensions 2 and 3.

Pág. 221 (227) - Chapter 11 -
Topology and Calculus.

"So far as the theories of mathematics are about reality, they are not certain; so far they are certain, they are not about reality".
Albert Einstein.

11.1 - Vector fields and differential equations in R^n.

7) Linear Algebra Done Right, 3rd Edition/
Linear algebra done right... pdf
Obj.: Livro todo!!! 352 pages!
→ Vector spaces.

Pág. 131 (147) - Chapter 5

Eigenvalues, Eigenvectors, and Invariant Subspaces.

→ Linear maps from a finite-dimensional vector space to itself.
Their study constitutes the most important part of linear algebra.

8) "Linear Algebra Illustrated/

Pág. 207 - Theorem 3.6.7

Pythagorean theorem

$$a^2 + b^2 = c^2$$

obs: Há a prova no texto.

Pág. 209 - Theorem 3.6.12.

Distance Formula for Dimension 2

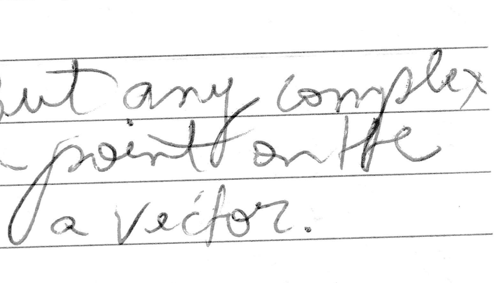
$P = (x, y)$ and $Q = (x', y')$ is

$$d(P,Q) = \sqrt{(x-x')^2 + (y-y')^2}$$

Pág. 233 - 3.10

The Complex Plane $\mathbb{C}$ is the Euclidean space R^2

$$z = a + bi.$$



Therefore, a and b are thought of as the coordinates of z as a point of the plane. But any complex numbers is not only a point on the complex plane but also a vector.

$\mathbb{C} \Longleftrightarrow R^2$ given by

$$\boxed{a+bi \leftrightarrow \langle a,b\rangle}$$

The algebra of vectors in R^2 applies!

Warning:

In spite of this fundamental correspondence, we will continue to think of complex numbers as numbers (and use the lower case letters).

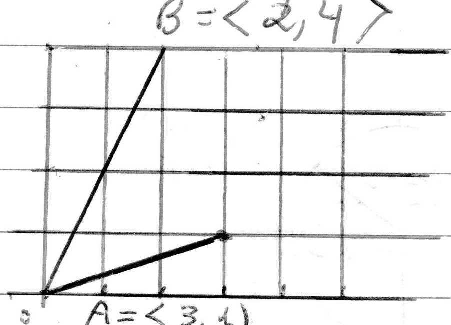
Obs: Pag. 234 → interessante !!!

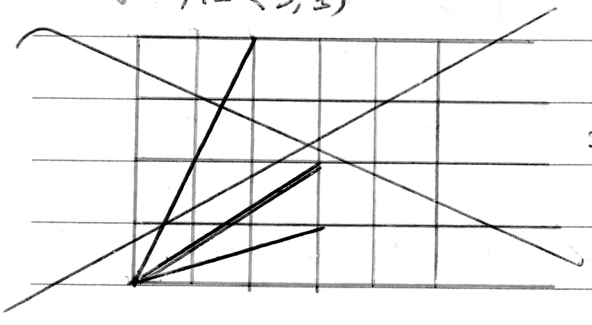
Addition of complex numbers:

$$(a+bi)+(c+di)=(a+c)+(b+d)i$$

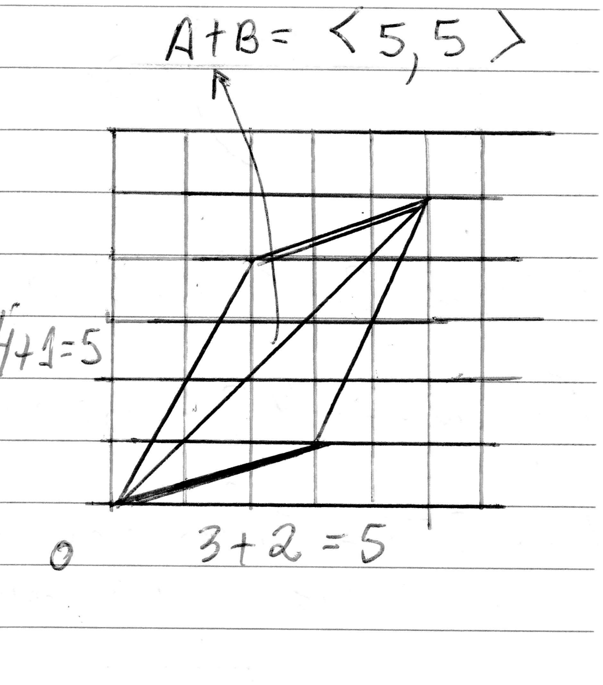
$$\langle a,b\rangle+\langle c,d\rangle=\langle a+c,\ b+d\rangle$$

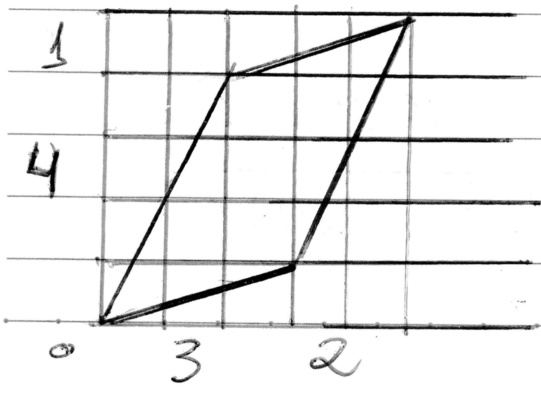
This corresponds to addition of vectors:





⇒





Second, we can easily multiply complex numbers by real ones:

$$(a+bi)\,c = (ac) + (bc)\,i,$$

$$\langle a, b \rangle\, c = \langle ac, bc \rangle.$$

It corresponds to scalar multiplication of vectors.

Warning!

Vector algebra of R^2 is complex algebra, but not vice versa. Complex multiplication is what makes it different.

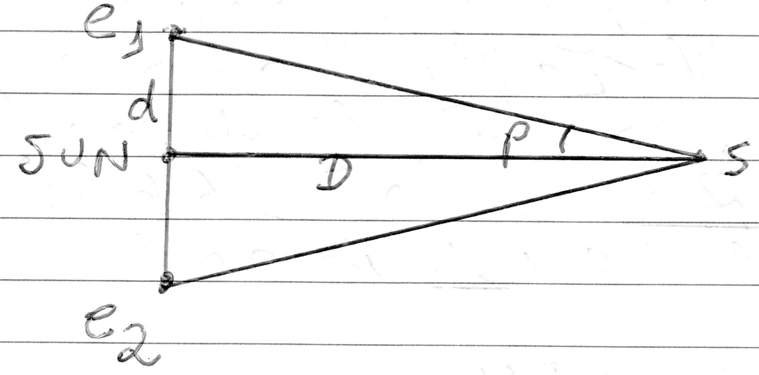
d) GCTprint.pdf
Pág 155 (165) - Parallax.

The angle p is called the parallax, and in a Euclidean universe p determines the star's distance from the Sun, D, by the equation

$$D = d/\tan(p), \text{ where}$$

d is the Earth's distance from the Sun.



We may determine p by observation and d is the radius of Earth's orbit around the Sun
(d is about 8.3 light-minutes).
In practice, p is quite small, so a working formula is $\boxed{D = \frac{d}{p}}$.

The first accurate measurement of parallax was recorded in 1837 by Friedrich Bessel (1784-1846). He found the stellar parallax of 0.3 arc seconds
(1 arc second = 1/3600°)
for star 61 Cygni which put the star at about 10.5 light-years away.

Important:

If we live in a hyperbolic universe with curvature k, a detected parallax puts a 'bound (coloca um limite) on how curved the universe can be

Consider Fig. 7.3.5, p. 156 (166).

As before, e_1 and e_2 represent the position of the Earth at opposite points of its orbit, so that the distance between them is $2d$, or about 16.6 light-minutes.

Assume star s is on the

positive real axis

and we have detected a parallax p, so that angle $\angle e_2 s e_1 = 2p$.

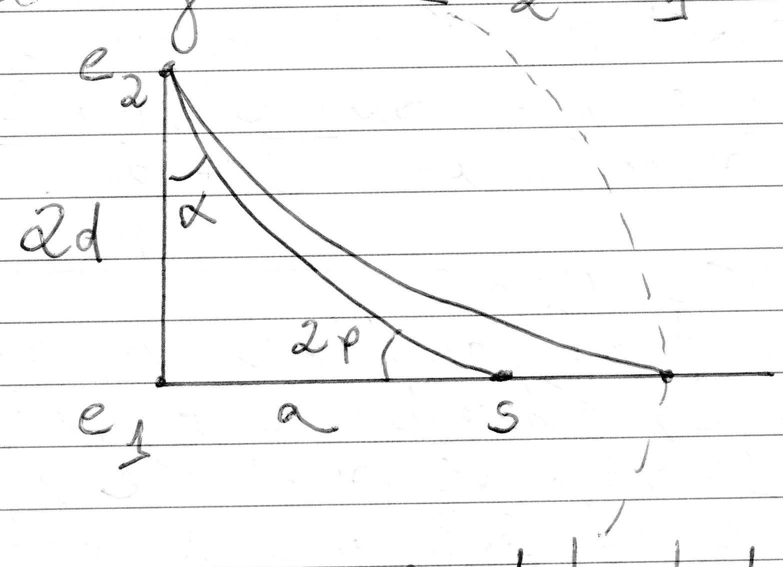


Figure 7.3.5 – A detected parallax in a hyperbolic universe puts a bound on its curvature.

The angle $\alpha = \angle e_1 e_2 s$ in figure 7.3.5, p.156(166) is less than the angle of parallelism

$$\theta = \angle e_1 e_2 u.$$

Nothing that $\tan(x)$ is an increasing function and applying Lobatchevsky's formula it follows that

$$\tan(\alpha/2) < \tan(\theta/2) =$$

$$e^{-\sqrt{|K|/2d}} \quad . \quad e^{-\sqrt{|K|}\,2d}$$

We may solve this inequality for $|K|$:

$$\tan(\alpha/2) < e^{-\sqrt{|K|}\,2d}$$

$$\ln(\tan(\alpha/2)) < -\sqrt{|K|}\,2d$$

$\ln(x)$ is increasing

$$\left[\frac{\ln(\tan(\alpha/2))}{2d}\right]^2 > |K|.$$

x^2 is decreasing for $x < 0$.

To get a bound for $|K|$ in terms of ρ, noted that $\alpha \approx \pi/2 - 2\rho$ (the triangles used in stellar parallax have no detectable angular deviation from 180°), so

$$|K| < \left[\frac{\ln(\tan(\pi/4-p))}{2d}\right]^2.$$

We remark that for values of p near 0, the repression

$\ln(\tan(\pi/4-p))$ has

linear approximation equal to $-2p$, so a writing for K, which appeared in Schwarzschild's 1900 paper

[27], is $|K| < (p/d)^2$.

Pág. 179(189) - 7.6

Geometry of Surfaces

We have seen that any surface is homeomorphic to a polygonal surface representing H_g or C_g, for some g, and we now show that each of these may be given a homogeneous, isotropic and metric geometry (so that it has constant curvature).

A polygonal surface can only run into trouble homogeneity-wise where the corners come together.

Pág. 25(41) §9 -

The Transcendence of π.

The definition of the number π is derived from Euler's formula

$$e^{x\sqrt{-1}} = \cos x + \sqrt{-1} \sin x;$$

by replacing x by π,

$$e^{\pi\sqrt{-1}} = -1 \qquad (1).$$

If π is assumed to be an algebraic number,

$\pi\sqrt{-1}$ is also an algebraic number and is the root of an irreducible (irreducible) algebraic equation $F(x)=0$ whose coefficients are integers.

Applied General Relativity...pdf

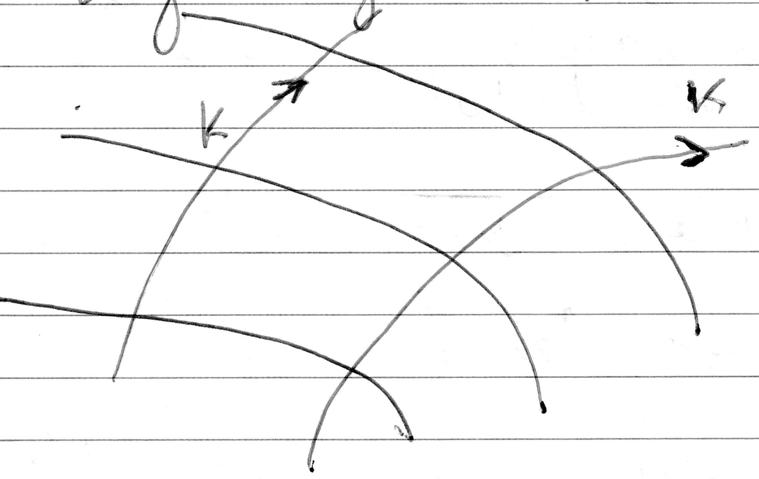
Pág. 120(137) - 4.3

The Minkowskian Metric,
Lorentz-Transformation

Pág. 121(138) -

$$K^{\mu} = (-k_0, k_i) \qquad (4.3.6)$$

Fig. 4.1 Surfaces of constant phase, light rays and wave-vectors.



Pág. 122(139) - Metric Property 1

Light-rays are curves of zero length (null-curves). In Minkowskian coordinates this simply means that

$$0 = ds^2 = -c^2 dt^2 + dx^2,$$

i.e. the speed of light c takes a constant value in every Minkowskian coordinate system.

Pág. 123 (140) – to the Pythagorean theorem we now get

$$L^2 + \left(\frac{v\,\Delta t}{2}\right)^2 = \left(\frac{c\,\Delta t}{2}\right)^2$$

from which we are

$$\Delta t = \frac{\Delta \tau}{\sqrt{1 - v^2/c^2}} \qquad (4.3.9)$$

In words: a moving clock appears to go slower.

Metric and normed linear spaces

We will be dealing with sets of functions or operators or other objects and we will often a way of measuring the distance between the objects in the sets. It is reasonable to define a notion of distance that has the most important properties of ordinary distance in $\mathbb{R}^3$.

Definition - A metric space is a set M and a real-valued function $d(\cdot,\cdot)$ on $M \times M$ which satisfies:

(i) $d(x, y) \geq 0$
(ii) $d(x, y) = 0$ if and only iff $x = y$
(iii) $d(x, y) = d(y, x)$
(iv) $d(x, z) \leq d(x, y) + d(y, z)$
[triangle inequality)

Obs.:
Triangle inequality, in Euclidean geometry, theorem that the sum of any two
(trocas de careta) ⇐
sides of a triangle is greater than or equal to the third side, in symbols,

$a + b \geq c$. In essence, the theorem states that the shortest distance between two points is a straight line.

The function d is called a metric on M.

Distance:

$d(x,y) = \sqrt{(x_1-y_1)^2 + \ldots + (x_n-y_n)^2}$

Example:

Let M be the unit circle in $\mathbb{R}^2$, that is, the set of all pairs of real numbers $\langle\alpha,\beta\rangle$ with $\alpha^2+\beta^2=1$, and let

$d_1(\langle\alpha,\beta\rangle,\langle\alpha',\beta'\rangle) = \sqrt{(\alpha-\alpha')^2+(\beta-\beta')^2}$

Another possible metric is $d_2[p,p'] =$ arc length between the points p, p'

1.1. The Lorentz Group

A point in the spacetime manifold[1] is

denoted by

$(x^\mu) = (x^0, x^1, x^2, x^3)$, where

$x^0 = t$, and x^1, x^2, x^3 are the space components of the four-vector x^μ.

This space is called Minkowski space and denoted by M4.

The laws of physics formulated in M4 are invariant under the Lorentz group.

TRANSFORMATIONS of this group are linear transformations acting on four-vectors[2].

z
P
O
y
x
z
P
θ
r
O
y
φ
x

Fig. 2.1 · Cartesian (left) and spherical (right) coordinates of a point P.

Cartesian and spherical coordinates are related by

$$X = r \sin\theta \cos\varphi$$
$$Y = r \sin\theta \sin\varphi$$
$$Z = r \cos\theta$$

Notation: Abstract notation

$$(x^i) = (x^1, x^2, x^3)$$

For example:

spherical coordinates,

$x^1 = r$, $x^2 = \theta$, and $x^3 = \varphi$.

Cartesian coordinates:

$$(X^a) = (X, Y, Z).$$

Pag. 05 (15) – 2.1.2 METRIC:

$$\boxed{r^2 = X^2 + Y^2 + Z^2}$$

→ That is to say the Pythagorean theorem of Euclidean geometry.

d_{AB} = distance between two points A, B.
(Cartesian coordinates)

$$d_{AB}^2 = (X_B - X_A)^2 + (Y_B - Y_A)^2 + (Z_B - Z_A)^2 \qquad (2.4)$$

$$= \sum_{a=1}^{3}\sum_{b=1}^{3} \delta_{ab}(X_B^a - X_A^a)(X_B^b - X_A^b) \qquad (2.5)$$

$$\equiv \delta_{ab}(X_B^a - X_A^a)(X_B^b - X_A^b) \qquad (2.6)$$

[Einstein's notation].

Obs.: where, in Eq (2.5) we introduced the Kronecker symbol

$$\delta_{ab} \equiv \begin{cases} 1 & \text{if } a = b \\ 0 & \text{if } a \neq b \end{cases} \qquad (2.7)$$

and, in Eq (2.6) we used Einstein's convention for the summation over repeated indices.

EUCLIDEAN METRIC

for non-Cartesian coordinates, one cannot directly use the expression (2.4) to calculate d_{AB}. For example, with spherical coordinates

$$d_{AB}^2 \neq (r_B - r_A)^2 + (\theta_B - \theta_A)^2 + (\varphi_B - \varphi_A)^2 ; \qquad (2.8)$$

the above expression is even dimensionally incorrect.

Distance P, P' (Cartesian coordinates)

$$X_P^a \text{ and } X_{P'}^a = X_P^a + dX^a.$$

Then, applying Eq. (2.6), we have

$$d_{PP'}^2 \equiv dl^2 = \delta_{ab}\, dX^a dX^b \qquad (2.9)$$

obs: (X^a) and (x^i) describe the same space, they are related by three functions f^a such that $X^a = f^a(x^i)$.

Example:
if (x^i) denote spherical coordinates, you have derived these functions in Exercise 1:

$$f^1(r, \theta, \varphi) = r \sin\theta \cos\varphi,$$

$$f^2(r, \theta, \varphi) = r \sin\theta \underset{\hookrightarrow \text{ no exercício é } \underline{\sin}}{\cos\varphi},$$

$$f^3(r, \theta, \varphi) = r \cos\theta$$

...

Pág. 06(16) - symmetric matrix, is called the METRIC TENSOR.

→

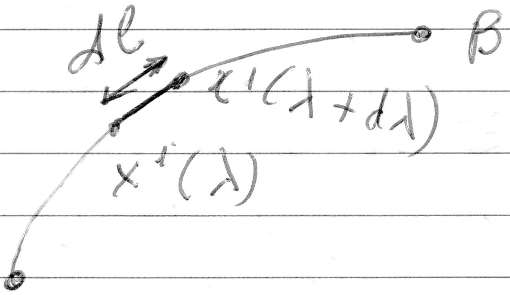
IMPORTANT:

The metric is a machine which transforms coordinates into distances.

CURVILINEAR DISTANCE

Fig. 2.2

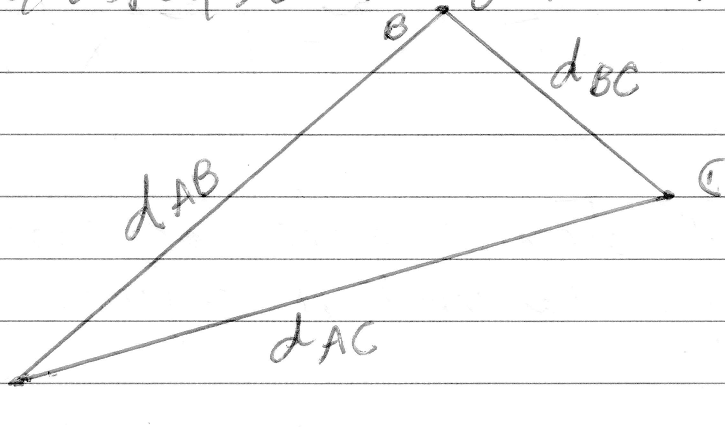
(LEFT)



dl
B
$x^i(\lambda + d\lambda)$
$x^i(\lambda)$
A

Parametrised curve between A and B.

(RIGHT)



B
d_{BC}
C
d_{AB}
d_{AC}
A

Angles and distances.

(LEFT) → This curve can be parametrised by three functions $x^i(\lambda)$, where

λ is an arbitrary parameter which allows one to move along the curve, assumed to be strictly increasing from λ_A to λ_B on the way from A to B.

→

The length of the curve is obtained by summing the lengths of every infinitesimal step from A to B, that is

$$l_{AB} = \int_A^B dl = \int_A^B \sqrt{e_{ij}\, dx^i dx^j} =$$

$$\int_{\lambda_A}^{\lambda_B} \sqrt{e_{ij} \frac{dx^i}{d\lambda} \frac{dx^j}{d\lambda}}\, d\lambda \quad (2.14).$$

curve → is called a geodesic.
In Euclidean geometry and in the absence of constraints, it is simply a straight line; on the surface of a sphere, it is a great circle.

Pág. 39(49) - 3.1.2

Minkowski Metric and Four-Vectors

$$(x^\mu) \equiv (x^0, x^1, x^2, x^3).$$

$$X^\alpha \longrightarrow x^\mu$$

$$X^\alpha + dX^\alpha \longrightarrow x^\mu + dx^\mu.$$

The space-time interval between those events can then be written as

→

$$\boxed{ds^2 = \eta_{\alpha\beta}\, dX^\alpha dX^\beta = f_{\mu\nu}\, dx^\mu dx^\nu,} \quad (3.6)$$

where we introduced the

MINKOWSKI METRIC f (flat), with components

$$f_{\mu\nu} = \eta_{\alpha\beta} \frac{\partial X^\alpha}{\partial x^\mu} \frac{\partial X^\beta}{\partial x^\nu} \quad (3.7)$$

in arbitrary coordinates (x^μ), which can be seen as a four-dimensional extension of the Euclidean metric.

Pag. 40 (50) Exercise 1

Consider the transformation

$$(X^\alpha) \to (x^\mu) = (ct, r, \theta, \varphi),$$

$$T = t \quad (3.8)$$

$$X = r \sin\theta \cos(\varphi - \Omega t) \quad (3.9)$$

$$Y = r \sin\theta \sin(\varphi - \Omega t) \quad (3.10)$$

$$Z = r \cos\theta$$

where Ω is a constant

Pág. 141(154) — Explanation 3.3
Path of light in a gravitational field.

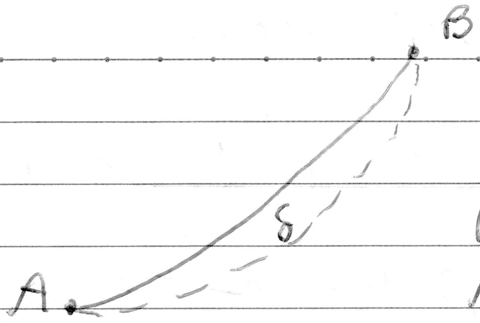

Fig. E3.3 →

Path of light passing A to B in a gravitational field

(the broken line is the new path with variation δ).

According to Fermat's principle, the path of light passing from A to B, as shown in Fig. 3.3, is the path that requires the minimum time to navigate.

This path is given by the light path decided by the solution of the

EULER EQUATION

derived from the variational principle minimizing the sum of time

$d\sigma / w$

for the propagating spatial segment $d\sigma$.

Because the Euler equation contains the gradient of the gravitational scalar potential the light path depends on gravitation, that is,

through (no entanto) the light path
is a linear line when there is no
gravitation, when there is gravitation,
the light path is not a linear but
results in the

"phenomenon of bending of light due to
gravitation".

Einstein expressed the bending angle of
light passing near the SUN as

$4kM/(c^2 r_m)$, where

k is the universal gravitational
constant,

M is the mass of the SUN,

c is the velocity of light, and

r_m is the radius of the SUN.

Obs.: From this, he predicted that
the bending angle is 1.7"

(Møller, Nagata & Ito, 1959).

Pag. 308 (326) – 117.

Propagation of light in a static gravitational field. Fermat's principle.

Pag. 309 (327) –

According to (17) this term is equal to $(1/u'^4)\,G$, where G is the gravitational force on a unit mass, thus the light ray will be

STRAIGHTEST LINE

only if the gravitational force K is zero.

Fermat's principle of least time thus holds in every static gravitational field.

Pag. 312 (328) – 310 (328)

Chapter XI – the Fundamental Laws of Gravitation in the General theory of Relativity.

The most important problem in gravitational theory, which consists in finding the general equations determining the gravitational field variables (γ_{ik}, γ_i, χ) or the g_{ik} from a given distribution of mass.

↳ Einstein in 1915 - solution

In Newton's theory of gravitation, the corresponding problem may be stated in the form of Poisson's equation

$$\Delta \chi = 4\pi K \mathring{\mu} \qquad (1)$$

where $K = 6.664 \times 10^{-8}\ cm^3\ gm^{-1}\ sec^{-2}$ (2) is the gravitational constant.

This equation enables us to calculate the gravitational potential χ when the mass density $\mathring{\mu}$ is given as a function of the space coordinates.

Pág. 300 (302) - In view of the incompatibility of

Newton's law with the observed uniform distribution of matter, Neumann and Seeliger in 1896 suggested a slight modification of the law ~~the~~ of gravitation, which would have for effect to render a uniform distribution possible.

The equivalent of

POISSON'S EQUATION

when the Neumann-Seeliger law is used, is

$$\Delta \phi - \lambda \phi = 4 \pi k \mu,$$

where λ is a positive constant, which may be as small as we choose.

Assuming the density μ to be constant, this modified law, contrary to Poisson's, is compatible with the constancy of the potential, and so is compatible with a

Pag. 23(45) - π

π lies between $\frac{223}{71}$ and $\frac{22}{7}$

"... In the Quadrature of the Parabola, which contains 24 propositions it is show that the area of a parabolic segment is $\frac{4}{3}$ that of the inscribe triangle having the same base and having its opposite vertex at the point where the tangent is parallel to the base.
The summation of a convergent geometric series is involved.

"... One Arabian writer claims that Archimedes was the discoverer of the celebrated formula

$\Rightarrow$ ~~$K = \sqrt{s(s-a}$~~ $\boxed{K = \sqrt{s(s-a)(s-b)(s-c)}}$

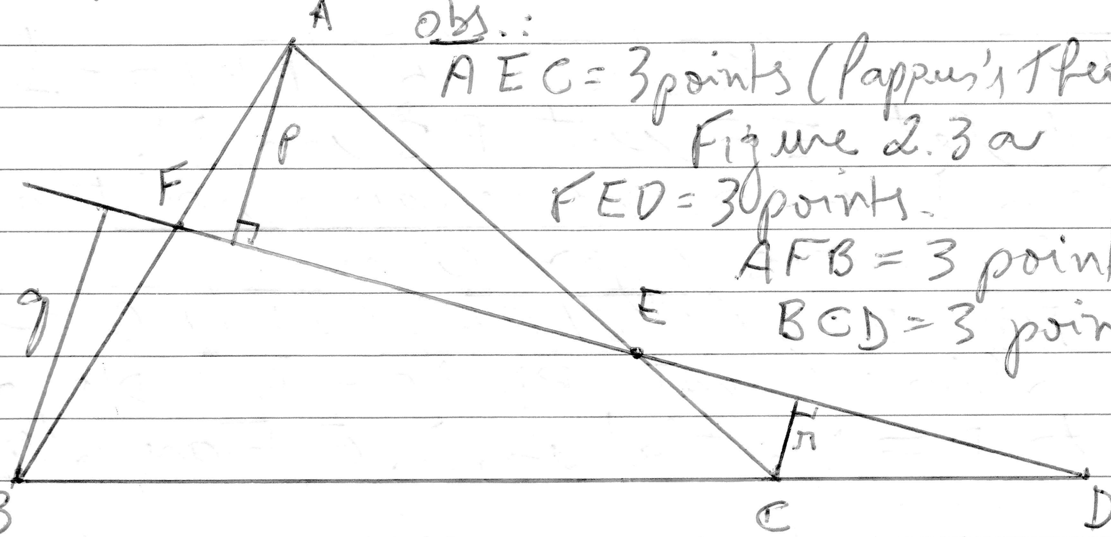
for the area of a triangle in terms of its three sides. This formula is found in a latter work of Heron of Alexandria.

Pág. 64 (86) - 2.3.2

Menelau's Theorem. A necessary and sufficient condition for three menelaus points D, E, F for the sides BC, CA, AB of an ordinary triangle ABC to be collinear is that

$$(\overline{BD}/\overline{DC})(\overline{CE}/\overline{EA})(\overline{AF}/\overline{FB}) = -1.$$

Necessity. Suppose (see Figure 2.3a) D, E, F are collinear on a line l ⇙



obs.:
AEC = 3 points (Pappus's Theorem)
Figure 2.3a Ⓐ
FED = 3 points.
AFB = 3 points.
BCD = 3 points.

which is not the line at infinity. Drop perpendiculars p, q, r on l from A, B, C. Then, disregarding signs,

$$BD/DC = q/r, \quad CE/EA = r/p,$$

$$AF/FB = p/q.$$

⇒

It follows that

$$(\overline{BD}/\overline{DC})(\overline{CE}/\overline{EA})(\overline{AF}/\overline{FB}) = \pm 1.$$

Since (uma vez que), however (porém), l must cut one or all three sides externally, we see that we can have only the − sign.

If l is the line at infinity, the proof is simple.

Sufficiency. Suppose

$$(\overline{BD}/\overline{DC})(\overline{CE}/\overline{EA})(\overline{AF}/\overline{FB}) = -1$$

and let EF cut BC in D'. Then D' is a Menelaus point and, by the above (por cima)

$$(\overline{BD'}/\overline{D'C})(\overline{CE}/\overline{EA})(\overline{AF}/\overline{FB}) = -1.$$

It follows that $\overline{BD}/\overline{DC} = \overline{BD'}/\overline{D'C}$, or that $D \equiv D'$. That is, D, E, F are collinear.

many gravitational phenomena (like the bending of light rays near a massive body), usually described in terms of the curved (Riemannian) structure of space-time, can be treated by considering (in an Euclidean space) the vacuum as a polarizable medium endowed with an effective refraction index (see (3.72)), in which light propagates [16, 29].

⟶ [16] [29] } à frente

IMPORTANT:

Pág. 37(56) – In the case of an isotropic 3D space (i.e., $b_1^2(E) = b_2^2(E) = b_3^2(E) \equiv b^2(E)$) the corresponding deformed metric is given by (2.14), (2.19) and one gets, for any component of u:

$$u = \frac{b_0(E)}{b(E)}\, c. \qquad (3.70)$$

Cf.: Complemento (2.14) ↙

Pág. 13(32) – The orthogonality of the coordinates axes is of course expressed by

$\widehat{x^{\mu}_{SR}} \cdot \widehat{x^{\nu}_{SR}} = \delta^{\mu\nu}$ and

$$\hat{x}^{\mu}_{DSR}(\{\mathcal{O}\}) * \hat{x}^{\nu}_{DSR}(\{\mathcal{O}\}) = \delta^{\mu\nu}.$$

It follows by the earlier relation that the unit vectors in the standard Minkowski space M and in the deformed one $\tilde{M}(\{\mathcal{O}\})$ are proportional, and therefore they specify the same directions in either space (qualquer spaço) (this is due of the

METRIC TENSOR,

while destroying its isochrony and spatial isotropy).

However, since coordinate unit vector is rescaled by a different coefficient in the metric deformation, vectors with the same components in the spaces M and $\tilde{M}(\{\mathcal{O}\})$ are not parallel to each other.

...

Pag. 14(33) – equation (2.14)

Isotropic 3D Space

$$b_1^2(\{\mathcal{O}\}) = b_2^2(\{\mathcal{O}\}) = b_3^2(\{\mathcal{O}\}) \equiv b^2(\{\mathcal{O}\}), \quad (2.13)$$

Corresponding deformed metric ~~field~~ reads:

$$g_{\mu\nu}[\delta_{\mu 0} b^2(\{0\}) -$$

$$(\delta_{\mu 1} + \delta_{\mu 1} + \delta_{\mu 1}) b^2(\{0\})]. \quad (2.14)$$

……

pág. 15(34)

Therefore, the energy-dependent deformation of the MINKOWSKI METRIC implements a generalization of the concept of geometrization of an interaction (in accordance with Finzi's principle).

The GR theory implements a geometrization (at a global scale) of the gravitational ~~inter~~ interaction, based on its derivability from a potential and on the equivalence between the inertial mass of a body and its

"gravitational charge".

Obs: Esta página aborda:
- gravitational
- electromagnetic,
- strong
- weak.

Pág. 16 (35) - (2.19) equation

1. A space $\tilde{M}$ spatially isotropic:

$b_1(E) = b_2(E) = b_3(E) = b(E)$ (2.19)

2. A space $\tilde{M}$ locally conform with the MINKOWSKI space M:

$b_0(E) = b_1(E) = b_2(E) = b_3(E) = b(E)$ (2.20)

this is a particular case of the

MIRON-TAVAKOL METRIC [13]
which satisfies the

Ehlers-Pirani-Schild axiomatics.

Pág. 06(18) - 6 - The Fire Element.

We know that the geometry on the surface of a sphere is Riemannian.
Consider a point P on the surface of a sphere of unit radius (Figure 1a). Its position is given by two polar coordinates
(θ, φ), θ being the colatitude
($\angle NOP$) and φ the longitude
($\varphi = \angle XOP$).

Obs.: COLATITUDE →

A colatitude é utilizada em

astronomia porque se refere à distância zenital dos polos celestes.

↳ Sistema de Coordenadas Celestes.

Uma coordenada mede a posição do astro nesse círculo máximo, e a segunda, perpendicular mede a distância do astro a esse plano.

Paralaxe — a posição de uma estrela é medida 2 vezes em momentos diferentes, pois a Terra está em outra posição. Desta forma, através da observação da estrela nas posições A e B, os astrônomos são capazes de medir o ângulo e com isto, determinado a distância da estrela com o uso deste ângulo e a trigonometria.

Paralaxe heliocêntrica ou anual → é definida com a diferença de posição de uma estrela com vista da Terra e do Sol. Como não podemos ver a estrela do Sol, a observação é feita entre dois pontos opostos da órbita da Terra e o resultado dividido por 2 (dois).

O parsec é a distância para a qual a paralaxe anual é de um segundo de arco ou arcseg. Um parsec é igual a 3,26 anos-luz.

Para cálculo do Parsec utilizamos a translação da Terra em volta do Sol, cujo raio é de 1 AU (Unidade Astronômica).

Portanto, um parsec é a distância do Sol a um objeto astronômico que tem um ângulo de paralaxe de um segundo de arco.

Em agosto de 2015, a IAU (União Astronômica Internacional) aprovou a resolução B2 que, como parte da definição de uma escala de

MAGNITUDE BOLOMÉTRICA ABSOLUTA

e aparentemente padronizada, mencionou uma definição explícita existente do parsec como exatamente

$$\boxed{\frac{648000}{\pi}\ \text{au}}$$, ou aproximadamente

3.0856775814913673 x 10^{16} metros (com base na definição exata do SI da IAU de 2012 da unidade astronômica).

Calculando o valor de um parsec

1 au = 149 597 870 700 m
(exatamente pela definição de 2012 do au)

Definição de 2015:

1 au de comprimento de arco subtende um ângulo de 1" no centro do círculo de raio de 1 pc.
Ou seja, $1\ pc = \dfrac{au}{\tan(1'')} \cong$
206,264.8 au por definição.(9)

(9) Source:

Books-013-2022/20220629/
To the Sun and Beyond/
s41567-019-0685-3.pdf
→ 1 page
Copy: ARQ/GGB-Geogebra-2022/
20220629/
To the Sun and Beyond/

Conversão de unidades de graus/minuto/segundo em radianos,

$$\frac{1\ pc}{1\ au} = \frac{180 \times 60 \times 60}{\pi}, \text{ e}$$

1 au = 149597480 000 m
(def. de 2012)

Portanto,

π pc = 180 × 60 × 60 au =

180 × 60 × 60 × 149 597 870 700 =

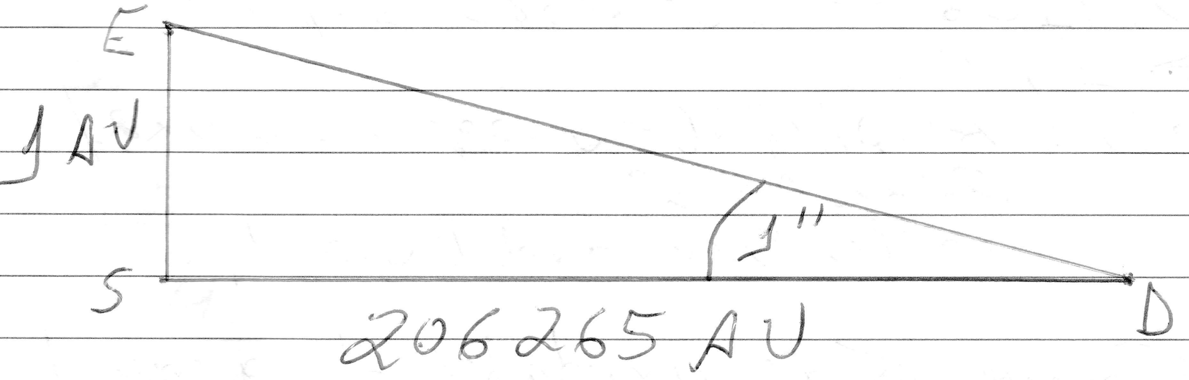
96 939 420 213 600 000 m
(exatamente pela definição de 2015)

Portanto,

$$1 \text{ pc} = \frac{96939420213600000}{\pi}$$

$\cong$ 30 856 775 814 913 673 m
(para o metro mais próximo)

Aproximadamente,



S representa o Sol
E a Terra em um ponto de sua órbita
ES = 1 AU

→

O ângulo SDE é de um segundo de arco ($\frac{1}{3600}$ de um grau), então, por definição, D é um ponto no espaço a uma distância de um parsec do Sol.

Por meio da trigonometria, a distância SD é calculada da seguinte forma:

$$SD = \frac{ES}{\tan 1''}$$

$$SD \approx \frac{ES}{1''} = \frac{1\ \text{au}}{\frac{1}{60\times60}\times\frac{\pi}{180}} = \frac{648000}{\pi}\ \text{au}$$

≈ 206241.81 a u.

obs.: 1 pc ≈ 3.261563777 ly
(light-years)

Um corolário afirma que um parsec é também a distância a partir da qual um disco de uma unidade astronômica de diâmetro (penso de raio) (→ conforme desenho anterior) deve ser visto para ter um diâmetro angular de um segundo de arco.

Matematicamente, para calcular a distância, dada as medidas angulares obtidas a partir de instrumentos em segundos de arco, a fórmula seria:

$$\text{Distância}_{\text{estrela}} = \frac{\text{Distância}_{\text{Terra-Sol}}}{\tan \frac{\theta}{3600}}$$

θ é o ângulo medido em segundos de arco.
Distância Terra-Sol é uma constante (1 au ou 1.5813×10^{-5} ly).

A distância estelar calculada estará na mesma unidade de medida usada em Distância Terra-Sol.

Obs: Parsec $\frac{648000}{\pi}$ au

Este valor difere da definição clássica de tangente inversa em cerca de 200 km, ou seja, somente após o 11° algarismo significativo.

Complementando:

Magnitude Absoluta - Magnitude Bolométrica

⟹

Magnitude Absoluta →
é a medida de brilho intrínseco de um objeto celeste.
É a magnitude aparente hipotética do objeto a uma distância padrão de exatamente 10 parsecs (32,6 anos-luz) do observador, assumindo-se nenhuma extinção astronômica da luz da estrela.

Magnitude Bolométrica →

Mbol leva em consideração a radiação eletromagnética em todos os comprimentos de ondas.

Voltando: COLATITUDE

A colatitude é utilizada em astronomia porque se refere à distância zenital dos polos celestes.
Por exemplo para um observador localizado sobre a Terra em um ponto de latitude 42°N, o arco esférico entre a estrela Polar (aproximadamente situada sobre o polo Norte celeste) e o Zênite (ponto imaginário acima da cabeça do observador) é de
90 - 42 = 48°.

Projetando-se o zênute (zênite) do observador sobre a esfera celeste, a sua colatitude é de 48°.

Adicionando a declinação de uma estrela

obs.: declinação (δ) de um astro é o arco do meridiano do astro compreendido entre o plano do equador celeste e o astro.
→ latitude.

Adicionando a declinação de uma estrela à colatitude do observador obtém-se a máxima latitude desta estrela
(seu ângulo do horizonte à culminação ou trânsito superior)
Por exemplo, se Alfa Centauri é vista com uma latitude de 72° norte (108° Sul) e sua declinação é conhecida (60° S), então pode-se determinar que a colatitude do observador é
108 − 60 = 48
(i.e. sua latitude é 90 − 48 = 42° S

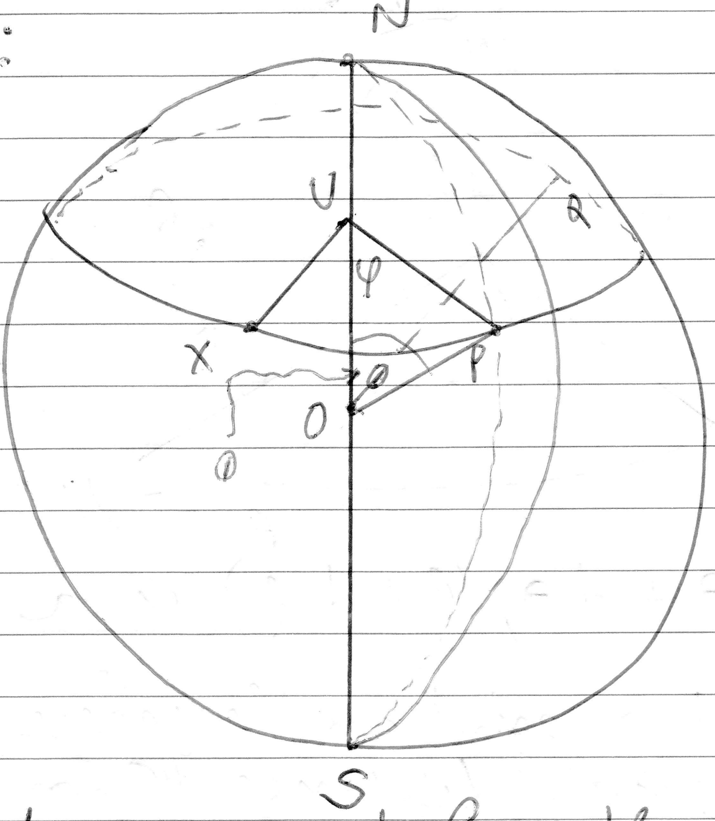
IMPORT: Usar bending of light rays.



geometry on the surface of a sphere is Riemannian.

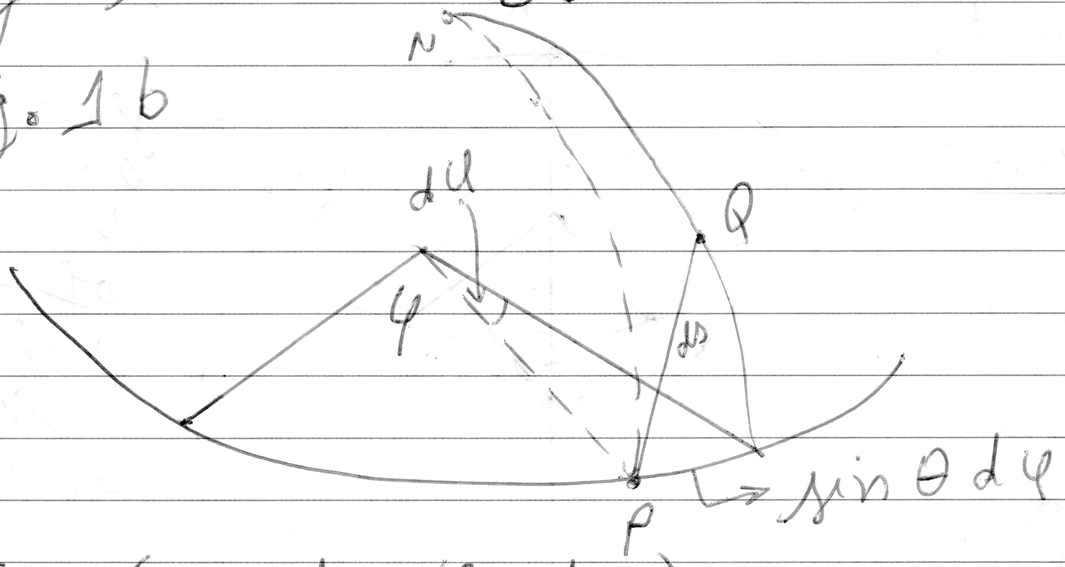
Consider a point P on the surface of a sphere of unit radius. Its position is given by two angular coordinates (θ, φ),

θ being the colatitude ($\angle NOP$) and φ the longitude ($\varphi = \angle XUP$).

If θ is constant and φ varies from 0 to 2π, the point P moves along the small circle of radius $\sin\theta$.

If φ is constant and θ varies from from 0 to π (90°),
the point P moves along the meridiano large circle NPS.

Fig. 1b



If $Q(\theta + d\theta, \varphi + d\varphi)$ is a neighbouring point on the sphere at an infinitesimal distance from P (Figure 1b) then

$$ds^2 = d\theta^2 + \sin^2\theta\, d\varphi^2 \qquad (1).$$

It is customary to regard relations like (1) as defining a line element.

Formula (1) is the line element on the surface of a sphere or a line element of a two-dimensional Riemannian space.

If, however, we were considering two neighbouring points on a plane with coordinates (x, y),

$(x + dx, y + dy)$,

the line element would be

$$\boxed{ds^2 = dx^2 + dy^2.} \qquad (2)$$

↳ Equation (2) is a line element of a two-dimensional Euclidean space.

Pág. 08 (20) - Riemannian spacetime

$(x^1 + dx^1, x^2 + dx^2, x^3 + dx^3, x^4 + dx^4)$

We take the line element as a quadratic in dx^1, dx^2, dx^3, dx^4.

$$ds^2 = g_{11}(dx^1)^2 + 2g_{12}(dx^1)(dx^2) +$$
$$2g_{13}(dx^1)(dx^3) + 2g_{14}(dx^1)(dx^4) +$$
$$g_{22}(dx^2)^2 + 2g_{23}(dx^2)(dx^3) +$$
$$2g_{24}(dx^2)(dx^4) + g_{33}(dx^3)^2 +$$
$$2g_{34}(dx^3)(dx^4) + g_{44}(dx^4)^2$$

or we may write it as

⇒

$$ds^2 = \sum_{i=1}^{4} \sum_{k=1}^{4} g_{ik}\, dx^i dx^k ,$$

where
g_{ik} are 10 functions of "position",
i.e. of the four variables x^1, x^2, x^3, x^4,
symmetric in i and

k, $g_{ik} = g_{ki}$.

→ Vector-valued Distance and Gyrocalculus on the Space of Symmetric Positive Definite Matrices.

Pág. 02 – 3 – The Space SPDn.

The space SPD_n is a Riemannian manifold of non-positive curvature of $\boxed{\underbrace{n(n+1)/2}}$ dimensions.

Points in SPDn are positive definite real symmetric n x n matrices, with the identity matrix I being a natural basepoint.

The tangent space to any point of SPD_n can be identified with the vector spaces S_n of real symmetric n x n matrices.

SPD_n contains n-dimensional

Euclidean subspaces, (n-1)-dimensional hyperbolic subspaces as well as products of $\left[\frac{n}{2}\right]$ hyperbolic planes.

Verdade Matemática.

As afirmações matemáticas que sabemos demonstrar serem verdade recebem o nome de teorema.

São verdades incondicionais e eternas.

Importante. Trata-se de uma prerrogativa existente somente na matemática.

Verdade: (?) → até agora.

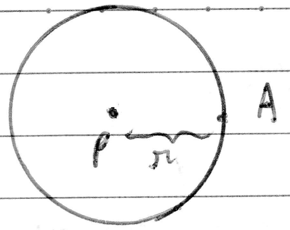
Dada uma circunferência qualquer, a razão entre o seu perímetro e o seu diâmetro é π.

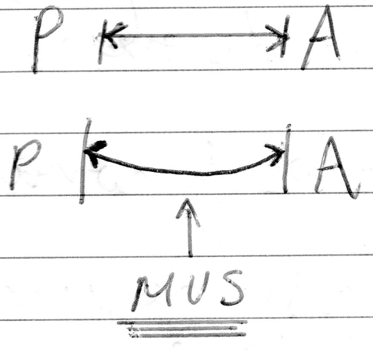
Matemática → Circunferência Ideal.
(abstrato)

Circunferência é um objeto matemático.

Os teoremas sobre circunferências valem para a circunferência matemática que é bem definida.

Definição: Uma circunferência de centro P e raio r é o conjunto de pontos que distam r do ponto P.





(ideal)

(real)

A circunferência matemática é perfeita (e abstrata).

Definições:

Em uma nova teoria defina todos os termos que você irá utilizar. (important)

Todo número inteiro, par, maior ou igual a 4, é a soma de dois números primos.

Conjunto dos números naturais (ou inteiros não-negativos)

$\mathbb{N} = \{0, 1, 2, 3, \dots\}$

↳ é um número natural.

0 é divisor de algum número inteiro?

Segundo a definição, para que 0 divida um inteiro b, é preciso existir um número inteiro x tal que $0 . x = b$.

↳ tem que ser 0 (zero)

Obs.:
x pode ser qualquer inteiro.

0 é divisor de 0 e também é verdade que o único inteiro que 0 divide é ele próprio.

Outras definições:

Definição 2 → Um inteiro a é par se $2|a$.

Definição 3 → Um inteiro a é ímpar se existe um inteiro k tal que

$a = 2.k + 1$.

Definição 4 → Um inteiro p é primo se $p > 1$ e se os únicos divisores positivos de p são 1 e p.
Obs.: 1 não é primo.

Afirmações:

- A soma de dois inteiros pares é um inteiro par.

- Se o produto de dois inteiros a e b for par, então a é par ou b é par.
  ↳ pode ser um número ou os dois.

F Se a e b são inteiros tais que $a|b$ e $b|a$ então $a = b$. (transitiva)
↳ Falsa. Prova da falsidade: $a = 2$ e $b = -2$.

- Todo número inteiro par, maior ou igual a 4, é a soma de dois números primos.

Obs: Foi testado por computador até

$$n \leq 4 . 10^{18}.$$

Todos os inteiros pares entre

4 e $4 . 10^{18}$ eram somas de dois primos.

Na verdade, não se sabe se é verdadeira ou falsa.
⇒ conjectura.

A soma de dois inteiros pares é um inteiro par ⇒ é um teorema
(afirmação verdadeira).

Se o produto de dois inteiros a e b foi par, então a é par ou b é par.
→ é um teorema (afirmação verdadeira).

Todo número inteiro par, maior ou igual a 4, é a soma de dois números primos
→ é uma conjectura, conhecida como Conjectura de Goldbach (1742).

Euclides (300 A.C.) fez uma demonstração de que existem infinitos números primos.
Considerada um belo exemplo de raciocínio lógico.

$$MUS(\pi) = \underset{\substack{\downarrow \\ \text{matemático} \\ \text{(conceito)}}}{\pi} \cdot \underbrace{G_L \cdot G_U}_{\underbrace{\text{bending of the light}}_{\text{real}}}$$

Obs: Importantíssimo!!!

"G_L" = Gravidade Local (Terra)

"G_U" = Gravidade do Universo (Universo)

$$MUS(\pi) = \pi \cdot GL \cdot GU$$

$\pi \downarrow$ conceito matemático

$GL \downarrow$ Gravidade Local

$GU \downarrow$ Gravidade Universo.

Three Fundamental Forces

1) Electromagnetism
2) Strong Nuclear Force
3) Weak Nuclear Force

$$GL = \underbrace{E + SNF + WNF}_{\text{Bending of light}}$$

$$GU = \text{Gauss's Curvature}\ (\text{Universe})(E + SNF + WNF)$$

Obs: GL and GU → são efeitos destas 3 forças fundamentais.

Important: π é uma constante fixa estipulada por cálculos

matemáticos que demonstrem que
este coeficiente não seja transcendental.

Ex.:

$3,14$

Podendo ser:

$3,13 \leq x \leq 3,14$

Obs.:

Certo dizer que o valor é menor que 3,14, pois temos os outros fatores como

GL e GU como elementos, fatores que alteram o π conceitual.

$3,14 \cdot 0,\dots \cdot 0,\dots =$

o resultado é obviamente menor.

Portanto: Teremos

$\Pi_L = \pi \cdot GL$

$\Pi_U = \pi \cdot GL \cdot GU$

GU interfere também GL (local)

ou mais precisamente:

$\Pi_L = \pi \cdot F_L$ Obs.: $F_L = TFF_L$ (Three Fund. Forces)

$\Pi_U = \pi \cdot F_L + F_U$ obs.: $F_U = TFF_U$ (Three Fund. Forces Universe)

(FL)

$$F_L = TFF_L = E_L + SNF_L + WNF_L$$

$$F_U = TFF_U = E_U + SNF_U + WNF_U$$

Important:

$$\Pi_L = \Pi \cdot F_L \cdot \underbrace{F_U}_{\text{valor menor}}$$

$$\Pi_U = \tilde{\Pi} \cdot F_L \cdot \underset{\sim}{F_U}$$

Valor maior pois abrange o Universo como um todo.
(Gauss's curvature)

Poderíamos dizer que o F_U localmente é pequeno, mas não pode ser desprezado.

Assim:

$$\tilde{\Pi} = \underbrace{\underbrace{\tilde{\Pi} \cdot F_L}_{\text{LOCAL}} \cdot F_U}_{\text{Universal.}}$$

$$\Big\downarrow$$

$$\Pi < \tilde{\Pi}.$$

GCTprint.pdf (001---GCTprint.pdf)

Pág. 154 (164) - Figure 7.3.2.

The angle of parallelism θ of a point z to a line L.

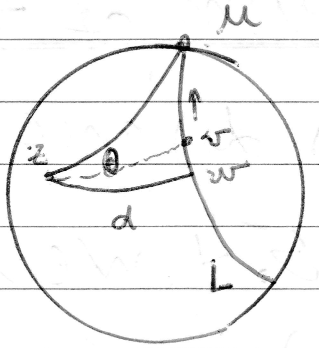

Figure 7.3.2.

Observing negative curvature:

Suppose we are located at a point z in a hyperbolic universe with curvature K.
We see in the distance a hyperbolic line L that seems to extend indefinitely.
We might intuitively see the point w (w)

on the line that is closest to us, as suggested in Figure 7.3.2, p. 154.

Now suppose we look down the road a bit to a point v.

If v is close to w the angle $\angle wzv$ will be close to 0.

As v gets further and further away from w, the angle will grow, getting closer and closer to the angle $\theta = \angle wzu$, where u is an ideal point of the line L.

→ A curious fact about hyperbolic geometry is that this angle θ, which is called the

angle of parallelism of z to L,

is a function of z's distance d to L.

Obs.: In Section 5.4 we saw that $\cosh(d) = 1/\sin\theta)$ in $(\mathbb{D}, \mathcal{H})$.

Section 5.4 - Area and Triangle Trigonometry

→ Pág. 100 (110)

Análise: Pág. 103 (113) →

Theorem 5.4.9

The area of a hyperbolic triangle in $(\mathbb{D}, \mathcal{H})$ having interior angles α, β, and γ is

$$A = \pi - (\alpha + \beta + \gamma).$$

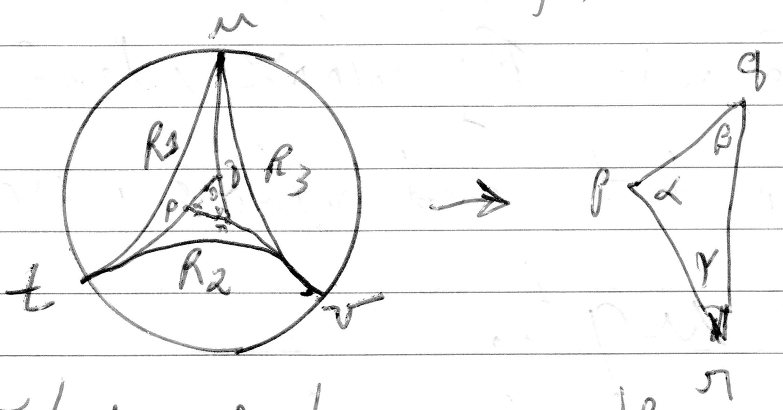

Figure 5.4.10. Determining the area of a hyperbolic triangle.)

Obs: IMPORTANT:

A área está errada, pois o π is wrong.

Vejamos: Δpqr

We have extended segment qp to the ideal point t, u is an ideal point of line rq, and v is an ideal point of line pr. The area of the ideal triangle Δtuv is π.

→ wrong!!!

(continuando o estudo). →

Notice that regions R_1, R_2, and R_3 are all $\frac{2}{3}$ - ideal triangles contained within the ideal triangle.

Consider R_1, whose ideal points are u and t, and whose interior angle is $\angle uqt$.

Since the line through q and r has ideal point u, the interior angle of R_1 is

$\angle uqt = \pi - \beta$.

Similarly, R_2 has interior angle $\pi - \alpha$ and

R_3 has interior angle $\pi - \gamma$.

Let R denote the triangle region Δpqr whose area $A(R)$ we want to compute.

Vejamos:

We then have the following relationships among areas:

$$\pi = A(R) + A(R_1) + A(R_2) + A(R_3)$$

$$= A(R) + [\pi - (\pi - \beta)] + [\pi - (\pi - \alpha)] + [\pi - (\pi - \gamma)].$$

Solving for $A(R)$,

$$A(R) = \pi - (\alpha + \beta + \gamma),$$

and this completes the proof.

Voltando:

Pág. 154(164) –

$$\cosh(d) = 1/\sin(\theta) \text{ in } (\mathbb{D}, \mathcal{H}_L).$$

In particular, one may deduce the distance d to the line L by computing θ.

Obs: In a Euclidean geometry, if one looks farther and farther down (mais para baixo) the line L, the angle will approach 90°, no matter one's distance d from the line.

The following theorem provides another formula relating the angle of parallelism to a point's distance to a line.

Theorem 7.3.3

Lobatchevsky's formula

In hyperbolic geometry with curvature k, the hyperbolic distance d of a point z to a hyperbolic line L is related to the angle of parallelism θ by the formula

$$\tan(\theta/2) = e^{-\sqrt{|k|}\,d}.$$

IMPORTANT:

⇘ A prova deste teorema deverá ser adequada à nova geometria baseada III (M.U.S.).

PROOF: For this proof, let

$$s = \frac{1}{\sqrt{|k|}}.$$

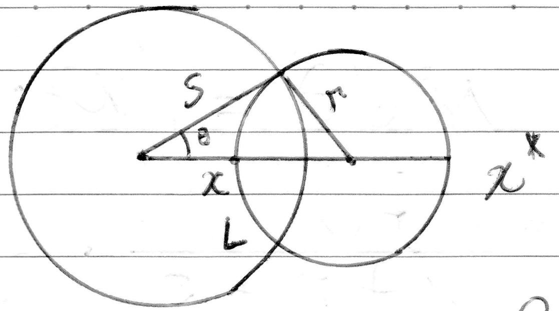

Figure 7.3.4 Deriving Lobatchevsky's formula.

Note that s is the Euclidean radius of the circle at infinite (infinite) in the disk model for hyperbolic geometry with curvature K.

Since angles and lines and distances are preserved, assume z is the origin and L is orthogonal to the positive real axis, intersecting it at the point x
(with $0 < x < s$).

Recall the half-angle formula

$$\tan(\theta/2) = \frac{\tan(\theta)}{\sec(\theta) + 1}.$$

According to Figure 7.3.4, p.154, $\tan(\theta) = \frac{r}{s}$, where r is the

Euclidean radius of the circle containing the hyperbolic line L.

Furthermore, $\sec(\theta) = (x+r)/s$, so

$$\tan(\theta/2) = \frac{r}{x+r+s}. \qquad (1)$$

We may express x and r in terms of the hyperbolic distance d from 0 to x.

In Exercise 7.3.2, we prove the hyperbolic distance from 0 to x in $(\mathbb{D}_K, \mathcal{H}_K)$ is

$$d = s \ln\left(\frac{s+x}{s-x}\right) \text{ so that}$$

$$x = s \cdot \frac{e^{d/s}-1}{e^{d/s}+1}.$$

Express r in terms of d by first expressing it in terms of x.

Note that segment $x\,x^*$ is a diameter of the circle containing L, where $x^* = \frac{-1}{Kx}$ is the point symmetric to x with respect to the circle at infinity.

→

Thus, r is half the distance from x to x^*!

$$r = \frac{1 + \kappa x^2}{2\kappa x}.$$

Replacing κ with $-1/s^2$, we have

$$r = \frac{s^2 + x^2}{2x}.$$

One checks that after writing x in terms of d, r is given by

$$r = \frac{2 s e^{d/s}}{e^{2d/s} - 1}.$$

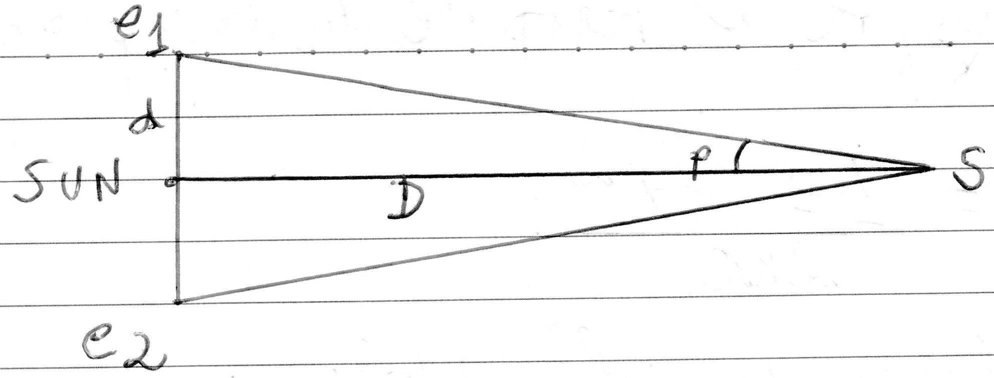
Substitute this expression for r into the equation labelled (1) in this proof, and after, we are

$$\tan(\theta/2) = e^{-d/s}.$$

Since $s = 1/\sqrt{|\kappa|}$ this completes the proof.

INTERESSANTE:

PARALLAX (prestar atenção!!!)



e_1 and e_2 denote the Earth's position points of its orbit, and the star S is orthogonal to the plane of the Earth's orbit.

The angle p is called the parallax, and in a Euclidean universe, p determines the star's distance from the Sun, D, by the equation

$D = d / \tan(p)$, where d is the Earth's distance from the Sun.

Obs.: d is about 8.3 light-minutes.

In practice, p is quite small, so a working formula is

$$D = \frac{d}{p}.$$

The first accurate measurement of parallax was recorded in 1837 by Friedrich Bessel (1784-1846).

He found the stellar parallax of 0.3 arc-seconds (1 arc second = 1/3600°) for star 61 Cygni, which put the star at about 10.5 light-years away.

Interessante:

If we live in a hyperbolic universe with curvature K, a detected parallax puts a bound on how curved the universe can be.

Obs.: $2d \cong 16.6$ light-minutes.

Assume star s is on the positive real axis and we have detected a parallax p, so that angle

$$\angle e_2 s e_1 = 2p.$$

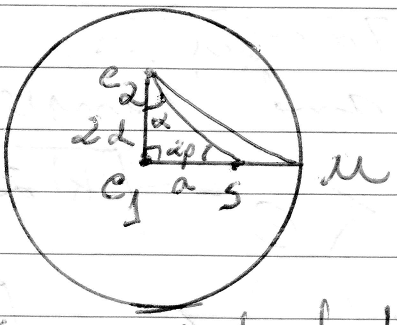


Figure 7.3.5 A detected parallax in a hyperbolic universe puts a bound on its curvature

→

The angle $\alpha = \angle e_1 e_2 s$ in Figure 7.3.5, p. 156 is less than the angle of parallelism

$$\theta = \angle e_1 e_2 u.$$

Noting that $\tan(x)$ is an increasing function and applying Lobatchevsky's formula it follows that

$$\tan(\alpha/2) < \tan(\theta/2) = e^{-\sqrt{|k|2d}}.$$

We may solve this inequality for $|k|$:

Off: $$e^{\text{In}\,x} = x$$

In = natural logarithm
e = natural exponent
x = real number

$e \cong 2.718281828459\ldots$
(irrational and transcendental number).

$$\tan(\alpha/2) < e^{-\sqrt{|k|2d}}$$

$$\text{In}(\tan(\alpha/2)) < -\sqrt{|k|2d}$$

In(x) is increasing

$$\left[\frac{\ln(\tan(\alpha/2))}{2d}\right]^2 > |K|.$$

x^2 is decreasing for $x < 0$.

To get a bound for $|K|$ in terms of p, note that $\alpha \approx \pi/2 - 2p$ (the triangles used in stellar parallax have no detectable angular deviation from 180°), so

$$|K| < \left[\frac{\ln(\tan(\pi/4 - p))}{2d}\right]^2.$$

We remark that for values of p near 0, the expression $\ln(\tan(\pi/4 - p))$ has linear approximation equal to $-2p$, so a working bound for K, which appeared in Schwarzschild's 1900 paper [27], is $|K| < (p/d)^2$.

↳ Schwarzschild, K.
On the Permissible Curvature of Space.

Pág 158(168) – 7.4

The Family of Geometries (X_K, G_K)

A strong connection exists between the family $(\mathbb{P}^2_K, S_K)$ of elliptic geometries with curvature $K > 0$ and the family $(\mathbb{D}_K, \mathcal{H}_K)$ of hyperbolic geometries with curvature $K < 0$.

The two families sport identical descriptions of the transformation group, identical descriptions of straight lines, identical arc-length and area formulas, as well as identical formulas for the area of a triangle.

Definition 7.4.1

For each real number K the geometry (X_K, G_K) has space

$$X_K = \begin{cases} \mathbb{D}_K & \text{if } K < 0; \\ \mathbb{C} & \text{if } K = 0; \\ \mathbb{P}^2_K & \text{if } K > 0, \end{cases}$$

and group of transformations G_K

consisting of all Möbius transformations of the form

$$T(z) = e^{i\theta}\,\frac{z - z_0}{1 + K\bar{z}_0 z},$$

where $\theta \in \mathbb{R}$ and z_0 is a point in X_K. Moreover, the unique line through two points p and q in (X_K, G_K) is the unique cline through the points p, q, and $-1/(K\bar{p})$.

A smooth curve $r : [a, b] \to X_K$ has arc-length given by

$$L(r) = \int_a^b \frac{2|r'(t)|}{1 + K|r(t)|^2}\,dt.$$

The area of a polar region R (R) in (X_K, G_K) is given by

$$A(R) = \iint_R \frac{4r}{(1 + Kr^2)^2}\,dr\,d\theta.$$

obs: If $K > 0$, the sum of the angles of a triangle must be greater than π; and

If $K < 0$ the sum of the angles

of a triangle must be less than π.

If $K > 0$ the space $X_K = P^2_K$ has finite area;

If $K < 0$, $X_K = \mathbb{D}_K$ has infinite area.

If $K > 0$ the circumference of a circle with radius r is less than $2\pi r$;

if $K < 0$ the circumference is greater than $2\pi r$.

Obs: $K = 0$

(X_0, g_0) corresponds to Euclidean geometry though (no entanto) with a scaled metric.

In particular, lines in (X_0, g_0) correspond to Euclidean lines (since $K = 0$, $-1/(K\bar{p}) = \infty$, so the unique line through p and q is the Euclidean line), and when $K = 0$ the arc-length is simply twice the usual Euclidean arc-length.

So while we are scaling distances in (X_0, G_0), Euclidean geometry applies:

triangles are Euclidean triangles and have angle sum equal to 180°.

Triangles with a right angle are Euclidean right triangles and satisfy the Pythagorean theorem.

We treat (X_K, G_K) as one big family of geometries.

The sign of K dictates the type of geometry we have, and the

magnitude of K dictates the radius of the disk in which we model the geometry
(unless (a não ser que)
$K=0$ in which case the
space is $\mathbb{C}$).

Moreover, Euclidean geometry (X_0, G_0) marks the edge from which we move into a hyperbolic world if K drops below 0, and into an elliptic world if K rises above 0.

We now summarize some results established in the previous section and emphasize key features common to all (X_K, G_K).

Arc-length is an invariant function of $(X_K\ G_K)$ and that the arc-length ~~that~~ ensures that the shortest path from p to q in (X_K, G_K) is along the line between them.

We have discussed these facts in the cases $K = -1, 0, 1$, and the result holds for arbitrary K. So the arc-length formula provides a metric on (X_K, G_K):

Given $p, q \in X_K$, we define

$d_K(p,q)$ to be the length of the shortest path from p to q.

The circle in (X_K, G_K) centered at p through q consists of all points in X_K whose distance from p equals $d_K(p,q)$.

Pág. 15(27) -

Pág. 14(26) - Even in Euclidean geometry, we did not add two vectors at different points, but we have almost forgotten this

Pág. 15(27) - this disability of ours because, in order to add a vector $\bar{A}$ at P and a vector $\bar{B}$ at Q, we could always replace $\bar{B}$ at Q by a parallel vector at P and then add the two (say, by parallelogram rule).

⇒

IMPORTANT: In Riemannian Geometry,
we do not have a parallel vector at P because of the absense (ausente) of a parallel postulate,

↓

⟹ Criar um novo postulado baseado na nova geometria TTT (M.V.S.)

and so we cannot afford to forget this disability.

14. Covariant Derivative of a Contravariant Vector

... "We cannot do this because we do not have a parallel postulate which would have enable us to transfer a vector A^a at P to a parallel and equal vector at Q.

Pag. 26 (38) – Einstein postulated his law off gravitation as $G^{ab} = -KT^{ab}$

K is a constant and
T^{ab} is the matter enery tensor.

Estudar:

On comparing his equations with Newtonian equations of gravity, he found that if the gravitational field is weak enough and if the velocities involved are much smaller compared to the velocity of light, then to that order of approximation, his theory gives the exact Newton Poisson equation, provided

$$\boxed{K = + \frac{8\pi G}{c^2}}$$

Thus, if there are strong gravitational fields and if high velocities are involved, one must use the full Einstein equations

$$R^{ab} - \frac{1}{2} g^{ab} R = - \frac{8\pi G}{c^2} T^{ab}.$$

In space devoid of matter (see).
$T^{ab} = 0$ and we get

$$R^{ab} - \frac{1}{2} g^{ab} R = 0 ; \quad R^{ab} = \frac{1}{2} g^{ab} R ,$$

→

$$g_{ab} R^{ab} = \frac{1}{2} g_{ab} g^{ab} R.$$

$R = 2R$ ou $R = 0$,

therefore $R^{ab} = 0$.

Einstein's equations of gravitation in empty space satisfy

$$R_{ab} = 0.$$ (20220819)

Pág. 110 (120) – 4. Killing Vector Fields.

We have mentioned symmetry transformations for a spacetime.

Such symmetries are characterized by the existence of the so-calling

Killing vector fields in M.

Pág. 111 (121) – Suppose now that the local one-parameter group of diffeomorphisms ϕ_t generated by a vector field K is a group of isometries,

i.e. for every t, ϕ_t is an isometry,

$$\phi_{t*} g_{ab} = g_{ab} \text{ for all } t, \qquad (18)$$

then K is called a Killing vector field and we have

$$L_K g = \lim_{t \to 0} \frac{1}{t} [g - (\phi_{-t})_* g] = 0 \qquad (19)$$

Thus, the necessary and sufficient condition for $\underline{\underline{K}}$ to be a KILLING VECTOR FIELD is

that the Lie derivative of g along K vanishes.

Next, since

$$L_K g_{ab} = K_{b;a} + K_{a;b}, \qquad (20)$$

for a Killing vector field we get

$$K_{b;a} + K_{a;b} = 0 \qquad (21)$$

which is called the KILLING EQUATION.

Pág. 112(122) - Riemann tensor [8] [24]

(3) Killing vector field in a spacetime

↳ Next, consider the following equation defining the Riemann tensor [8]

→

METRIC → ∇ ∇

$$\nabla_a \nabla_b \xi_c - \nabla_b \nabla_a \xi_c = R_{abc}{}^{d} \xi_d . \quad (24)$$

If now ξ^a, appearing in the above, is a KILLING VECTOR FIELD, then using the KILLING EQUATION (23) and the symmetries of the Riemann tensor (24), gives

$$\nabla_a \nabla_b \xi_c = -R_{bca}{}^{d} \xi_d \quad (25)$$

↘ Interessante:

As a consequence of (25) a Killing vector field ξ^a is completely determined by values

ξ^a and $L_{ab} = \nabla_a \xi_b$ at any $p \in M$. this means that given (ξ^a, L_{ab}) at p, the values (ξ^a, L_{ab}) at any other q are determined by integrating the ordinary differential equations (26) ⇒

$$\left.\begin{aligned} v^a \nabla_a \xi_b &= v^a L_{ab}, \\ v^a \nabla_a L_{bc} &= -R^d{}_{bca}\, \xi_d\, v^a \end{aligned}\right\} \qquad (26)$$

along any curve joining p to q,

where v^a denotes the tangent vector to that curve.

Pág. 119 (128) - 8 - Differential Forms and Einstein-Cartan Theory.

⇒ Lorentz metric with signature -2..

Pág. 297 (305) - 15 — Quantum Field Theory in Curved Spacetime: Canonical Quantization.

The Planck dimensions represent scales on which the quantum effects of the gravitational field become important. For a system, say dust confined to a length scale L,

$$A_G \sim \frac{c^4}{16\pi G} \cdot \frac{8\pi G\rho}{c^4} \cdot \frac{4\pi L^3}{3} \cdot \frac{L}{c} = \frac{2\pi\rho L^4 c}{3}.$$

But

$$L > \frac{2G}{c^2}\left(\frac{4}{3}\pi L^3 \rho\right) \Rightarrow \rho L^2 \leq \frac{3c^2}{8\pi G}.$$

Consequently, Pág. 238(306)

$$A_G \leq \frac{2\pi L^2 c}{3} \cdot \frac{3c^2}{8\pi G} = \frac{L^2 c^3}{4G},$$

so that quantum effects of the gravitational field are significant, if

$$\frac{L^2 c^3}{4G} \leq \hbar, \text{ i.e. } L \leq 2L_p.$$

obs: QFT in CST →
quantum field theory in curved spacetime.

value of the energy momentum tensor for matter, i.e.

$$G_{\mu\nu}(g_{\alpha\beta}) = 8\pi \langle T_{\mu\nu} \rangle \quad (2).$$

There is a problem with the above semi-classical Einstein equation that gives the back reaction of the quantum field on the gravitational field.

According the equivalence principle which lies at the foundation of all metric theories of gravity all forms of matter and energy couple equally to gravity.

Pág. 405 (411) - 19 - The Photon, the Graviton and the Gravitino.

Pág. 407 (413) - 2. The Graviton

The existence of the Graviton field can be seen by carrying out a straightforward flat space expansion of the Einstein-Hilbert Lagrangian density,

$$S = \int \mathcal{L}_{E-H}\, d^4x, \quad \mathcal{L}_{E-H} = \sqrt{-g}\, R, \quad (17)$$

where g is the determinant of the metric tensor, $g_{\mu\nu}$ and R is the scalar curvature.

→ Non-euclidean geometry -
Roberto Bonola (003-noneuclideangeom00bonorich.pdf)
Pág. 67(83) - §34 -

Gauss defines parallels as follows:
↳(Source: Gauss Werke, Bd VIII, p. 202-'9).

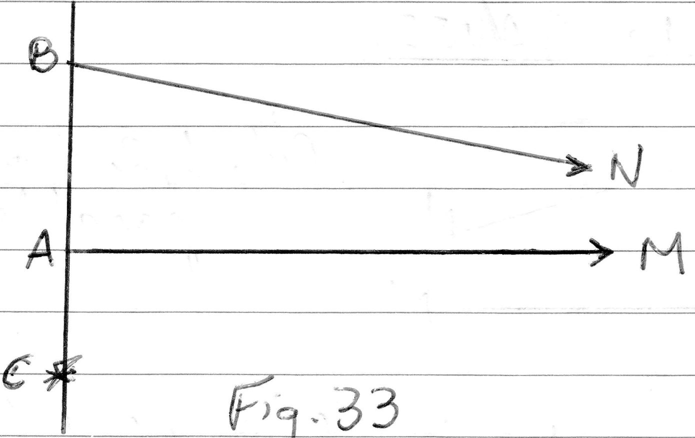

Fig. 33

If the coplanar straight lines AM, BN do not intersect each other, while,
every straight line through (através) A between AM and AB cuts BN, then AM is said to be parallel to BN [fig. 33].

He supposes a straight line passing through A, to start from the position AB, and then to rotate continuously on the side towards (em direção) which

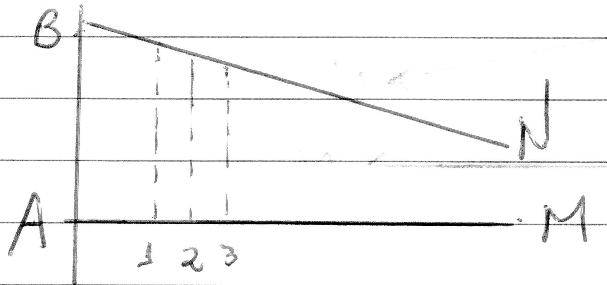
BN is drawn, till it reaches (até atingir) the position A'C, in BA produced.

This line begins by cutting BN and in the end it does not cut it.

Thus there can be one and only one position, separating the lines which intersect BN from those which do not intersect it. (...)

Gauss's definition only the first of these is said to be parallel to BN.

Analisando GAUSS:



Obs. 1, 2, 3 are parallels

Portanto:

I. He proceeds to show that the parallelism of the line AM to the line BN is independent of the points A and B, provided the sense in which the lines are to be produced indefinitely remains the same.

It is obvious that we would obtain the same parallel AM

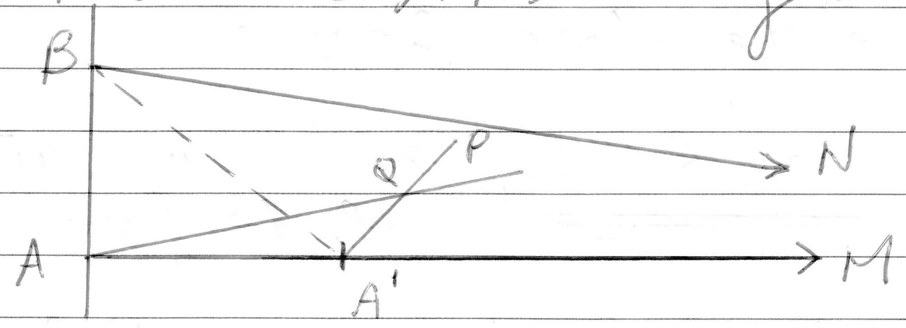
Pag. 69 (85)

if we kept A fixed and took instead (em vez de) of B another point B' on the line BN, or on that line produced backwards (para trás).

It remains to prove that if AM is parallel to BN for the point A ~~or on that one (line)~~) it also the parallel to BN any point upon AM, or upon AM produced backwards.

Instead of (término de careta)

Instead of A [Fig. 34] take another starting point A' upon AM. Through A', between A'B and A'M, draw the line A'P in any direction.



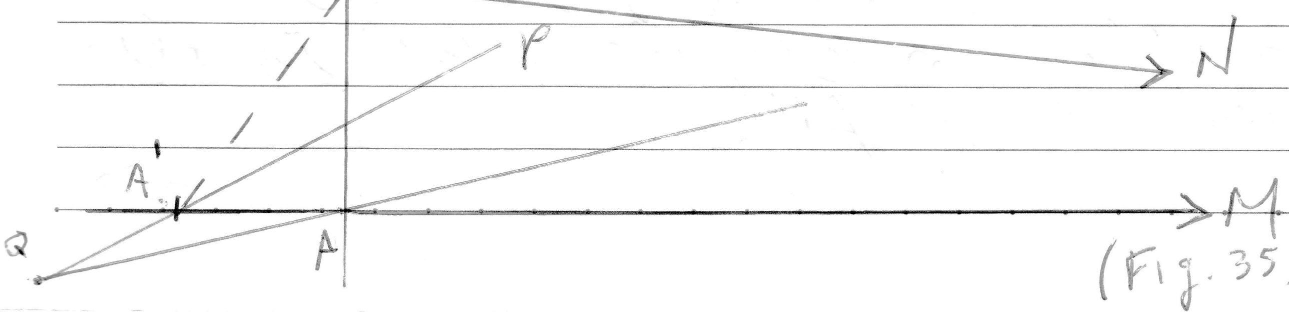
(Fig. 34)

Through Q, any point on A'P, between A' and P, draw the line AQ.

Then, from the definition, AQ must cut BN, so that it is clear QP must must also cut BN.

Thus AA'M is the first of the lines which do not cut BN, and A'M is parallel to BN. (checar!!!)

Again take the point A' upon AM produced backwards [Fig. 35]



(Fig. 35)

Draw through A' between $A'B$ and $A'M$, the line $A'P$ in any direction.
Produce $A'P$ backwards and upon it take any point Q.
Then, by the definition, QA must cut BN, for example,

Pag. 70 (86) ... cont.

in R. Therefore $A'P$ lies (encontra-se) within the closed figure

$A'ARB$, and must cut one of the four sides

$A'A$, AR, RB, and BA'.

Obviously this must be the third side RB, and therefore

$A'M$ is parallel to BN.

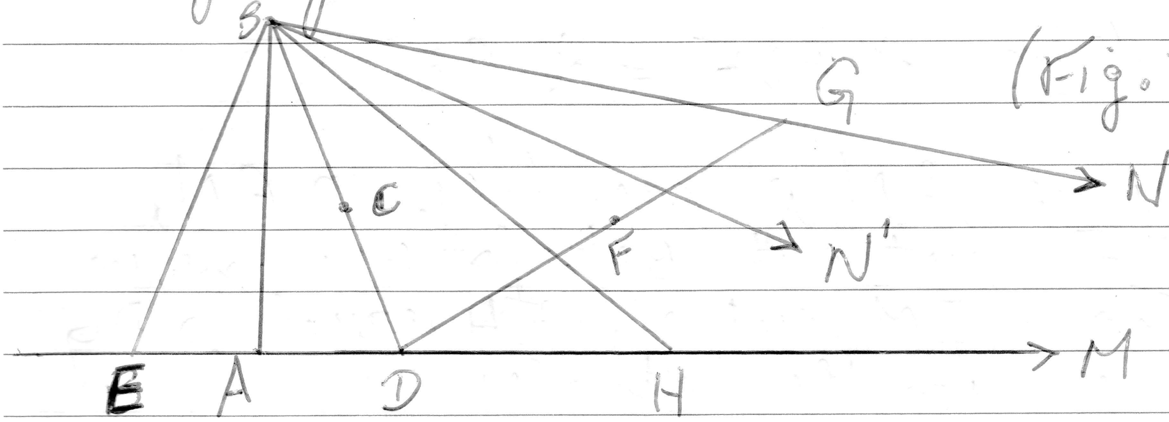
II. The Reciprocity of the Parallelism can also be established.

In other words, if AM is parallel to BN, then BN is also parallel to AM!

⇒

GAUSS proves this results as follows:

From any point B upon BN draw BA perpendicular to AM.



(Fig. 36)

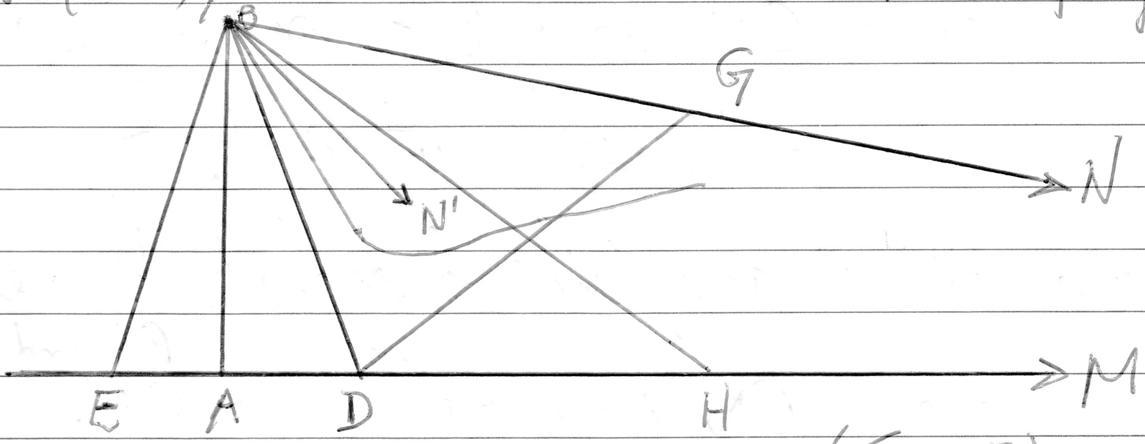
At B, on the same side of AB as BN, make

$\sphericalangle ABG = 1/2 \sphericalangle N'BN.$

There are two possible cases:

Case (i), when BG cuts AM [cf. Fig. 36].

Case (ii), when BG does not cut AM [cf. Fig. 37].



(Fig. 37)

Voltando: case (i)

Let BG cut AM in D.
Take AE = AD, and join BE.

Make $\measuredangle BDF = \measuredangle BED$.

Since AM is parallel to BN, DF must cut BN, for example, in G. From EM cut off EH equal to DG. Then, in the triangles

BEH and BDG, it follows that

Pág. 71(87)

$\measuredangle EBH = \measuredangle DBG$.

Therefore $\measuredangle EBD = \measuredangle HBG$.

But $\measuredangle EBD = \measuredangle N'BN$.

Therefore BN' and BH coincide, and BN' must cut AM.

But BN' is any line through B, between BA and BN.

Therefore BN is parallel to AM.

20220820 III

Case (ii) - In this case let D ~~that~~ be any arbitrary point upon AM.

Then with the same argument as above,

$\measuredangle EBD = \measuredangle GBH$.

But $\measuredangle ABD < \measuredangle ABC$.

Therefore $\measuredangle EBD < \measuredangle N'BN$.

Therefore $\measuredangle GBH < \measuredangle N'BN$.

Therefore BN'' must cut AM.

But BN' is any line through B, between BA and BN.

Therefore BN is parallel to AM.

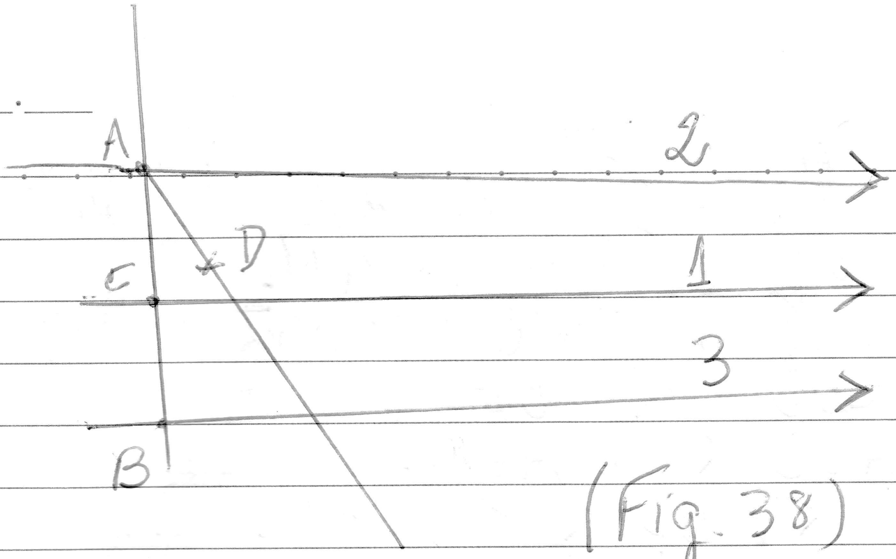
Thus in both cases we have proved that if AM is parallel to BN, then BN is parallel to AM.(I)

(I) → Gauss's second proof of this theorem is given in the German translation. However it will be found that in it he assumes that BC cuts AM, and to prove this the argument (argument) used above is necessary.

The next theorem proved by Gauss in this synopsis is as follows:

III. If the line (1) is parallel to the line (2) and to line (3), then (2) and (3) are parallel to each other. (Pag. 72 (88)).

Case (1) - Let the line (1) lie between (deitar entre) (2) and (3) [cf. Fig. 38].



(Fig. 38)

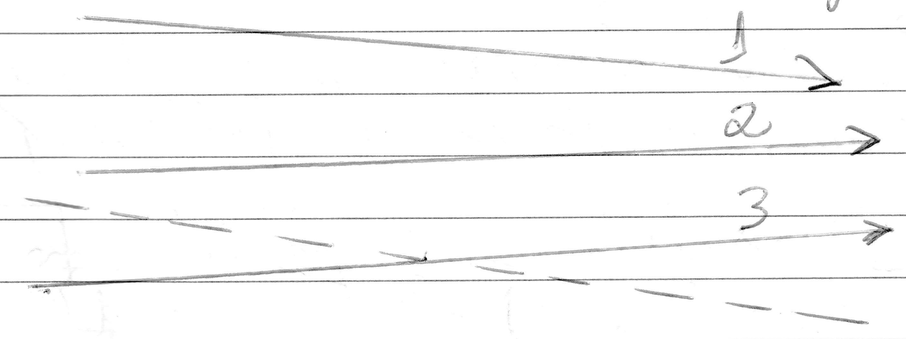
Let A and B be two points on (2) and (3), and let AB cut (1) in C.

Through A let an arbitrary line AD be drawn between AB and (2).

then it must cut (1), and on being produced must also cut (3).

Since this holds for every line such as (tal como) AD, (2) is parallel to (3).

Case (ii) – Let the line (1) be outside both (2) and (3), and let (2) lie between (1) and (3) [cf. Fig. 39].



(Fig. 39)

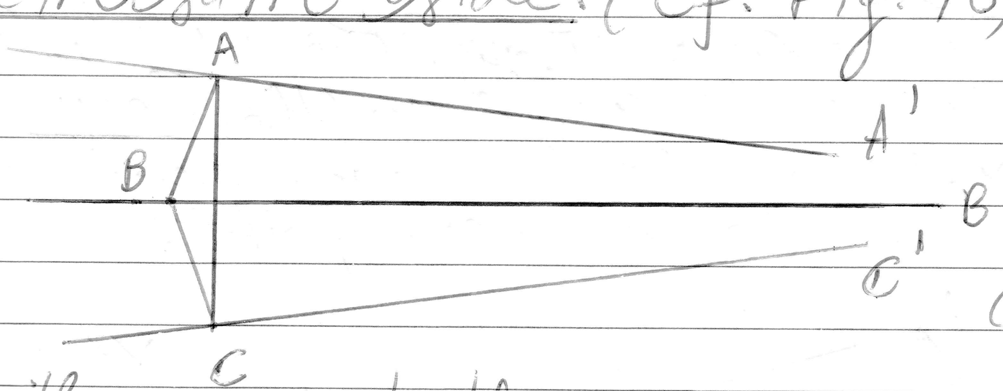
If (2) is not parallel to (3), through any point chosen at random upon (3), a line different from (3) can be drawn which is parallel to (2).

This, by Case (1), is also parallel to (1), which is absurd.

This short Note on Parallels closes (closes) with the theorem that if two lines AM and BN are parallel, these lines produced backwards cannot meet.

Pág. 73 (89) - In a second memorandum on parallels, Gauss goes over (passa por cima) the same ground, but adds the idea of CORRESPONDING POINTS on two parallel AA', BB'.

⟹ Two points A, B are said to correspond, when AB makes equal internal angles with the parallels on the same side. (cf. Fig. 40)



(Fig. 40)

With regards to these Corresponding Points he states the following theorems:

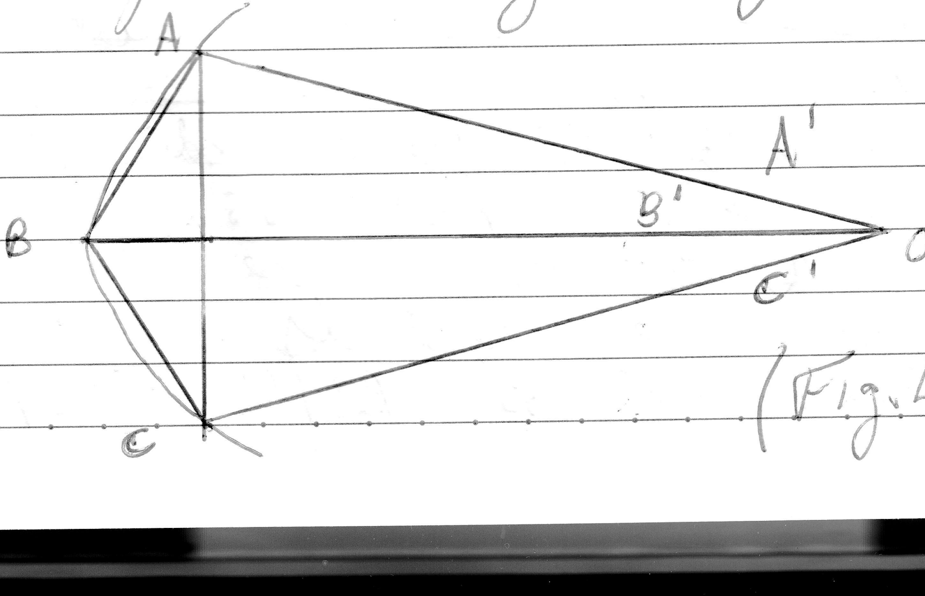
(i) If A, B are two corresponding points upon two parallels, and M is the middle point of AB, the line MN, perpendicular to AB, is parallel to the two given lines, and every point on the same side of MN as A is nearer A than B.

(ii) - If A, B are two corresponding points upon the parallel (1) and (2), and A', B' two other corresponding points on the same lines, then

AA' = BB', and conversely.
(por outro lado)

(iii) - If A, B, C are three points on the parallels (1), (2) and (3), such that (de tal modo que) A and B, B and C, correspond, then A and C also correspond.

Pag. 74 (90) — The idea of Corresponding Points, when taken in connection with three lines of a pencil (that is, three concurrent lines [cf. Fig. 41]) allows us to define the circle as the locus of the points on the lines of a pencil which correspond to a given point.



Important!!!

(Fig. 41)

But this locus can also be constructed when the lines of the pencil are parallel.

In the Euclidean case the locus is a straight line: but putting aside the Euclidean hypothesis, the locus in question is a line, having many properties in common with the CIRCLE, but yet not itself a circle.
(itself)

Indeed if any three points are taken upon it, a circle cannot be drawn through them. ✓

This line can be regarded as the limiting case of a circle, when its radius become infinite.

In the Non-Euclidean geometry of LOBATSCHEWSKY and BOLYAI: this locus plays a most important part, and we shall meet it there under the name of the HOROCYCLE. (I)

*

Obs.: Horocycle in hyperbolic geometry, or limit circle, is a curve whose normal or perpendicular geodesics all converge asymptotically in the same direction.

(I) [LOBATSCHEWSKY: Grenzkreis, Courbe-limite or Horicycle.

BOLYAI; Parazykl, L-linie.

→ TROPE (discussion of the properties of this curve)

This work GAUSS did not need to complete, for in 1832 he received from Wolfgang Bolyai a copy of the work of his son Johann on Absolute Geometry. Ⓐ

off: Absolute Geometry - Bolyai.

Other book: ISBN 978-613-5-77145-9

obs.: Absolute geometry is a geometry based on an axiom system that does not assume the parallel postulate or any of its alternatives.

The term was introduced by János Bolyai in 1832. It is sometimes referred to as neutral geometry, as it is neutral with respect to the parallel postulate. The theorems of absolute geometry hold in some non-Euclidean geometries, such as hyperbolic geometry, as well as in Euclidean geometry. Absolute geometry is an extension of ordered geometry, and thus, all theorems in ordered geometry hold in absolute geometry.

The converse is not true.

Absolute geometry assumes the first four of Euclid's axioms, to be contrasted with affine geometry, which assume Euclid's first, second, and fifth (parallel postulate) axioms.

Ordered geometry is a common foundations of both absolute and affine geometry.

HOROCYCLE (*) Ⓐ

Pag. 74 (90) - From letters before and after the date at which he interrupted his work, we know that GAUSS has discovered in his geometry an

ABSOLUTE UNIT OF LENGTH

[cf. LAMBERT and LEGENDRE],

and that a constant K appeared in his formulae, by means of which all the problems of the Non-Euclidean Geometry could be solved [letter to Taurinus, Nov 8, 1824].

Speaking more fully of these matters in 1831 [letter to Schumacher], Pág. 75(90)— he gave the length of the circumference of a circle of radius r in the form

$$\pi k \left(\frac{r}{e^{k} - e} \quad \frac{r}{k} \right).$$

With regard to k, he says that, if we wish to make the new geometry agree with the facts of experience, we must suppose k infinitely great in comparison with all known measurements.

For $k = \infty$, GAUSS's expression takes the usual form for the perimeter of a circle.(I)

(I) To show this we need only use the exponential series.

The same remark holds for the whole of GAUSS's system of geometry. It contains EUCLID'S system as the limiting

case, when $k = \infty$.

Pag. 134(158) - 2.3. Hamilton.

Geometric optics may be approached either as a theory of systems of rays constructed by means of the elementary laws of refraction (Ibn Sahl, Snell, Descartes, Fermat, Newton), or as a theory based upon the consideration of systems of surfaces whose orthogonal trajectories are the rays (Huygens, Hamilton).

Pag. 135(159) - Hamilton optics, in which a characteristic function measures the time that light takes to travel from one point to another and it depends on the coordinates of both the initial and final points.

Pag. 136(160) - 2.3.1 Legendre Transform

One passes from Lagrangian to Hamiltonian dynamics through the Legendre transformation.

Voltando: (um pouco)

Pag. 112(136) - 2.2. Lagrange

solution to the isoperimetric problem

Among all closed curves of a given fixed perimeter in the plane, which curve maximizes the area that it encloses?

The circle does this.

Pag. 113(137) - Example 2.2.1

Stereographic projection of $S^2 \Rightarrow R^2$.

The unit sphere S^2 may be defined as a surface in R^3 given by the set of points satisfying

$$S^2 = \{(x, y, z) : x^2 + y^2 + z^2 = 1\}.$$

Important:

Utilize the M.U.S (TTT) para recalcular a equação acima pois nós devemos observar que o resultado obtido será diferente da apresentação clássica. A nova geometria irá revelar a real realidade do comportamento dos objetos dentro do Universo. O ajuste das equações será necessário para que a realidade seja representada de forma eficaz e produzirá os efeitos necessários para o real entendimento do mundo e do Universo.

Estudando:

$$\Pi\!\!\!\Pi = \pi . F_L . F_U \therefore \Pi\!\!\!\Pi < \pi$$

Vejamos:

$$S^2 = [\{(x,y,z) : x^2+y^2+z^2=1\} . \Pi\!\!\!\Pi]$$

or

$$S^2 = [\{(x,y,z) : x^2+y^2+z^2=1\} . \pi . F_L . F_U]$$

Important:

O π terá um valor fixado pois este número não representa a realidade a qual este número é usado para representá-lo.

π sendo um valor fixo, multiplicado por 2 coeficientes que alteram este número e para menor valor, nós teremos a real clareza do Universo que queremos descrever de forma mais precisa.

$\Pi\!\!\!\Pi < \pi$, o valor de $\Pi\!\!\!\Pi$.

representará a realidade do nosso mundo e o Universo.

The spherical polar angle θ and azimuthal angle ϕ are often used as coordinates on S^2. However, the angle ϕ cannot be defined uniquely at the north and south poles where $\theta = 0$ and $\theta = \pi$, respectively.

Important:

Checar que com o uso do π, nós obteremos outros referenciais esféricos. Ficar atento aos efeitos nas equações envolvidas.

RIEMANN'S treatment used PTOLEMY'S (Ptolemy's) STEREOGRAPHIC PROJECTION to define two overlapping subsets that satisfied the defining properties of a smooth manifold.

$$\text{Let } U_N = S^2 \setminus \{0,0,1\} \text{ and}$$

$$U_S = S^2 \setminus \{0,0,-1\}$$

be the subsets obtained by deleting the north and south poles of S^2 respectively. The stereographic projection

ϕ_N and ϕ_S from the north and south poles of the sphere onto the equatorial plane, $z = 0$, are defined respectively by

$$\phi_N : U_N \to \xi_N + i\eta_N = \frac{x+iy}{1-z} = e^{i\phi}\cot(\theta/2),$$

and

$$\phi_S : U_S \to \xi_S + i\eta_S = \frac{x-iy}{1+z} = e^{-i\phi}\tan(\theta/2).$$

The union of these two subsets covers S^2. On the overlap of their projections, the coordinates

$(\xi_N, \eta_N) \in \mathbb{R}^2$ and

$(\xi_S, \eta_S) \in \mathbb{R}^2$ are related by

$$(\xi_N + i\eta_N)(\xi_S + i\eta_S) = 1.$$

Important:

Nós devemos prestar a atenção de que o valor igual 1 representa uma projeção sobre um plano. Isto deverá acontecer posteriormente com o espelhamento (mirror) ortogonal sobre um plano desta projeção. Assim, o valor deverá ser menor que 1 pois o valor π (M.U.S.) gera uma real adequação da projeção sobre um plano.

Stereographic projection of the Riemann

Sphere - o nome do autor destes 2 volumes,
Prof. Darryl Holm - https://www.imperial.ac.uk/
people/d.holm - envie um email a ele dizendo:

a) Stereographic projection of Riemann Sphere -
Vol.1, 2nd Edition, p.115(139) - Figure 2.2 and
2.3 will need to be readjusted to a new reality.

b) In your publication, Solution properties of a
3D stochastic euler fluid equation
(https://spiral.imperial.ac.uk/handle/
10044/1/63498), you said on page 7
(Remark 32): "Euler fluid equations
treated here in Cartesian R3 coordinates,
the two velocities denoted u and v in the
previous section may be taken to be
identical vectors for the case at hand in
R3" (— R^3) there is a big problem in
calculating the vorticity (ω), because
the u and v value will need adjustment.
I discovered a new way to calculate pi
and I can say, for the moment, that this
number is not transcendental.
My research will have a direct impact
on your analyses.

Newton Principles

1.1. The Task of Natural Philosophy

Newton does not understand by MOTION - MOTUS - every kind of quantitative and qualitative change, but only that which formerly called

MOTUS LOCALIS, that is,

locomotion or change of place.[2]

(2) → Newton, "De Gravitatione et Aequipondio Fluidorum", Def. 4, in Hall and Hall (1978), p. 91.

Force - vis - is

"the causal principle of motion and rest".[3]

Newton distinguishes two kinds of force.

These two kinds of force are respectively, the subject of Definitions IV and III of the "PRINCIPIA"

where the latter is referred to as "innate force (vis insita) of matter", and the former as "impressed force (vis impressa).

Innate force is said to be proportional to the "quantity" of matter - also called by Newton its "body" (corpus) or "mass" (massa) - and it is said to differ from the natural (inertia) of matter in our conception only.

Obs: "For a body perseveres in every new state by its force of inertia alone".

Δs
$P_0(x_0, y_0)$
D_f

obs: A curvatura $z_0 z_1$ acompanha a curvatura da forma geométrica acima (≅telha).

$f: \mathbb{R}^2 \rightarrow \mathbb{R}$ of two variable is:

$$\lim_{P_1 \to P_0} \frac{f(x_0, y_0) - f(x_1, y_1)}{\sqrt{(x_1 - x_0)^2 + (y_1 - y_0)^2}} \qquad (2.1).$$

Vejamos:

The graphical foundation for the limit expression (2.1) is shown in Figure 2.3. The things to note are, firstly, the graph of f is suspended in 3D; secondly, the domain D_f lies in the xy-plane; thirdly, the points P_0 and P_1 in D_f give rise to values z_0 and z_1, respectively; and finally, the line in the domain joining P_0 and P_1 traces out the black curve in the graph of f.

In direct analogy with the 1D derivative we have

$$\Delta z = f(x_0, y_0) - f(x_1, y_1), \text{ and}$$

$$\Delta s = \sqrt{\Delta x^2 + \Delta y^2}.$$

Referring to Figure 2.3, for the limit process to make sense several related questions need to be addressed:

- does $f(x_0, y_0)$ exist, or equivalently, does (x_0, y_0) belong to D_f?

- is f continuous at (x_0, y_0)?
- does the limit $\lim\limits_{P_1 \to P_0}$ exist if $P_1 \in D_f$?

Pág. 31(38) - Chapter 2

Schwarzschild Solution for Spherical Symmetry

See: Pág. 39(46) - Fig. 2.1

Gravity of spherical shell

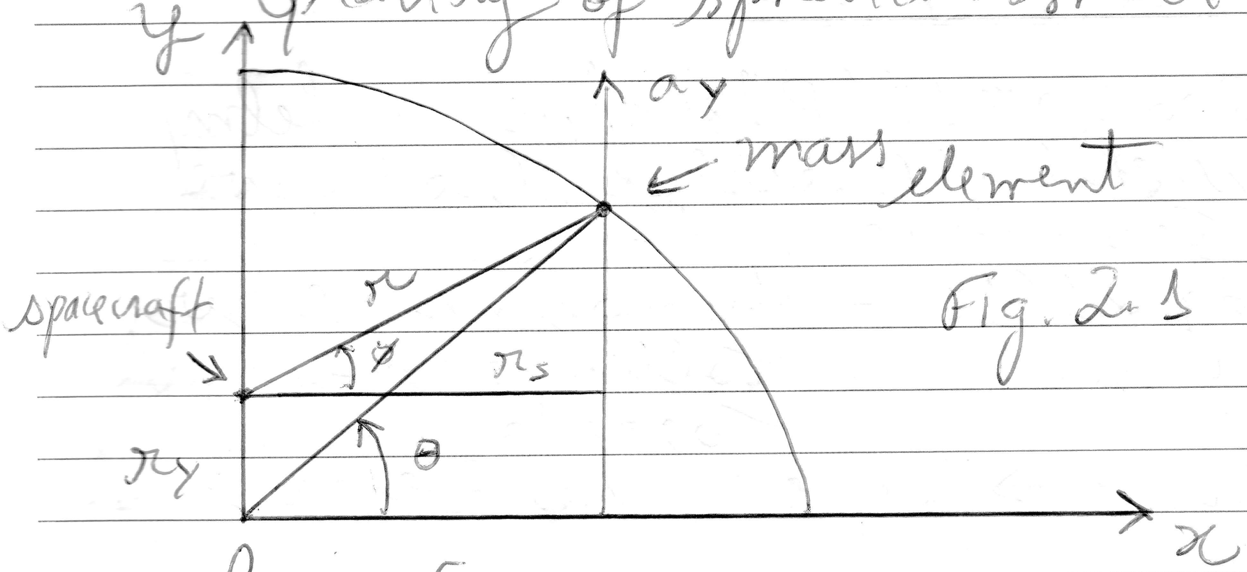

Fig. 2.1

We have for a_y

$$a_y = \frac{2\pi r_s \cos\theta\, u\,(r_s \sin\theta - r_y)}{r^3}$$

The acceleration of the spacecraft due to the sphericall shell or the acceleration of the spherical shell by the spacecraft is obtained by integrating a_y from θ equals -90 to 90 deg. The a_y component integrates to zero.

The Equation $\bar{a}_y = \int_{-\frac{\pi}{2}}^{+\frac{\pi}{2}}$ ⇒

$$\bar{a}_x = \int_{-\frac{\pi}{2}}^{+\frac{\pi}{2}} a_y \, d\theta = \left. \frac{2\pi M(r_y - r_y \sin\theta)}{r_y^2 (r_s^2 + r_y^2 - 2 r_s r_y \sin\theta)^{\frac{1}{2}}} \right|_{-\frac{\pi}{2}}^{+\frac{\pi}{2}} = 0$$

This proves the shell theorem for $r < r_s$, which was first obtained by Newton. When r is greater than r_s, the acceleration is mass divided by r^2.

The shell theorem is also true for general relativity.

Important:

The proof is difficult because we cannot use the Euclidean model shown in Fig. 2.1. ✓

Applications of Similarities to elementary Geometry.

27.2 Theorem - Three parallel lines cut off proportional segments from two transversals.

Pág. 158

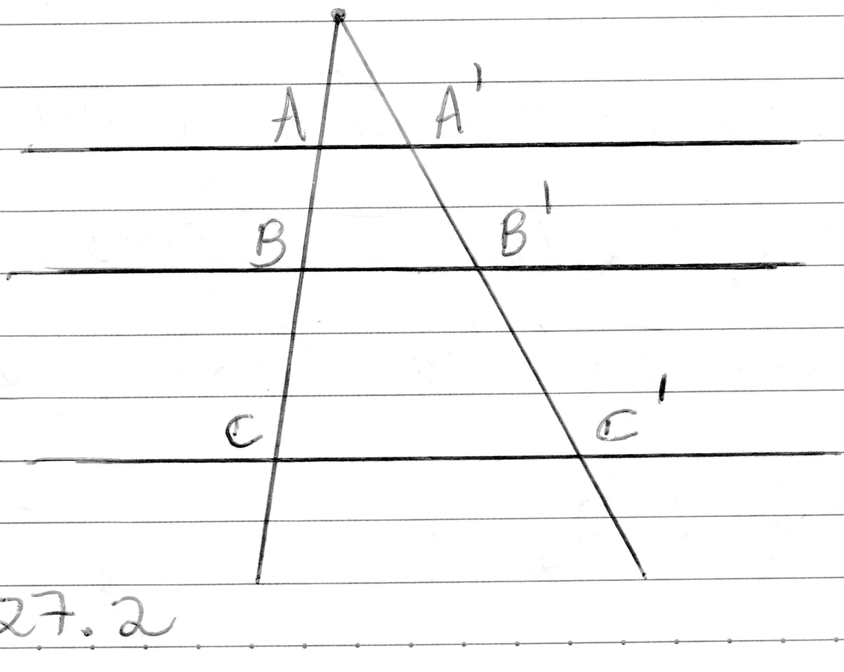

Figure 27.2

27.2 Theorem – Three parallel lines cut off proportional segments from two transversals.

If the transversals are parallel, then the theorem follows immediately since opposite sides of the resulting parallelograms are congruent.

So suppose transversals ABC and A'B'C' meet at P (Fig. 27.2).

Then H(P, PB/PA) maps triangle PAA' to PBB' and H(P, PC/PB) maps triangle PBB' to PCC'.

Now AB/BC = A'B'/B'C' follows from similar triangles.

IMPORTANT:

Usar TT! para recalcular as equações → MIRROR ORTHOGONAL.

Obs: Usar PAPPUS'S THEOREM (3 Points) com paralelismo de GAUSS (anteriormente abordado, mas com necessidade de aprofundamento).

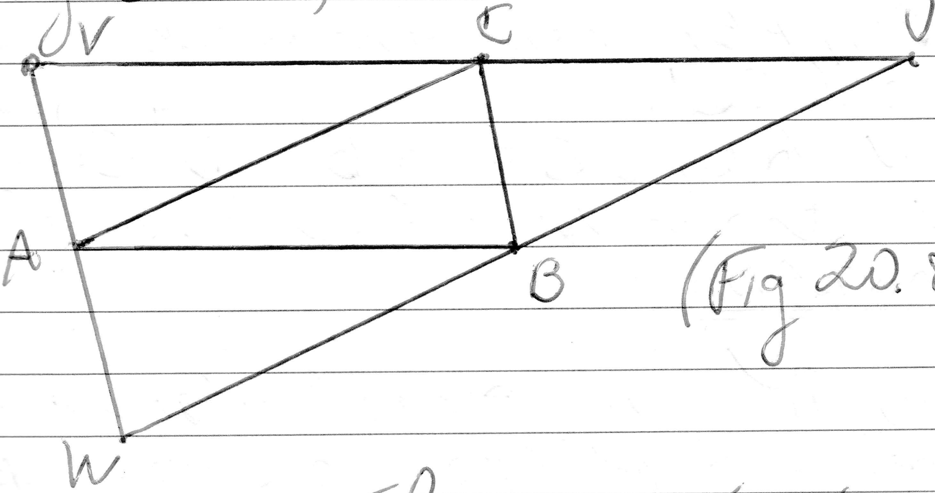
Pág. 166 – Figure 28.7

28.8 – Compare the proof of theorem 28.7

with Corollary 20.8. (Pág. 126)

20.8 Corollary — If CABU, ABCV, and BCAW are parallelograms, then ABC is the medial triangle for triangle UVW.

Furthermore, the altitudes of triangle ABC concur by Theorem 20.1 since they are the perpendicular bisectors of the sides of triangle UVW (Fig 20.8)



(Fig 20.8)

obs: 20.1 Theorem (pág. 124) —

The perpendicular bisectors of the sides of a triangle concur.

Voltando: 28.8

28.9 - The method of homothety is quite useful for constructions.

Pág. 218 – Section 37

Lines in the GAUSS PLANE

37.1 Theorem – Points A, B, C are collinear $\underbrace{\text{iff}}$

↳ definição matemática

Iff → if and only if (as a written abbreviation).

$$\begin{vmatrix} a & \bar{a} & 1 \\ b & \bar{b} & 1 \\ c & \bar{c} & 1 \end{vmatrix} = 0.$$

37.2 Theorem – An equation for the line passing through points A and B is

$$\begin{vmatrix} z & \bar{z} & 1 \\ a & \bar{a} & 1 \\ b & \bar{b} & 1 \end{vmatrix} = 0.$$

Clearly the equation is satisfied when $z = a$ and when $z = b$. The theorem then follows by Theorem 37.1.

As an alternative method of proof, expand the determinant to obtain the equation

$(\bar{a}-\bar{b})z-(a-b)\bar{z}+(a\bar{b}-\bar{a}b)=0.$

Writing $x+iy$ for z, so $\bar{z}=x-iy$, we find that the equation reduces to

$(\bar{a}-\bar{b}-a+b)x+i(\bar{a}-\bar{b}+a-b)$
$y(a\bar{b}-\bar{a}b)=0.$

Obs: Estudar!!!

Since each of these coefficients is pure imaginary, when we multiply through by i, we obtain an equation of the form

$ax+\beta y+\gamma=0$ for real

$\alpha, \beta, \gamma.$

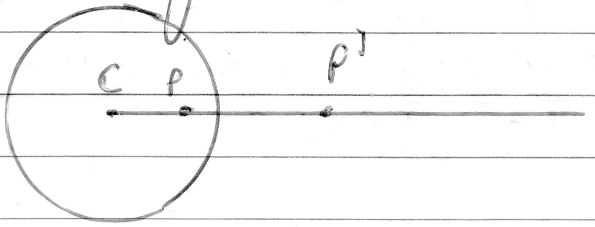
This is an equation for a

STRAIGHT LINE. (Pág. 219)

Pág. 227 – Section 39

Isometries and Similarities in the GAUSS PLANE.

Pág. 237 - Figure 41.4



41.5 Theorem → Inversion is a transformation of the inversive plane and is involutoric.

41.6 Theorem → Points inside the circle of inversion map to points outside the circle, and points outside map inside. Points on the circle are invariants (invariant) and are the only invariant points.

If P lies inside the circle of inversion with center C and radius r, then $CP < r$.

Since $CP \cdot CP' = r^2$, then CP' cannot be less than or equal to r, for then

$$CP \cdot CP' < r^2.$$

Hence (por isso) $CP' > r$, so P' lies outside of circle.

41.7 - Definition → A transformation of the plane is called conformal iff it preserves angles between curves.

It is directly conformal if it preserves the sense of the angle as well, and inversely conformal if it reverses the sense.

41.8 Theorem - Isometries and similarities are conformal; direct similarities are directly conformal and ~~[illegible]~~ opposite similarities are inversely conformal.

Pág. 238- 41.10 Theorem

Inversion is inversely conformal.

PAQ and P'A'Q' are oppositely congruent.

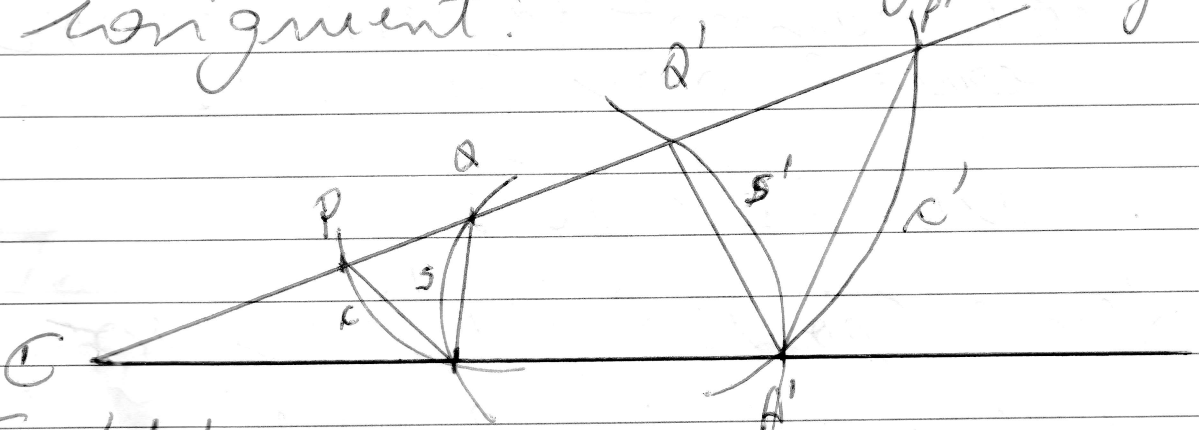


Fig 41.10

Obs: Interessante!!!

ATENÇÃO:

41.11 Theorem

A line through the center of inversion is invariant.

41.12 Theorem

A line not through the center C of inversion maps onto a circle through C.

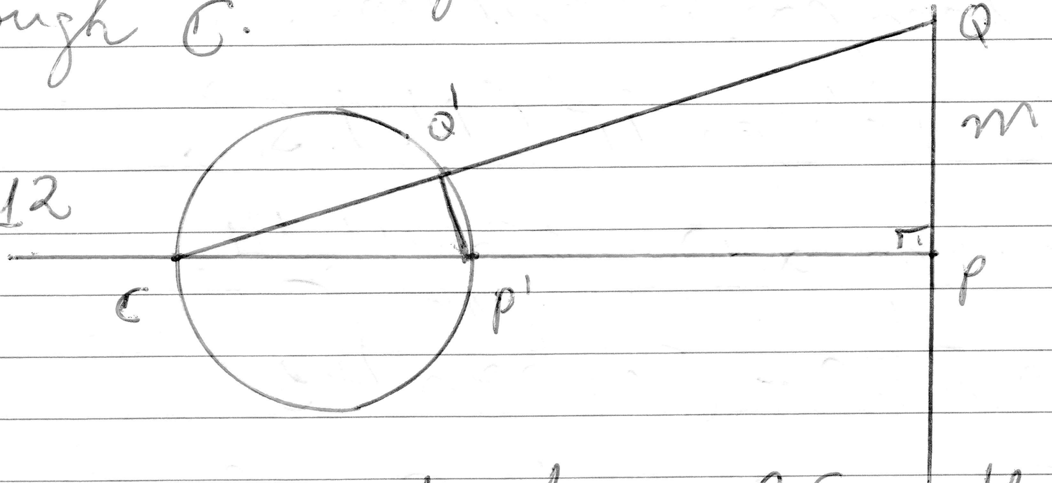

Fig 41.12

Drop a perpendicular CP from the center C to given line m.
Let Q be any other point on line m (see Fig. 41.12).
Let P' and Q' be the inverses of P an Q.
By Theorem 41.9, triangles CPQ and CQ'P' are similar.
Hence ∡ CQ'P' ≅ CPQ = 90°, so it follow that Q' lies on the circle of diameter CP'.
Since the ideal points maps to C, each point of line m maps to some point on that circle.

Furthermore, for each point Q' (other than C) on that circle, ray CQ' cuts line m in a point Q, and from the first paragraph of this argument, Q inverts to Q'. Hence the image of the line m is the entire circle on CP' as diameter.

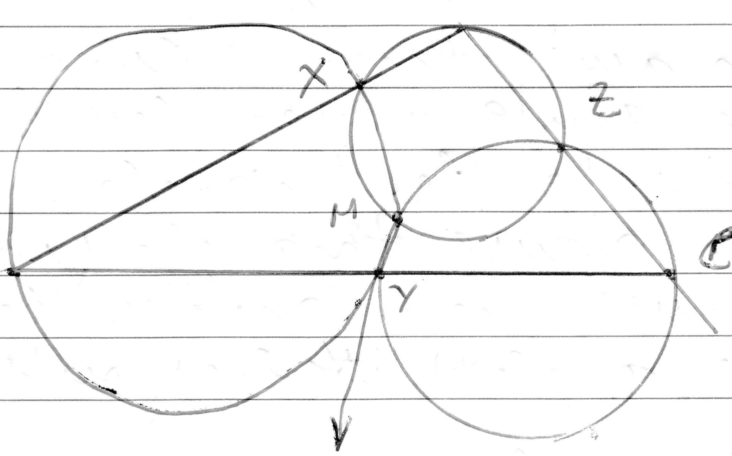
Given Δ ABC and three menelaus points X, Y and Z, one on each side (possibly extended) of the triangle, then the circles formed using a vertex and its two adjacent menelaus points are concurrent at a point M.
The point of concurrency is called Miquel Point.



esta diferença decorre do erro do π, com o advento do ΠI (M.V.S.) esperamos solucionar esta discrepância.

Obs: Estudar até pág. 176 (191).

Pág. 190 (205) - the Euler Line

Theorem 6.6.2 (Euler line)

Given a nonequilateral triangle ABC, the circumcenter S, the centroid G, and the orthocenter H are collinear and form the Euler line.

Obs: The circumcenter is the center of a triangle's circumcircle. It can be found as the intersection of the perpendicular bisectors.

The centroid is the centre point of the object. It is also defined as the point of intersection of all the three medians.

The median is a line that joins the midpoint of a side and the opposite vertex of the triangle.

The orthocenter is the intersection point of the altitudes drawn from the vertices of the triangle to the opposite sides.

For an acute triangle (is a triangle with three acute angles (less than 90°), it lies inside the triangle.

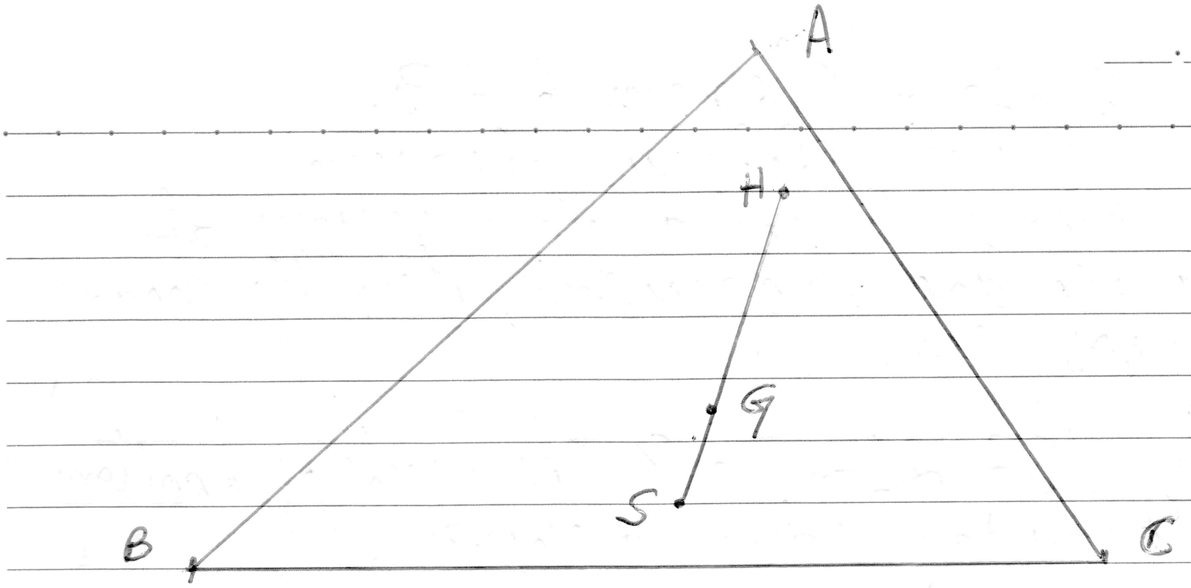
For an obtuse triangle (is a triangle with one obtuse angle (greater than 90°) and two acute angles), it lies outside of the triangle.

For a right-angled triangle, it lies on the vertex of the right angle.

In fact, G is a trisection of HS; that is, G is between H and S and GH = 2GS.

Note: If ΔABC is equilateral, then S = G = H, and conversely, if S = G = H, then ΔABC is equilateral.

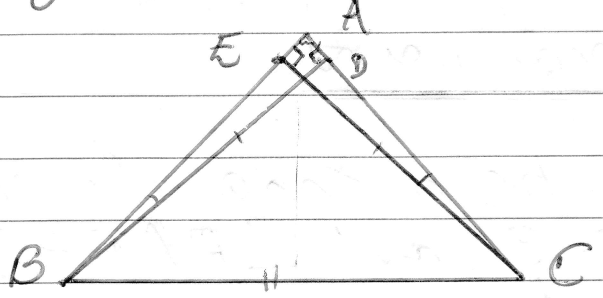
→



Obs: Veja a prova!!

Pag. 193(208) - 6.7 The Steiner-Lehmus Theorem

Theorem 6.7.1. If the altitudes of a triangle are congruentes, then the triangle is isosceles.
Proof. In the figure on the following page, if $BD \doteq EC$, then $\Delta BDC = \Delta CEB$ by the HSR congruence theorem.



Therefore, $\Delta ABD \equiv \Delta AEC$ by the ASA congruente theorem, so that $AB = AC$.
Therefore, $\angle B = \angle C$ and ΔABC is isosceles.

Theorem 6.7.2: If two medians of a triangle are congruent, then the triangle is isosceles.

Pág. 195(210) - Theorem 6.7.3.
(Steiner-Lehmus Theorem)

If two internal angle bisectors of a triangle are congruent, then the triangle is isosceles.

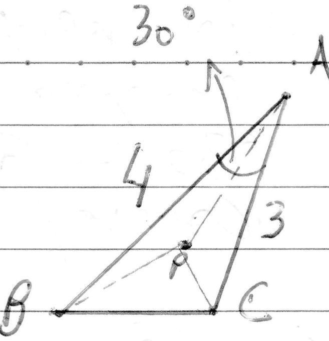
The Fermat Point

Let ABC be a triangle with $AB = 4$, $AC = 3$, and $\angle BAC = 30^\circ$. Determine the minimum value of

$$PA + PB + PC$$

where P is any point inside the triangle ABC, and find the location of the point P that yields this minimum value.

Pág. 224 (239)



Solution: Consider the effect of $R_{A,60°}$ on ΔABC, as in the figure below.
This maps ΔABC onto $\Delta A'B'C'$ and takes the point P to the point P'.
Since $\angle PAP' = 60°$, triangle APP' must be equilateral. Hence

$$\begin{aligned} PB + PA + PC &= BP + PP' + P'C' \\ &\geq BP' + P'C' \\ &\geq BC' \end{aligned}$$

by the Triangle Inequality.

In mathematics, the triangle inequality states that for any triangle, the sum of the lengths of any two sides must be greater than or equal to the length of the remaining side. [1][2]

cont. description Triangle Inequality:

This statement permits the inclusion of degenerate triangles, but some authors, especially those writing about elementary geometry, will exclude this possibility, thus leaving out the possibility of equality [3]. Ⓐ

[3] Jacobs, Harold R. Geometry.
p. 246 ISBN 0-7167-0456-0.

Obs: Degenerate triangle

A degenerate triangle has collinear vertices and zero area, and thus coincides with a segment covered twice (if the three vertices are not all equal; otherwise, the triangle degenerates to a single point). If the three vertice are pairwise (Emparelhados) distinct, it has 0° angles and one 180° angle.

If two vertices are equal, it has one 0° angle and two undefined angles.

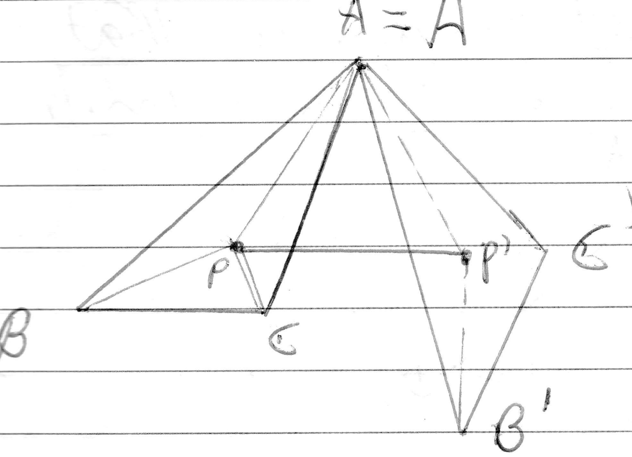
Theorem 39 → A quadrilateral is a parallelogram if its diagonals bisects each other.

Voltando ao estudo: Ⓐ

Triangle Inequality



Now, $\angle BAC' = \angle BAC + \angle CAC' = 90°$, so $BC' = 5$ by Pythagoras' Theorem. Therefore, the value of $PA + PB + PC$ is at least 5, and the value will be exactly 5 if B, P, P', and C' are collinear.

Thus, to attain the minimum value, P and P' would have to lie on BC'.

If this happens, then

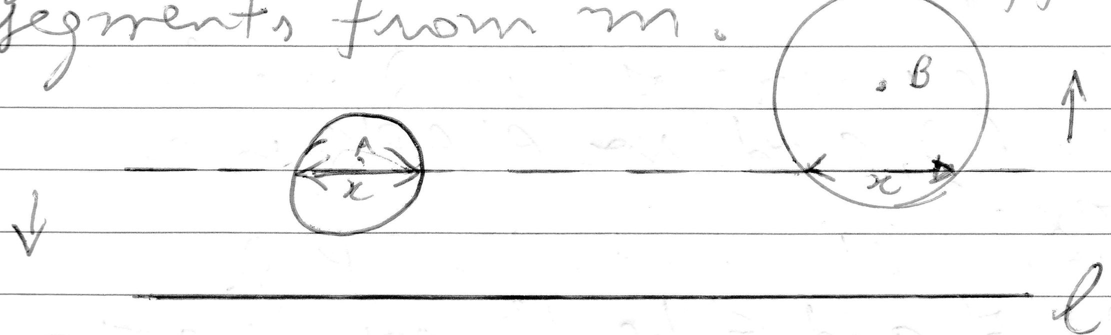
$\angle APB = 180° - \angle P'PA = 120°$ and

$\angle CPA = \angle C'P'A' = 120°$.

Now, this defines the point P uniquely, and since all three angles of triangle ABC are less than 120°, P is indeed inside Δ ABC.

Pág. 225(240) - Example 7.3.8.

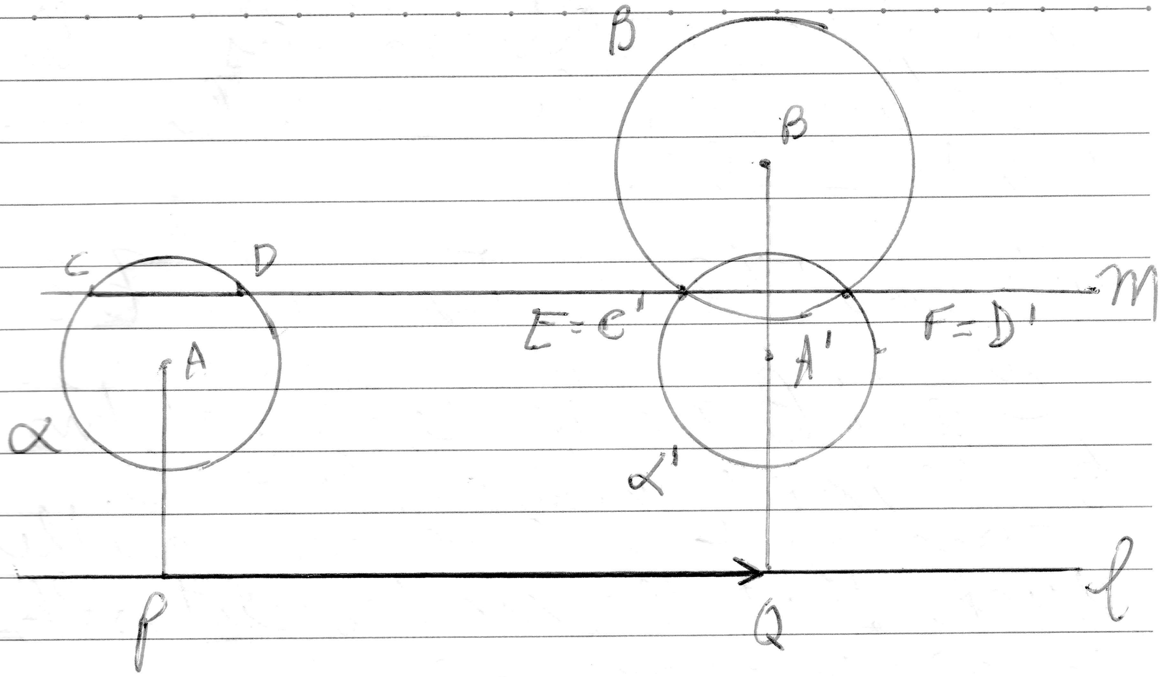
A and B are the centers of two circles on the same side of line l.
Construct a line m, parallel to l, such that the circles cut off equal segments from m.



Solution: Let α and β denotes circles centered at A and B, respectively.
Let P and Q be the feet of the perpendiculars from A and B upon l, respectively. The solution here is obtained by using the translation T_{PQ}.
Under this translation,
the circle α is mapped to the circle α' centered at A', as his figure below.

Veja figura

⟹



Since the image of P is Q, we have $AA' = PQ$, and so $A'AP'Q$ is a rectangle.

Thus, A' must be on BQ.

Let E and F be the points at which the translated circle intersects β, and let m be the line EF, cutting α at C and D.

Then $E = C'$ and $F = D'$, so that

$$EF = C'D' = CD.$$

The triangle inequality therefore states that

$$(x+y, x+y)^{1/2} \leq \|x\| + \|y\|;$$

on squaring and expanding, this is seen to be equivalent to the

CAUCHY-SCHWARZ INEQUALITY.

7) 033---Elementary Differential Geometry.pdf
→ 335 pp.

Pág. 22 (36) - Chapter 2 - Curve Theory.

Pág. 31 (45) - último parágrafo.

The first inequality above holds (acima detém) because of the
"TRIANGLE INEQUALITY"

$| \|x\| - \|y\| | \leq \|x-y\|$.

Pág. 66 (80)

The spherical side lengths are α_i, β_i and γ_i.

The triangle inequality gives that

$$\alpha_i \leq \beta_i + \gamma_i \qquad (2.18)$$

Using the spherical triangle with the vertices

$$\frac{a_{i+1} - a_i}{\|a_{i+1} - a_i\|}, \frac{a_{i+1} - a}{\|a_{i+1} - a\|} \text{ and }$$

$$\frac{a_{i+2} - a_{i+1}}{\|a_{i+2} - a_{i+1}\|}$$

We obtain analogously:

$$\alpha_{i+1} \leq \beta_{i+1} + \gamma_{i+1} \qquad (2.19)$$

We summarise:

$$K(P_2) - K(P_1) = \beta_i + \beta + \beta_{i+1} - (\alpha_1 + \alpha_{i+1})$$

$$= \beta_i - \alpha_i) + \beta + (\beta_{i+1} - \alpha_{i+1})$$

$\geqslant -\gamma_i + \beta - \gamma_{i+1}$

$= 0,$

and hence $\kappa(P_2) \geqslant \kappa(P_1)$.

(b) Let us now assume that we are dealing with the equality case:

$$\kappa(P_2) = \kappa(P_1).$$

Then we must have equality in the triangle inequality (2.108),

$$\alpha_i = \beta_i + \gamma_i$$

Pág. 67 (81) $\Longrightarrow$

Thus the vertices of the spherical triangle lie on a great circle, i.e,

$a_i - a_{i-1}$, $a - a_i$ and $a_{i+1} - a_i$

lie in a two-dimensional subspace $V_1 \subset \mathbb{R}^3$. For suitable

$\lambda_1, \lambda_2 \in \mathbb{R}$ we have that

$$a_i - a_{i-1} = \lambda_1 \cdot (a - a_i) + \lambda_2 (a_{i+1} - a_i)$$

and thus

$$a_{i-1} = -\lambda_1 \cdot a - \lambda_2 \cdot a_{i+1} + (1+\lambda_1+\lambda_2)\cdot a_i \quad (2.20)$$

We now suppose that a_i, a and a_{i+1} are not collinear,

else (senso) we would be dealing with case (1). Hence those three points span an affine plane

$$E \subset \mathbb{R}^3.$$

Because of (2.20) we also have $a_{i-1} \in E$.

It can be shown analogously that

$a_{i+2} \in E$. This proves (2).

Pag. 71 (85) →

To estimate the third term of (2.27) we observe that the triangle inequality for the spherical distances gives the inequality

$$|\alpha_j - \beta_j| \le \gamma_{j-1} + \gamma_j \quad (2.29)$$

Pag. 266 (284) – Appendix A

Shapiro effect via Fermat's principle

If a light signal is sent from Earth, located on the x-axis at $-x_E$, to Venus, say, which is located behind the Sun at x_V, as shown in Fig. 7.1, the light ray will be bent (dobrado) as it passes the gravitational field of the Sun!

Clocks will thus be slowed down, and the time it takes the ray to bounce (saltar) off the surface of Venus and return to Earth will be longer than if the sun were not present.

The simplest mechanical analog of the index of refraction is $n = \sqrt{(1-4\phi/c^2)}$, where ϕ is the potential energy per unit mass. We will justify this choice shortly. Since the gravitational field of the Sun makes the medium optically denser, ϕ can be identified as the gravitational potential, $-GM/r$, where G is Newton's gravitational constant, M the mass of the Sun, and

$r = \sqrt{(R^2 + x^2)}$ is the distance from the center of the Sun to Venus, with R as the Sun's radius.

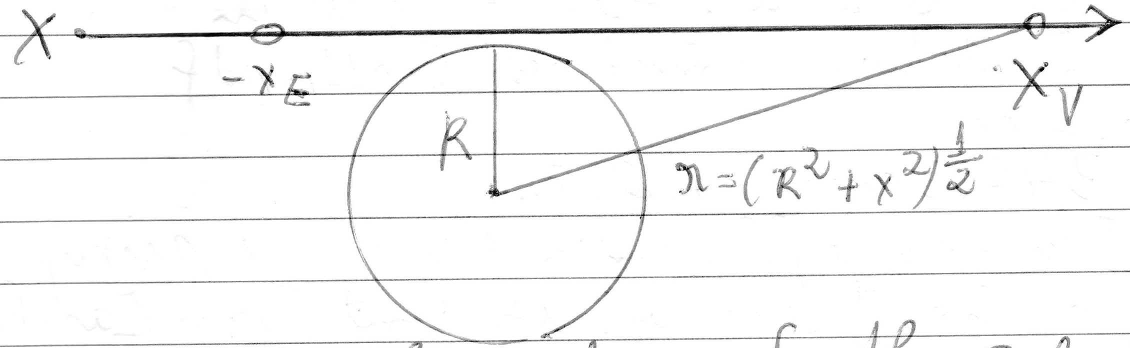

Fig. 7.1. The set-up for the ~~Spho~~ Shapiro effect.

Pág. 347(373)

Now, according to Fermat's principle, (7.2.3) the propagation time τ along a ray connecting the two end points $-x_E$ and x_V is given by

$$\tau = \int_{-x_E}^{x_V} \frac{\eta(r)}{c}\, dx = \int_{-x_E}^{x_V} \frac{\sqrt{(1+2\alpha/r)}}{c}\, dx,$$

where

$\alpha := 2GM/c^2$ is commonly referred to as the Schwarzschild radius.

Consider $\mathbb{R}^3$ with the Lorentz quadratic form $q_L(v) = -t^2 + x^2 + y^2$ (compare B.2).

The cone $\{q_L(v) < 0\}$ break up into two subsets

$\{t > +\sqrt{x^2+y^2}\} \cup \{t < -\sqrt{x^2+y^2}\}$.

I fix the positive choice $t > 0$ throughout.

Pag. 43(62) – 3.9 Hyperbolic distance

$-v \cdot_L w = \cosh d(P, Q)$, so that

$$d(P, Q) = \operatorname{arccosh}(-v \cdot_L w); \quad (4)$$

in other words,

$$d(P, Q) = \operatorname{arccosh}(t_1 t_2 - x_1 x_2 - y_1 y_2).$$

Lemma: the Lorentz inner product satisfies

$$-v \cdot_L w = t_1 t_2 - x_1 x_2 - y_1 y_2 \geq 1,$$

with equality only if $P = Q$.

→ See also Exercise 3.11.)

Hence the distance $d(P, Q)$ is defined and positive unless (a mos ser que) $P = Q$.

Pag. 49(68) – 3.13 The hyperbolic plane is non-Euclidean

Theorem: Let $\mathcal{L}$ be a hyperbolic line and P a point not lying on $\mathcal{L}$.
Then there exists a unique perpendicular line PQ to $\mathcal{L}$ through P.
Moreover,

(1) if M is orthogonal to PQ in P, then the lines $\mathcal{L}$ and M diverge;

(2) there exists (exists) an angle $\theta < \frac{\pi}{2}$ with the property that if $\mathcal{L}'$ is a line through P, then $\mathcal{L}'$ meets $\mathcal{L}$ if and only if the angle of $\mathcal{L}'$ and PQ is less than θ
(See Figure 3.13.)

Pág. 269 (290) - 2 -
Some Facts from Non-Euclidean Geometry.

(Angle sum of T) = π.

Let's take our first look at how these new geometries differ from Euclid's.

A very familiar theorem of Euclidean geometry states that in any triangle T.

$$\text{Angle sum of } T = \pi.$$

As indicated in [16], this result is actually equivalent to the

parallel axiom.

It follows that in non-Euclidean geometry the angle sum of a triangle differs from π. To measure this difference, we introduce the so-called angular excess E:

$$E(T) \equiv (\text{Angle sum of } T) - \pi.$$

Euclidean geometry is thus caracterized by the vanishing of E(T).

Note that, unlike the original formulation of the parallel axiom, this statement can be checked against experiment:

construct a triangle, measures its angles, and see if they add up to π.

Gauss was the first person to ever conceive of the possibility that physical space might not be Euclidean, and he even (late) attempted the above experiment, using three mountain tops as the vertices of his triangle, and using light rays for its edges.

Within the accuracy permitted by his equipment, he found $\underline{\underline{E = 0}}$.

Quite correctly, GAUSS did not conclude that physical space is definitely Euclidean in structure, but rather (em vez de) that if it is not Euclidean then its deviation from Euclidean geometry is extremely small.

Let us return from physics to mathematics. Using pure logic to work out the consequences of (2) and (3), both Gauss and Johann Heinrich Lambert independently discovered that the two non-Euclidean geometries departed from Euclid's in opposite ways:

- In spherical geometry the angle sum is greater than π: $E > 0$.

- In hyperbolic geometry the angle sum is less than π: $E < 0$.

Furthermore, they discovered the striking (impressionante) fact $E(T)$ is completely determined by the size of the triangle.
More precisely, $E(T)$ is simply proportional to the area $A(T)$ of the triangle T:

$$E(T) = k\,A(T),$$

where k is a constant that is positive in spherical geometry, and negative in hyperbolic geometry!

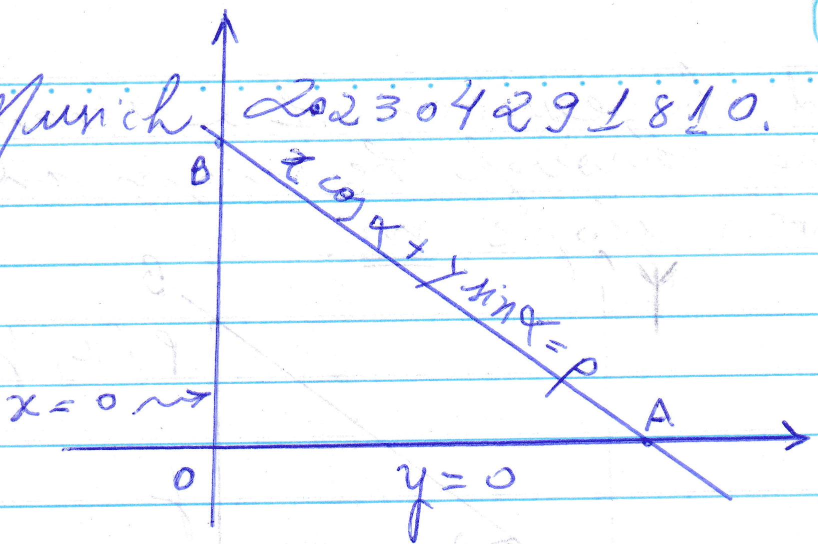
Stenis Munich. 2023042918 10.



- equation of the line is $x\cos\alpha + y\sin\alpha = p$ (1)
- coordinate axes are $x = 0$ and $y = 0$. (2)
- coordinate of O are $(0, 0)$. (3)

Solving 1 and 2,

a) coordinate of A are $\left(\frac{p}{\cos\alpha}, 0\right)$

b) coordinate of B are $\left(0, \frac{p}{\sin\alpha}\right)$

↳ solving 1 and 3

Also:

$$AB = \sqrt{\left(\frac{p}{\cos\alpha} - 0\right)^2 + \left(0 - \frac{p}{\sin\alpha}\right)^2} =$$

$$= \sqrt{\frac{p^2}{\cos^2\alpha} + \frac{p^2}{\sin^2\alpha}} =$$

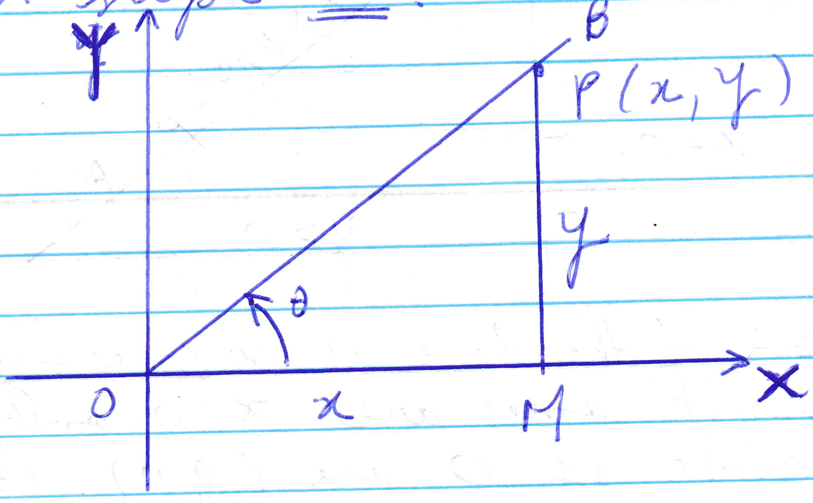
$$= \sqrt{\frac{p^2(\sin^2\alpha + \cos^2\alpha)}{\cos^2\alpha \sin^2\alpha}} =$$

$$\frac{p}{\cos\alpha \sin\alpha}$$

$OB = \frac{p}{\sin\alpha}$, $OA = \frac{p}{\cos\alpha}$

/ /

Find the equation of a straight line passing through the origin and having a given slope m.



∴ OB → straight line through O making an angle θ with the positive direction of x-axis.

Then its slope $m = \tan\theta$

Let $P(x, y)$ be any point on the line.

Draw $PM \perp$ x-axis so that

$OM = x$, $MP = y$.

From the right angled $\Delta\, OMP$, we have

$$\tan\theta = \frac{MP}{OM} \quad \text{or} \quad \frac{y}{x} = m$$

$$\therefore \quad y = mx$$

Research: Including Pythagoras theorem

$a^2 + b^2 = c^2$ (retangle triangle)

obs: Inverse

equation:

$0 + M$
$\therefore$
$(0, 0) + (M, 0)$
or
$(x_1, y_1) + (x_2, y_2)$

$\therefore (x_1, y_1) + (M, y_2)$

distance $\overline{OM}$ =

$\sqrt{(x_1 - M)^2 + (y_1 - y_2)}$ obs: slope

$\therefore$

$O = A$ and $P = B$.

See: $O = A$.
$P = B$.
$M = O + M$ (slope) $\therefore$ equation

$p = x - \cos\alpha + y \cdot \sin\alpha$ obs: checar $\begin{cases} y - \sin\alpha \\ \text{or} \\ y \operatorname{sen}\alpha \end{cases}$

Δ OMP is Pythagoras triangles.

SÃO DOMINGOS

Em resumo: Eu estou fazendo a unificação da equação da linha com a equação do triângulo retângulo pitagórico.

Há portanto, uma equação principal que poderá ser resolvida com os cálculos trigonométricos mais a equação da linha e uma subequação utilizando-se a equação de pitágoras. (triângulo inverso)

A primeira equação tem como origem (0,0) x-axis and y-axis

∴ x-axis → abscissae

y-axis → ordinate

A segunda equação em relação ao ponto M, origem do ângulo reto (90°).

Interessante:

Tive uma idéia:

a) criar equações trigonométricas em relação ao ponto M.

Obs: objetivo é fazer calculos complementares em relação aos cálculos trigonométricos tradicionais.

a_1) primeiras equações em relação ao ponto O (0,0)

a_2) segundas equações em relação ao ponto M (x_2, y_2)

Importante:

Estas equações serão úteis para manter a integridade dos cálculos aplicáveis à curvatura tempo-espaço de Einstein.

↳ dinâmica.

Falando em pefeit Einstein vejamos:

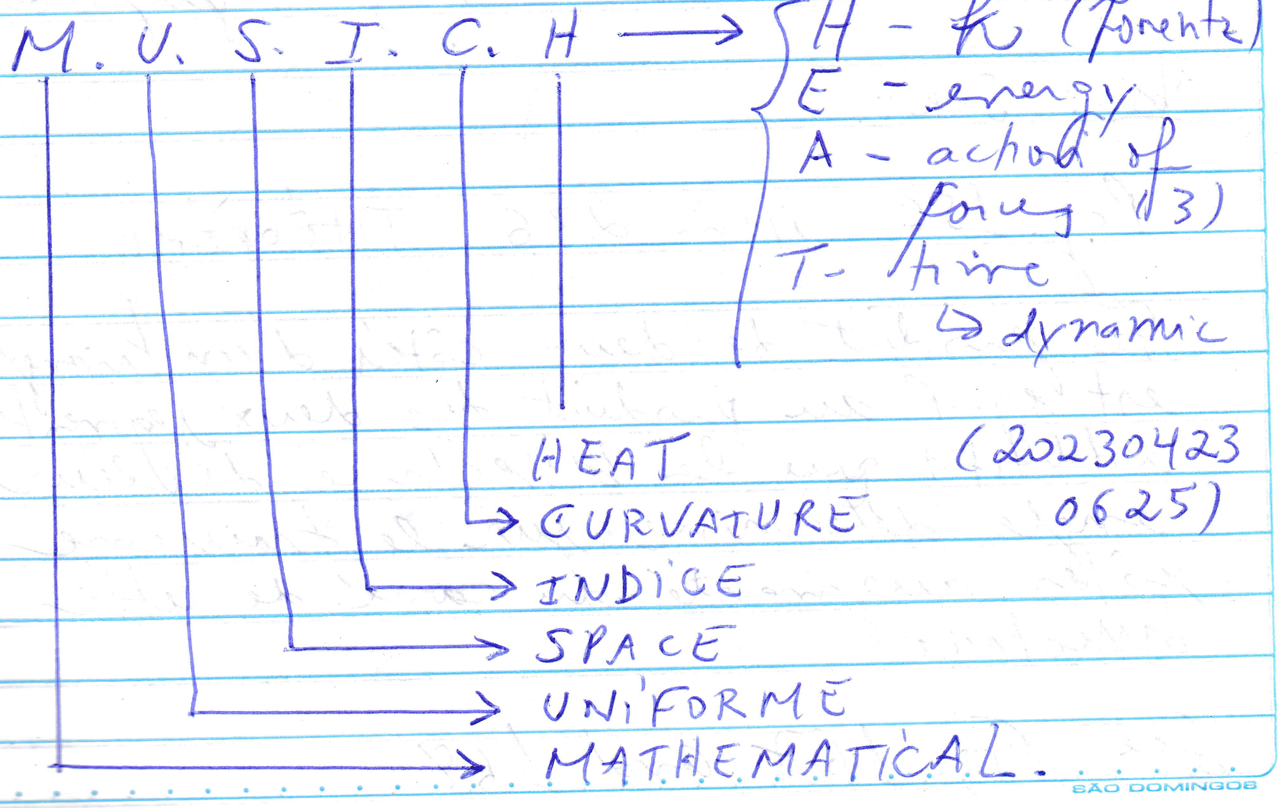
A unificação da teoria da relatividade e da teoria quântica depende do ajuste das equações à nova realidade considerando a gravidade como efeito das forças fundamentais da física.

a) eletromagnetismo;
b) força forte e
c) força fraca.

∴ A gravidade não existe!!!

Tanto é verdade, que no ambiente quântico a gravidade é desprezada por ser inexistente e o que há é a existência das forças fundamentais da física aplicáveis ao ambiente quântico.

Vejamos a seguinte equação:



M. U. S. I. C. H
H - h (Lorentz)
E - energy
A - achord of forces (3)
T - time
dynamic

25. Geometria - Posição, Métrica e

Analítica – Curso Objetivo
Livro 25
Mauro Gruspan, Jorge Kritomian

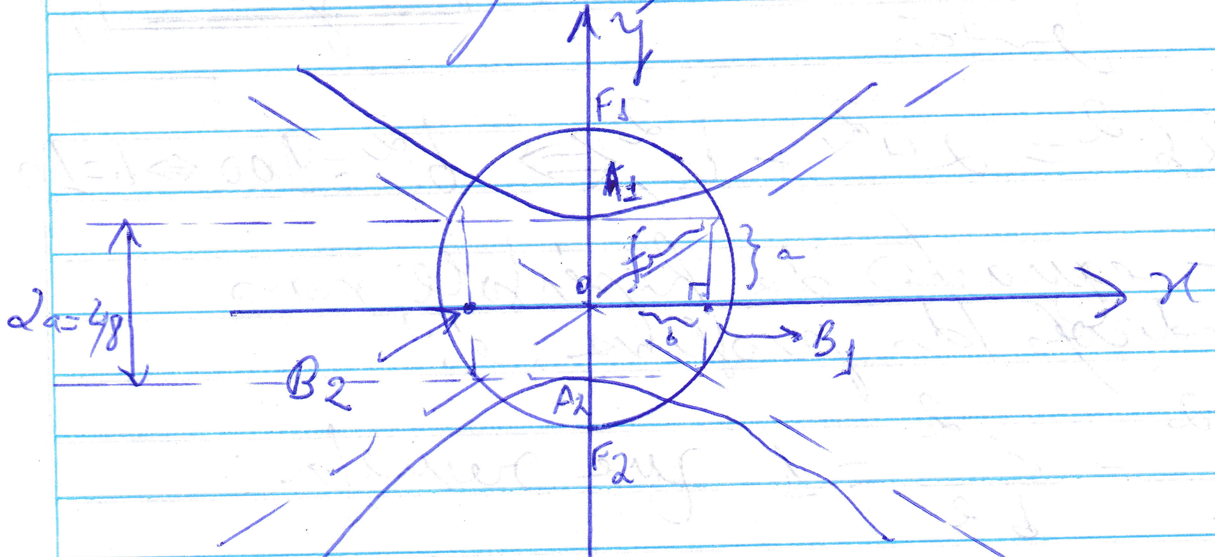
Pag. 157 – nº 16

Determinar a equação da hipérbole cujos focos estão situados simetricamente em relação à origem e no eixo das ordenadas, sabendo que sua excentricidade vale $\frac{13}{12}$

↳ valor ajustável à pesquisa

e que a distância entre seus vértices vale 48 unidades

↳ ajustável à necessidade



Obs: Esta hipérbole pode representar a curvatura do espaço, acrescentado às equações trigonométricas tradicionais com a pitagórica (inversa).

→ início deste texto..

Calculando:

A partir do enunciado, temos:

Centro O (0,0)

- Eixo transverso: $2a = 48 \Leftrightarrow a = 24$
- Excentricidade:

$$e = \frac{f}{a} = \frac{13}{12} = \frac{f}{24} \Leftrightarrow f = 26$$

Como $f^2 = a^2 + b^2$ (Pitágoras), então

$$26^2 = 24^2 + b^2 \Leftrightarrow b^2 = 100 \Leftrightarrow b = 10$$

A equação da hipérbole, nas condições do problema, é:

$\frac{y^2}{a^2} - \frac{x^2}{b^2} = 1$, que resulta:

(seg)

$$\frac{y^2}{24^2} - \frac{x^2}{10^2} = 1 \Leftrightarrow \frac{y^2}{576} - \frac{x^2}{100} = 1$$

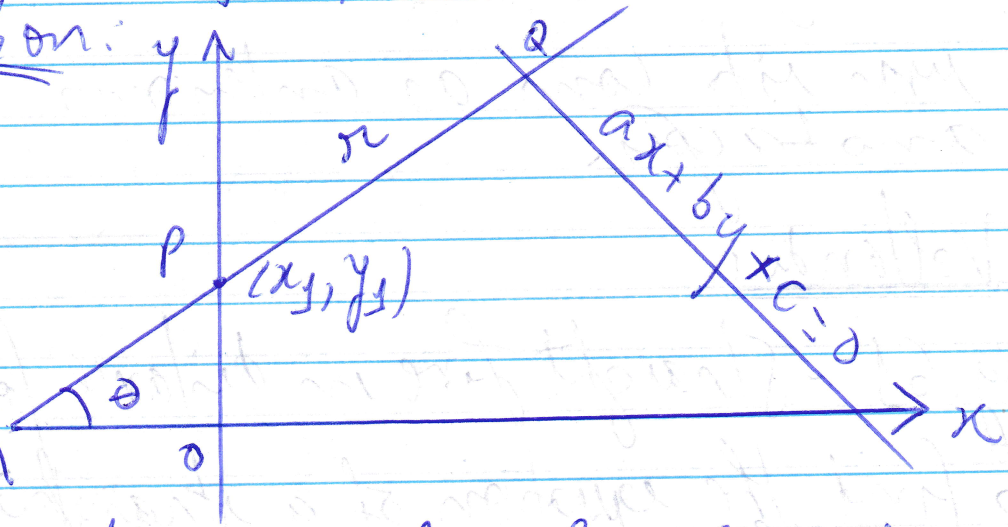
① Livro Co-ordinate Geometry

Pág. 64(67) - Example 5

Show that the distance of $P(x_1, y_1)$ from the line $ax+by+c=0$ in the direction making an angle θ with x-axis is

$$-\frac{ax_1+by_1+c}{a\cos\theta+b\sin\theta}$$

Solution:



Let the line through $P(x_1, y_1)$ and inclined at an angle θ with x-axis meet the line $ax+by+c=0$ in Q

Let $PQ = r$. We have to find r.

Co-ords. of ∴ Q are $(x_1 + r\cos\theta, y_1 + r\sin\theta)$

SÃO DOMINGOS

Q lies on $ax + by + c = 0$

$\therefore \; a(x_1 + r\cos\theta) + b(y_1 + r\sin\theta) + c = 0$

or

$(ax_1 + by_1 + c) + r(a\cos\theta + b\sin\theta) = 0$

or

$r(a\cos\theta + b\sin\theta) = -(ax_1 + by_1 + c)$

Hence $r = \dfrac{ax_1 + by_1 + c}{a\cos\theta + b\sin\theta}$, which

is the required distance.

obs: usar isto com as anteriores anotações.

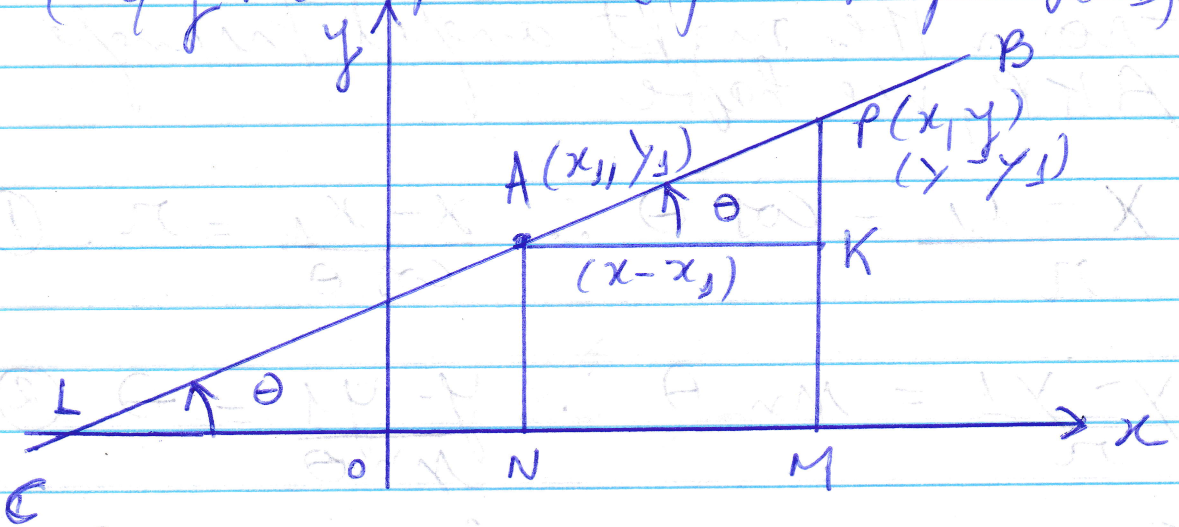
Voltando:

Pág. 61 - Straight line in distance form

To find the equation of a straight line passing through a given point (x_1, y_1) and making angle θ with the x-axis in the form

$$\frac{x - x_1}{\cos\theta} = \frac{y - y_1}{\sin\theta} = r$$

where r is the distance of any point (x, y) on the line from the point (x_1, y_1).



- Let $A(x_1, y_1)$ be the given point and AB the line through A making an angle θ with the x-axis.

- Let $P(x, y)$ be any point on line such that

$AP = r$.

(Pág. 62) cont.

- Draw AL and PM perpendicular on the x-axis and AK perpendicular on MP.

then $AK = NM = OM - ON = x - x_1$

$KP = MP - MK = MP - NA = y - y_1$

SAO DOMINGOS

$\angle KAP = \angle XLP = \theta$

From the right angled triangle AKP, we have

$$\frac{x - x_1}{r} = \cos\theta \quad \therefore \quad \frac{x - x_1}{\cos\theta} = r. \quad ①$$

$$\frac{y - y_1}{r} = \sin\theta \quad \therefore \quad \frac{y - y_1}{\sin\theta} = \theta \quad ②$$

From 1 and 2, we have

$$\frac{x - x_1}{\cos\theta} = \frac{y - y_1}{\sin\theta} = r$$

which is the required equation

Cor. From $\frac{x - x_1}{\cos\theta} = \frac{y - y_1}{\sin\theta} = r$,

we have $\frac{x - x_1}{\cos\theta} = r$ and $\frac{y - y_1}{\sin\theta} = r$

$x = x_1 + r\cos\theta$;

$y = y_1 + r\sin\theta \quad \therefore$

thus the co-ordinates of the general point on the line are $(x_1 + r\cos\theta, \; y_1 + r\sin\theta)$.

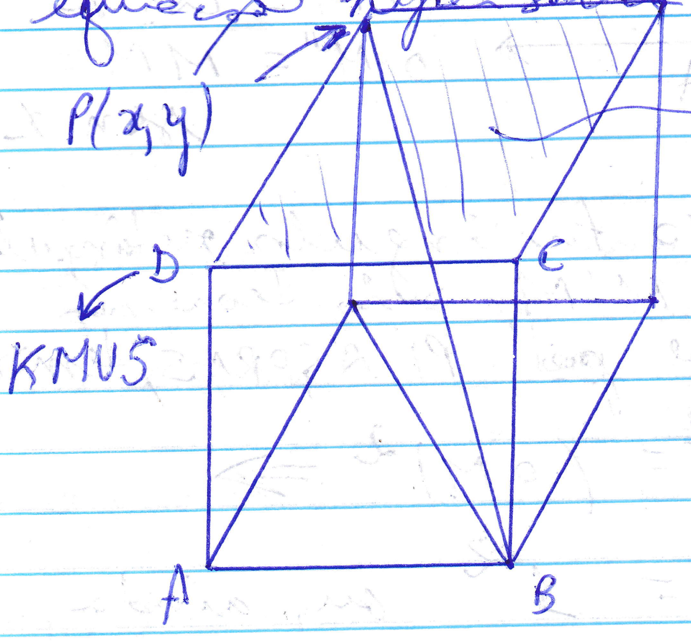
Usar o cálculo da distância entre os pontos diagonais de um cubo para calcular a distância entre a órbita elíptica de um planeta e o eixo x e y da equação hiperbólica.



P(x,y)
D
KMUS
C
A
B

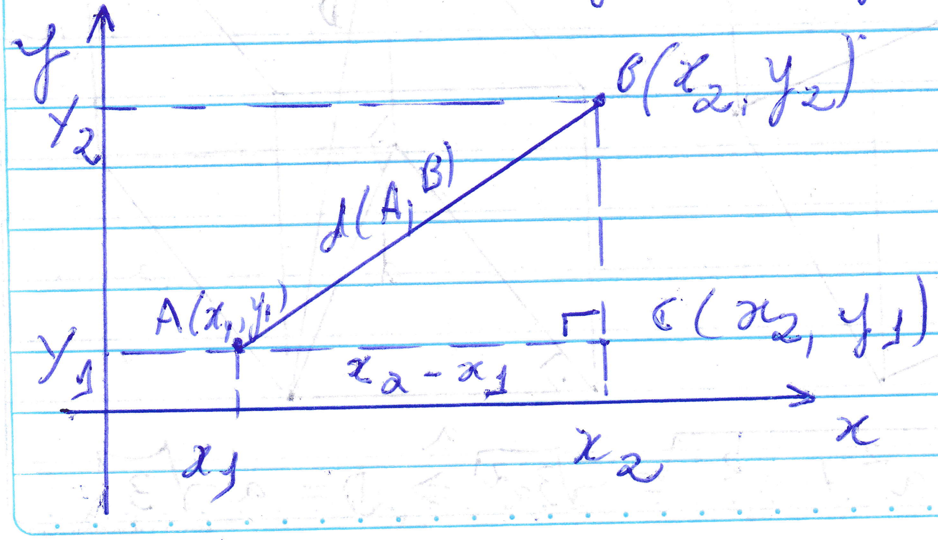
plano da órbita elíptica do planeta Terra ao redor do Sol.

□ ABCD representa o plano da equação hiperbólica

$\overline{AB}$ = abscissa x

$\overline{DA}$ = ordenada y

Distância entre dois pontos no plano cartesiano:



y
y_2
$B(x_2, y_2)$
$d(A, B)$
$A(x_1, y_1)$
y_1
$C(x_2, y_1)$
$x_2 - x_1$
x
x_1
x_2

Pitágoras.

$[d(A,B)]^2 = [d(A,C)]^2 + [d(B,C)]^2$

Sendo $\overline{AC} \,//\, Ox$ e $\overline{BC} \,//\, Oy$, temos:

$d(A,C) = |x_2 - x_1|$ e

$d(B,C) = |y_2 - y_1|$

$d(A,B)^2 = |x_2 - x_1|^2 + |y_2 - y_1|^2$

Como:

$|x_2 - x_1|^2 = (x_2 - x_1)^2$ e

$|y_2 - y_1|^2 = (y_2 - y_1)^2$, concluímos

que a distância entre os pontos A e B é dada

$d(A,B)^2 = (x_2 - x_1)^2 + (y_2 - y_1)^2$.

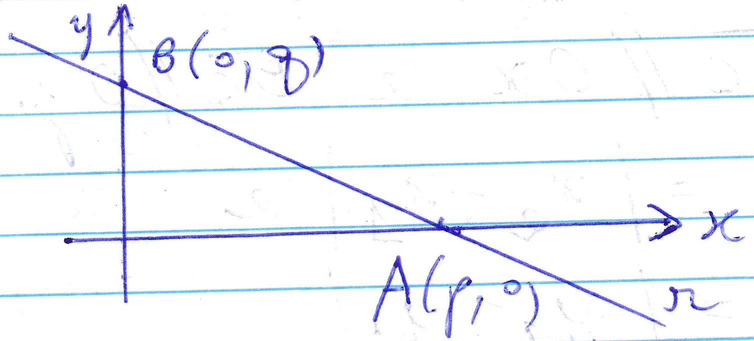
$$\boxed{d(A,B) = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}}$$

Voltando à equação reduzida da elipse:

$d(P,F_1) + d(P,F_2) = 2a \Rightarrow$

/ /

Antes de voltar:



Consideremos uma reta r que intercepta o eixo x no ponto A(p,0) e o eixo y no ponto B(0,q), com $p \neq 0$ e $q \neq 0$.

O coeficiente angular dessa reta é:

$$m = \frac{q-0}{0-q} = \frac{q}{-p} = -\frac{q}{p}$$

Então, a equação da reta r é:

$$y - y_1 = m(x - x_1) \Longrightarrow$$

$$y - 0 = -\frac{q}{p}(x-p)$$

$$y = -\frac{q}{p}x + q$$

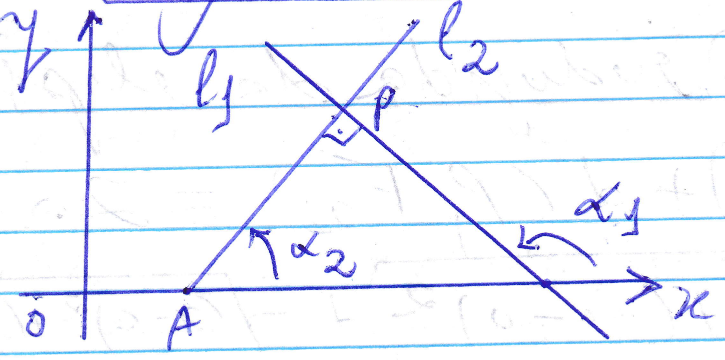
$$py = -qx + pq$$

$$qx + py = pq.$$

Dividindo ambos os membros por $pq \neq 0$, temos:

$$\frac{qx}{pq} + \frac{py}{pq} = \frac{pq}{pq} \Rightarrow \frac{x}{p} + \frac{y}{q} = 1$$ ///

Sec. Posições relativas de duas retas



l_1 e l_2 são perpendiculares ($l_1 \perp l_2$).

Consideremos duas retas l_1 e l_2 concorrentes num ponto P, de tal forma que nenhuma delas seja vertical e $l_1 \perp l_2$.
Do triângulo APB, vem

$$\alpha_1 = \alpha_2 + 90^\circ = tg\,\alpha_1 (\alpha_2 + 90^\circ)$$

$$tg\,\alpha_1 = \frac{sen(\alpha_2 + 90^\circ)}{cos(\alpha_2 + 90^\circ)}$$

$$tg\,\alpha_1 = \frac{sen\,\alpha_2 . cos\,90^\circ + sen\,90^\circ . cos\,\alpha_2}{cos\,\alpha_2 . cos\,90^\circ - sen\,\alpha_2 . sen\,90^\circ}$$

$$tg\,\alpha_1 = \frac{cos\,\alpha_2}{sen\,\alpha_2} \Rightarrow tg\,\alpha_1 = \frac{1}{tg\,\alpha_2}$$

Como $tg\,\alpha_1 = m_1$ e $tg\,\alpha_2 = m_2$, temos

SÃO DOMINGOS

$tg\,\alpha_1 = -\dfrac{1}{tg\,\alpha_2} \Leftrightarrow m_1 = -\dfrac{1}{m_2}$.

Voltando:

Equação reduzida da elipse

$d(P,F_1) + d(P,F_2) = 2a \Rightarrow$

$$\sqrt{(x+c)^2+(y-0)^2} + \sqrt{(x-c)^2+(y-0)^2} = 2a$$

$$\sqrt{(x+c)^2+y^2} = 2a - \sqrt{(x-c)^2+y^2}$$

Tendo como: $F_1(\underset{\substack{\uparrow\\ x}}{-c},0)$ e $F_2(\underset{\substack{\uparrow\\ x}}{c},0)$

$$x-(-c) = \boxed{(x+c)^2}$$

Elevando os dois membros ao quadrado:

$$(x+c)^2+y^2 = 4a^2 - 4a\sqrt{(x-c)^2+y^2} + (x-c)^2+y^2$$

Resolvendo a equação: teremos

$$\cancel{x^2} + 2cx + \cancel{c^2} + \cancel{y^2} =$$

$$4a^2 - 4a\sqrt{(x-c)^2+y^2} + \cancel{x^2} - 2cx + \cancel{c^2} + \cancel{y^2}$$

Eliminando os dois lados, teremos:

$$4a\sqrt{(x-c)^2+y^2} = 4a^2 - 4cx$$

Dividindo os 2 membros por 4, teremos:

$$a\sqrt{(x-c)^2+y^2} = a^2 - cx$$

Elevando os dois membros ao quadrado:

$$a^2[(x-c)^2+y^2] = (a^2-cx)^2$$

$$a^2(x^2 - 2cx + c^2 + y^2) = a^4 - 2a^2cx + c^2x^2$$

$$a^2x^2 - \cancel{2a^2cx} + a^2c^2 + a^2y^2 =$$

$$a^4 - \cancel{2a^2cx} + c^2x^2$$

$$x^2(a^2+c^2) + a^2y^2 = a^2(a^2-c^2)$$

Como ~~$a^2 = b$~~ $a^2 = b^2 + c^2$, podemos escrever

$$a^2 - c^2 = b^2$$

$$b^2x^2 + a^2y^2 = a^2b^2$$

SÃO DOMINGOS

Dividindo os dois membros por a^2b^2 ($b>0$, $a>0$):

$$\frac{b^2x^2}{a^2b^2}+\frac{a^2y^2}{a^2y^2}=\boxed{\frac{x^2}{a^2}+\frac{y^2}{b^2}=1}$$

Como o eixo maior da elipse está contido no eixo x e a e b são positivos, então $a > b$. Assim, o denominador de x^2 é maior que o denominador de y^2.

Resumo:

$\frac{x^2}{a^2}+\frac{y^2}{b^2}=1$ é a equação da elipse quando o eixo maior está contido no eixo x.

$\frac{x^2}{b^2}+\frac{y^2}{a^2}=1$ é a equação da elipse quando o eixo maior está contido no eixo y.

IMPORTANT: ✡

Aprofundar pesquisa para desenvolver os cálculos como uma função hiperbólica ou como uma função parabólica.

⇒ acho melhor, pois permite o uso de retas paralelas à diretriz e o uso do arco de circunferência como um elemento verificador redundante dos cálculos. + eixo de simetria

etc...

Logaritmos:

$\log_{10} 1385 = 3,141449...$

Important:

$\log_a b$ para existir, devemos ter

- logaritmando positivo: $b > 0$
- base positiva e diferente de 1:

$a > 0$ e $a \neq 1$.

SÃO DOMINGOS

Usar o logaritmo para representar a equação da curvatura do espaço.

Ex: Para quais valores reais de x existe

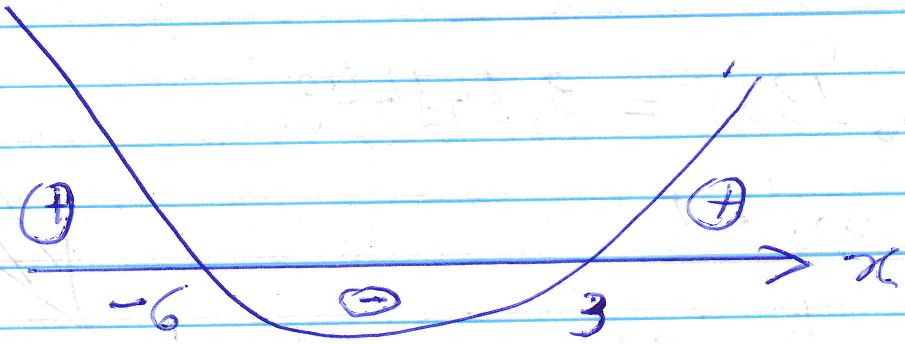
$$\log_{x+1}(x^2+3x-18)?$$

Devemos ter: $\begin{cases} x^2+3x-18 > 0 & (I) \\ x+1 > 0 \text{ e } x+1 \neq 1 & (II) \end{cases}$

Resolvendo as condições (I) e (II), temos:

$x^2+3x-18 > 0 \quad (I)$

$$x = \frac{-3 \pm 9}{2} \begin{cases} \nearrow x' = 3 \\ \searrow x'' = -6 \end{cases}$$

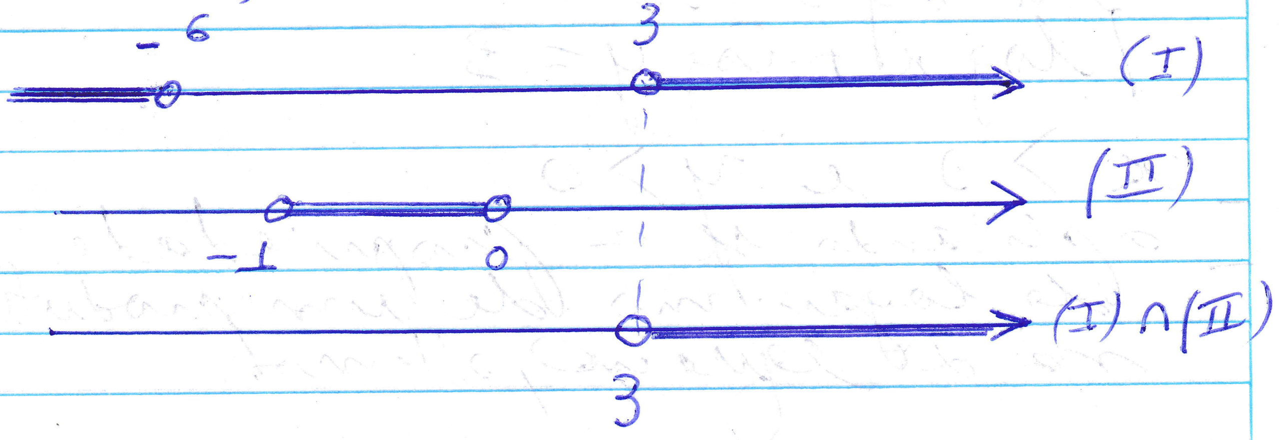


$x+1 > 0 \quad \text{e} \quad x+1 \neq 1 \quad (II)$

$\downarrow \qquad\qquad\qquad\qquad \downarrow$

$x > -1 \qquad\qquad\qquad x \neq 0$

Fazendo a intersecção dos conjuntos soluções de (I) e (II), obtemos:



$\log_{x+1}(x^2+3x-18)$ existe para $x>3$.

Propriedades dos logaritmos:

1) $\log_b (a.c) = \log_b a + \log_b c$, com
$a>0$, $c>0$ e $1 \neq b > 0$

2) $\log_b \frac{a}{c} = \log_b a - \log_b c$, com

$a>0$, $c>0$ e $1 \neq b > 0$.

3) $\log_b a^n = n \log_b a$, com
$a>0$, $1 \neq b > 0$ e $n \in \mathbb{R}$.

(prestar atenção)

Usando as propriedades dos logaritmos

SÃO DOMINGOS

/ /

na resolução de sistemas:

$$\begin{cases} x + y = 100 \\ \log x + \log y = 3 \end{cases}$$

$x > 0$ e $y > 0$

– aplicando-se a propriedade do logaritmo de um produto na 2ª equação, obtemos:

$$\log x + \log y = 3 \Rightarrow$$

$$\log(x \cdot y) = 3$$

– Usando a definição de logaritmo, vem:

$$\log(x \cdot y) = 3 \Rightarrow xy = 10^3$$

$$xy = 1000$$

Temos então o sistema equivalente

$$x + y = 110 \quad (I)$$

$$xy = 1000 \quad (II)$$

De (I), vem: $x = 110 - y$ (III)

Substituindo (III) em (II), resulta:

$(110 - y)\, y = 1000$

$y^2 - 110y + 1000 = 0$ $\begin{cases} y' = 100 \\ y'' = 10 \end{cases}$

Substituindo os valores de y em (III), obtemos:

$y = 100 \Rightarrow x = 110 - 100 \Rightarrow x = 10$

ou

$y = 10 \Rightarrow x = 110 - 10 \Rightarrow x = 100.$

Como esses valores satisfazem as condições de existência, temos:

$x = 10$ e $y = 100$ ou

$x = 100$ e $y = 10$

$S = \{(10, 100), (100, 10)\}$

Cologaritmo:

$\log_a \frac{1}{b} = -\log_a b = \operatorname{colog}_a b,$

com $b > 0$ e $1 \neq a > 0$

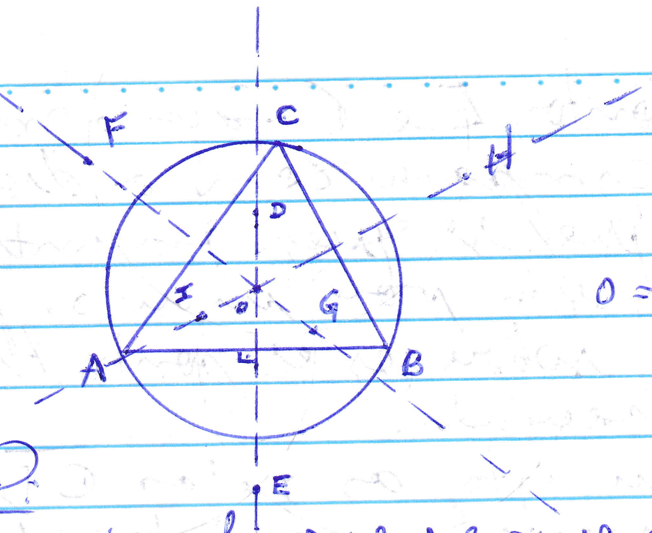
Usando mediatrices.

SÃO DOMINGOS



O = circumcentro
(centro do
círculo)

Demonstração:

1) Pegue o círculo que se quer achar o centro.

2) Desenhe um triângulo inscrito no círculo = ΔABC

3) Ache a mediatriz das faces do triângulo inscrito.

3a) Comece pelo ponto A;

3b) Faça o mesmo ponto B;

3c) depois faça no ponto C.

Desta forma, você achou todas as mediatrizes das faces de um triângulo inscrito.

Marcando os ponto:

3a) No ponto A faça um círculo com diâmetro maior que o raio e menor que o diâmetro do círculo no qual está inserido o ~~círculo~~ triângulo inscrito.

3b) No ponto B faça outro círculo utilizando-se da mesma medida utilizada no ponto A. Desta forma, você encontrará os pontos D e E, trace uma reta tracejada ligando estes pontos, neste ponto, esta reta irá interceptar a reta AB (face de um triângulo), fazendo um ângulo 90°.

3c) Com o compasso, utilize a mesma medida utilizada para desenhar os outros círculos sobre o ponto C. Neste momento, você acaba de criar os outros pontos para você achar a mediatriz das duas faces do triângulo inscrito restantes, ou seja, FG (pontos) e os pontos ~~D~~ H e I.

Portanto, teremos as retas:

a) $\overline{DE}$ (interseção dos círculos criados a partir dos pontos A e B).

b) $\overline{FG}$ e HI criadas pelo círculo criado sobre o ponto C.

obs: El circuncentro de un triángulo rectángulo se halla en el punto medio de su hipotenusa.

Important: Este procedimento para achar o centro de um círculo vale para o caso de uma circunferência inscrita em um triângulo qualquer (não precisa ser um triângulo retângulo).

obs. Las bisectrices de los ángulos interiores de un triángulo se cortan en un solo punto que coincide con el centro de la circunferencia inscrita en él.

Atenção: Com o triângulo retângulo você poderá utilizar a mediatriz.

SÃO DOMINGOS

2023 05230633

Lavenda wrote A New Perspective on Thermodynamics, published in 2009, by returning to Carnot's original conception that work can only be done when there is a difference in temperature, and the necessity of closing the cycle before that work can be assessed.
More recently Lavenda has directed his interests to relativity by providing it with a new foundation based on non-Euclidean geometries.

(Book: A New Perspective on
Relativity —
Bernard H. Lavenda
An Odyssey in Non-Euclidean
Geometries) — 2012 — 695 pp.

Rather than measuring distances in terms of the usual Euclidean metric, distances are defined in terms of what is know as a cross-ratio, a perspective invariante of four points, which, for the space of velocities, just happens to be compounding of longitudinal Doppler shifts.
Doppler shifts are fundamental to relativity: oblique Doppler shifts describe aberration, while second

order ones describe length contraction, but rather than being in the direction of the motion are perpendicular to it.

The uniform rotating disc which is considered by some to be missing link in Einstein's formulation of general relativity, is exactly described by the hyperbolic metric in polar coordinates, named after the nineteenth century italian geometer Eugenio Beltrami, which predicts the circumference of the disc to be greater when in motion than when it is at rest. Thus a uniform rotating disc belongs to hyperbolic, and not Euclidean, space and so, too, does relativity.

Critica:

Questa analisi è quasi del tutto vera ma non perpendicolarmente, ma secondo un nuovo approccio matematico. (20230522)

email: bhlavenda@gmail.com

This analysis is almost entirely true, but not perpendicularly, but according to a new mathematical approach

* Lavenda: (text) email 202305230619

The Doppler is well know that it is linked to special relativity. But considering the longitudinal Doppler, the displacement is proportional to the ratio $c + v$ and $c - v$, where v is the speed of the mobile. This seems to contradict the fact that nothing can travel faster than the speed of light (Ritz's ballistic theory of light). This was mentioned in the book by Louis Essen (1972) who criticized special relativity saying it is just a new unit of measurement instead of a previous new theory.

(Distance, time, and velocity.
Which of the two do you want to keep constant?)

Also, the logarithm of the longitudinal Doppler is a distance in the hyperbolic plane (Poincaré), where c is a unit of measure and not an absolute speed. So it depends on the geometry you're considering.

Research and analysis:

Longitudinal Doppler Effect

The longitudinal Doppler effect considers the simple case of a source moving

directly towards you or away from you along a straight line.

The transverse Doppler effect considers what is observed when the observer is displaced in a direction perpendicular to the direction of the motion.

Answer:

① Tanto the longitudinal Doppler Effect quanto the transverse Doppler Effect usam como parâmetro a linha reta (straight line)
→ referencial.

Para mim, a questão toda está como nós entendemos o conceito de uma linha reta em um Universo curvo, sua projeção ortogonal e as suas decorrentes conseqüências sobre o mundo e o universo no qual nós estamos inseridos.

O valor do número PI, ou melhor, o meu novo valor do número PI – M.V.S. traduz este conflito intrínseco ao qual os nossos estudos estão submetidos de forma quase inquestionável, mas que para mim, está errado e incompleto, sujeito, portanto, ao questionamento inevitável.

excerpt_001.pdf

50 pp.

Pag. ~~#~~4 (find: Essen)

If time dilatation and space contraction due to motion are actual processes then there is no symmetry between observers in different inertial frames. The first postulate of relativity is therefore violated [Essen 71].

obs: Einstein used gedanken experiments which is an oxymoron.

(figure language)

Einstein [16] has to say about a pair of local observers on a rotating disc
→ time slowly.

Pág. 5 → velocidade da luz.

SÃO DOMINGOS

If the velocity of light is independent of the velocity of its source, how then can the outward journey of a light signal to an observer moving at velocity

v be $c+v$,

on its return it travels with a velocity $c-v$?

Although this violates the second postulate, such assertion appears in the expression for the elapsed time of sending out a light signal from one point to another and back again in the

Michelson-Morley experiment

whose null result they hope to explain.

They also appear alongside Einstein's relativity velocity composition law in his famous 1905 paper "On the Electrodynamics of Moving Bodies".

Important:

Also in that paper is his "definition" of the velocity of light as the ratio of

"light path" to the "time interval"!

But we are not allowed to measure the path of the light ray and determine the time it took, for c has been elevated to a universal constant.

How can two units of measurement be made constant by definition?"
Essen queries.

obs: Pag. 5 - Book:
(ref.) Lavenda - New Perspective on Relativity".

Resposta Geral:

1) Levando em consideração a Termodinâmica e a entropy com os seus devidos repercussões no mundo físico.

2) Tanto the longitudinal doppler effect quanto the transverse doppler effect usam um parâmetro de

observação referencial atinente aos movimentos dos objetos em estudo.

Answer to Lavenda (20230523)

✡ in italian..
(tradução para o inglês)

Dear Lavenda

In the first place, we must note that both the longitudinal and the transversal Doppler effect use a reference observation parameter relating to the movements of the objects under study and, consequently, we cannot consider the velocity (log Doppler) correct, as there is a mathematical divergence in the calculation process.

Gauss and Weber built electrodynamics on its basis considering magnetic and induction forces as a consequence of changes in electric forces, but Weber was a proponent of the theory of action at a distance, where the value of c tends to infinity, ceasing of being a constant and becoming a limit of measurement.

Gauss adhering to the exact opposite principle, considering that the impact is transmitted not instantly, but with a delay (delay), through an intermediate agent (rheon - standard microparticles).

Ritz reducing magnetic effects to efetric (electric)

coneito: to electrical one, initiated by Ampere, considering magnetism as a fiction.

Ritz's theory, unlike the Biot-Savart law does not contradict the law of conservation of momentum, following Maxwell's theory.

Ritz explained not only all magnetic effects, but also the phenomenon of electromagnetic induction discovered by Faraday.

The electrodynamic effects are a direct consequence of the Doppler effects and Ritz (effects).

The electrodynamic effect are a direct consequence of the spatio-temporal relationships (space-time) discovered by the Ritz and delay electrical signals.

Doppler and Ritz effects generate the same induction.

Another important aspect has to be considered, most possibilities have emerged in this quantum spacetime phenomenology, influencing the standard kinematics of SR in a different way:

either the Lorentz invariance is broken, which implies the existence of a privileged ~~frame~~ frame of reference, or the SR symmetries are warped, as in the so-called "Special Double Relativity" (DSR) scenario, so that a relativity principle is still present.

I say this, because Essen, claiming that the first postulate of relativity has been violated, because there is no symmetry and observers in different inertial frames.
(entre)
(in between)

Therefore, we need to do a deeper analysis of these paradigms.

Tome light can travel beyond the speed established by Einstein's theory, depending on the reference used in the study light has speed, but accessing it can violate this postulate. The speed of light is not only higher due to thermodynamics and entropy.

The matter is in the "light path" and "time interval", criticized by Essen, and I go further, which is not the case here.

Em relação $\underline{K}$, devemos adaptar aos cálculos obtidos pelo Π (M.U.S.) – Mathematical Uniforme Space.

$K \geq 0$, $K = 0$ e $K \leq 0$, apresentamos deformados em relação à curvatura do espaço-tempo.

Π (M.U.S.) representa a real realidade do comportamento do espaço-tempo do Universo.

Portanto, obteremos

$$K\widehat{\Pi} \geq 0,\ \underbrace{K\widehat{\Pi} = 0}\ \text{e}\ K\Pi \leq 0$$

esta parte do cálculo é uma representação teórica ajustada aos parâmetros matemáticos mas na realidade uma representação plana de um Universo curvilíneo apresenta as suas peculiaridades bem interessantes.

O interessante que esta representação irá ajudar a comprovar os cálculos do Π (M.U.S.), pois ao calcular uma linha reta (distância entre dois pontos) com a curvatura do Universo devidamente projetado sobre um plano, nós teremos uma real visão da realidade do Universo.

(394 pages) → Papelier
Chapitre I - Ligne Droite
I. Points en ligne droite.

1. Démonter que dans un quadrilatère complet les milieux des diagonales sont en ligne droite.
Disassemble that in a complete quadrilateral the diagonal media are in a straight line.
Demonstre que em um quadrilátero completo o meio diagonal está em linha reta.
(Interessante)

On appelle quadrilatère complet la figure formée par quatre droites dont trois ne passent pas par un même point et dont deux ne sont pas parallèles

The figure formed by four lines is called complete quadrilateral, three of which do not pass through the same point and two of which are not parallel.

A figura formada por quatro linhas é chamada quadrilátero completo, três dos quais não passam pelo mesmo ponto e duas dos quais não são paralelas.

English:

1. Prove that in a complete quadrilateral the midpoints of the diagonals are in a straight line.

We call complete quadrilateral the figure formed by four straight lines, three of which do not pass through the same point and two of which are not parallel.

These lines are called the sides of the quadrilateral, and the meeting points of these lines taken two by two are the vertices of the quadrilateral; there are therefore six vertices.

If we join the meeting points of any two sides at the point of the other two, we obtain a line the diagonal of the quadrilateral. We then see that there are three diagonals and we propose to demonstrate that the midpoints of these diagonals are in a straight line.

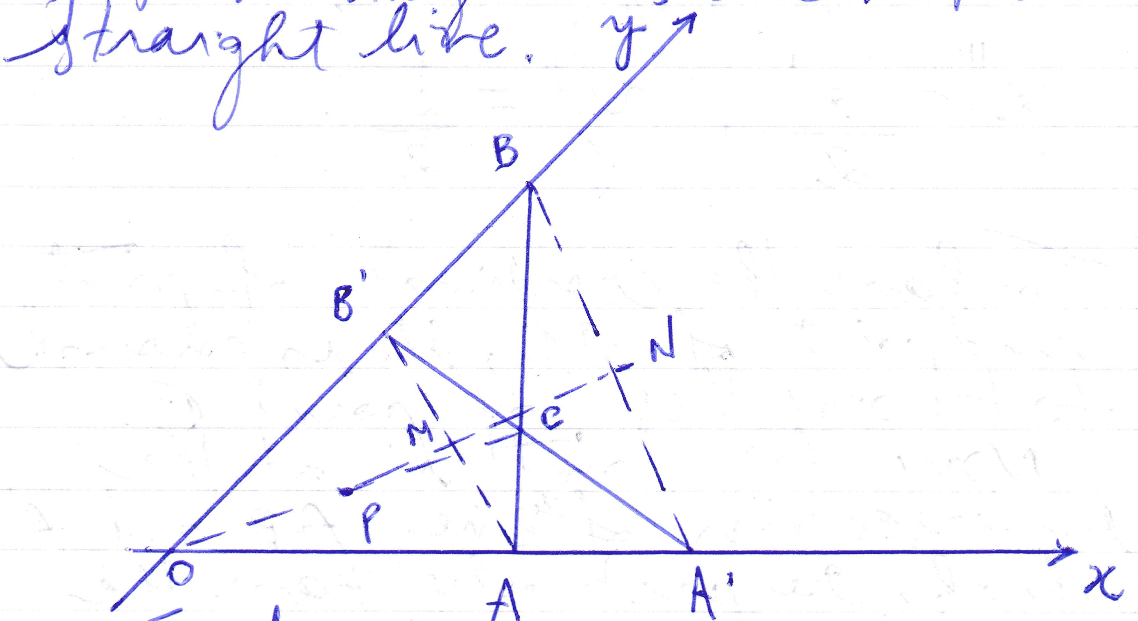

Fig. 1.

Let us take as coordinate axes two sides of the quadrilateral (x and y).

Let the other two be AB and $A'B'$, which intersect at point C.

The three diagonals are then AB' $A'B$ and OC;

their midpoints are the points M. N. P.

We will calculate the coordinates of these points.

Let a, a' be the abscissa of points A, A'; b and b' the ordinates of points B, B'.

The coordinates of point M are

$$x' = \frac{a}{2}, \quad y' = \frac{b'}{2},$$

and those of points N,

$$x'' = \frac{a'}{2}, \quad y'' = \frac{b}{2}.$$

To have the coordinates of point P, midpoint of OC, it is enough to know those of point C.

Now this point is at the intersection of the lines AB and A'B' which respectively have the equations

$$\frac{x}{a} + \frac{y}{b} - 1 = 0,$$

$$\frac{x}{a'} + \frac{y}{b'} - 1 = 0;$$

consequently, to have the coordinates of point C it is necessary to solve these two equations.

We thus obtain

$$x = \frac{aa'(b'-b)}{ab'-ba'}, \quad y = \frac{-bb'(a'-a)}{ab'-ba'};$$

the coordinates of point P, midpoint of OC, are then :

$$x''' = \frac{aa'(b'-b)}{2(ab'-ba')},$$

$$y''' = -\frac{bb'(a'-a)}{2(ab'-ba')}.$$

To establish that the points M, N, P are in a straight line it is necessary to prove the equality

$$\frac{y'''-y'}{x'''-x'} = \frac{y''-y'}{x''-x'}.$$

Or, on a

$$\frac{y'''-y'}{x'''-x'} = \frac{-\frac{bb'(a'-a)}{2(ab'-ba')} - \frac{b'}{2}}{\frac{aa'(b'-b)}{2(ab'-ba')} - \frac{a}{2}} =$$

$$\frac{-bb'(a'-a) - b'(ab'-ba')}{aa'(b'-b) - a(ab'-ba')},$$

$$\frac{y'''-y'}{x'''-x'} = \frac{b-b'}{a'-a}.$$

On the other hand, we easily see that

$$\frac{y''-y'}{x''-x'}$$ is equality

~~(is equality (is therefore verified and the proposition is established.)~~'

$$\frac{b-b'}{a'-a}.$$

The equality is therefore verified, and the proposition is established.

Análise:

Partindo-se do pressuposto que há uma linha reta e somando-se ao uso do teorema de Pappus, nós poderemos ter várias aplicações.

a) usando-se duas linhas partindo do ponto O, nós poderemos ter várias utilidades geométricas. Vejamos:

a1) no plano (qualquer)
traçamos duas linhas sem saber qual a sua relação entre si, ou seja, não sabemos qual é a equação que define cada linha.

Mesmo assim, nós poderemos achar esta linha reta.

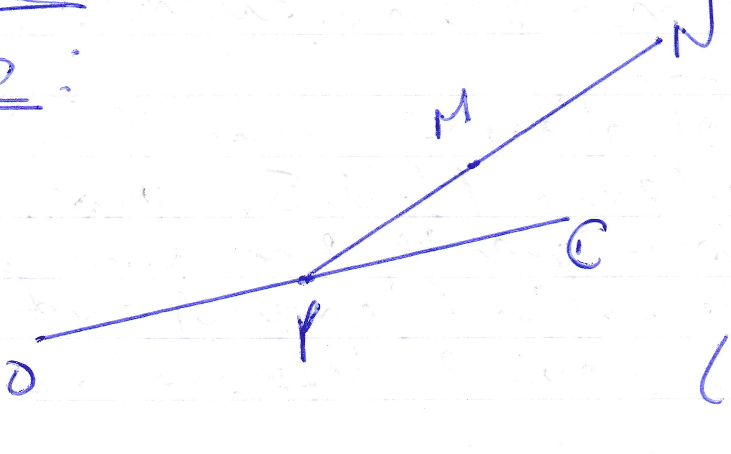
a₂b) plano curvo ou esfera
usando-se este princípio:
b1) duas retas
b2) partindo-se do mesmo ponto;

Nós poderemos continuar a obter uma/linha reta que está descrita sobre um plano curvo ou esfera.

b) utilizando-se duas retas e um mesmo ponto, nós poderemos utilizar o Teorema de Pappus (3 points) para estabelecer uma reta também.

Obs: Nós não podemos esquecer que
AB' e A'B não são linhas paralelas.
↳ importante uso para obtenção de uma linha reta em relação a um ponto fora destas duas retas e que no caso é o ponto O.

Vejamos:



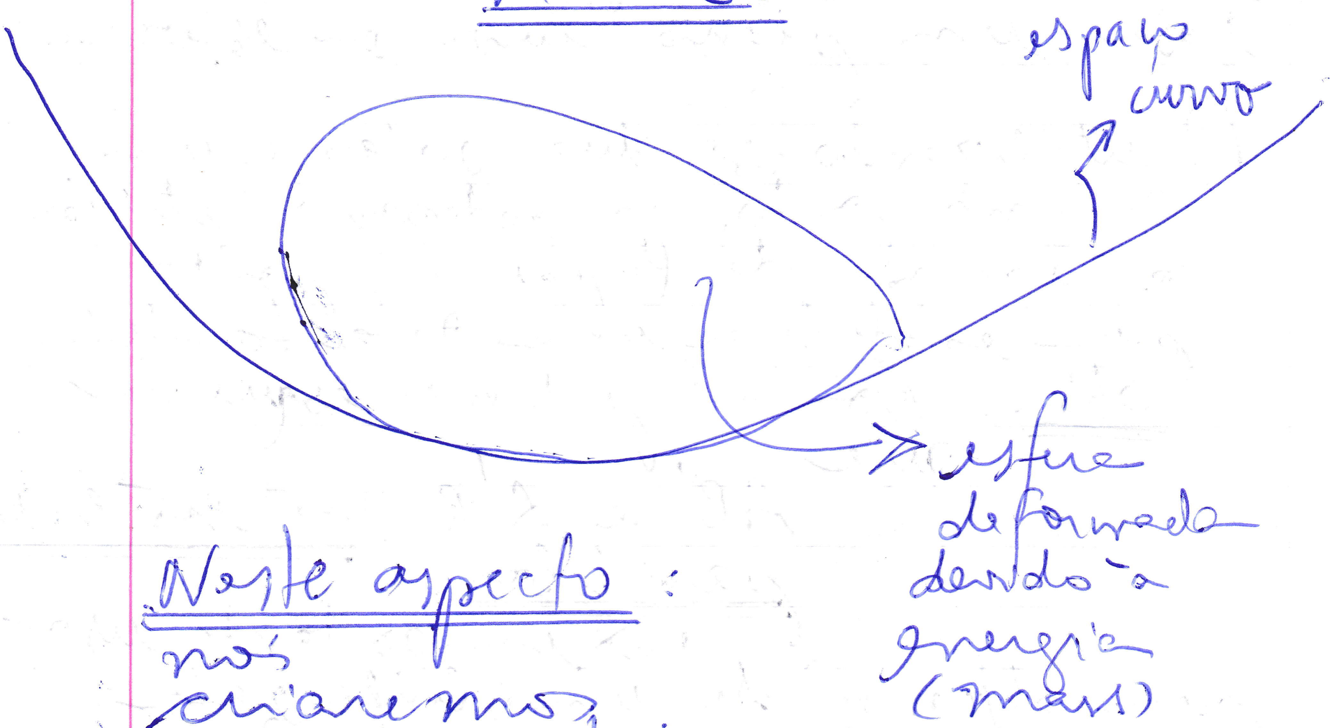
P, M and N
→ 3 points (Pappus)

Obs: Aplicar também ao plano curvo e a esfera.

Importantíssimo:

Aplicar também à minha pesquisa

M.U.S.



espaço curvo
esfera deformada devido à energia (massa)

Neste aspecto:

nós criaremos um novo tipo de linha reta, ou seja, não é uma linha reta no plano nem no plano curvo e nem na esfera.

Nós offeremos uma linha reta no plano M.U.S. projetado ortogonalmente em um plano matemático (teórico), mas não real sendo o real deformado e outros valores!

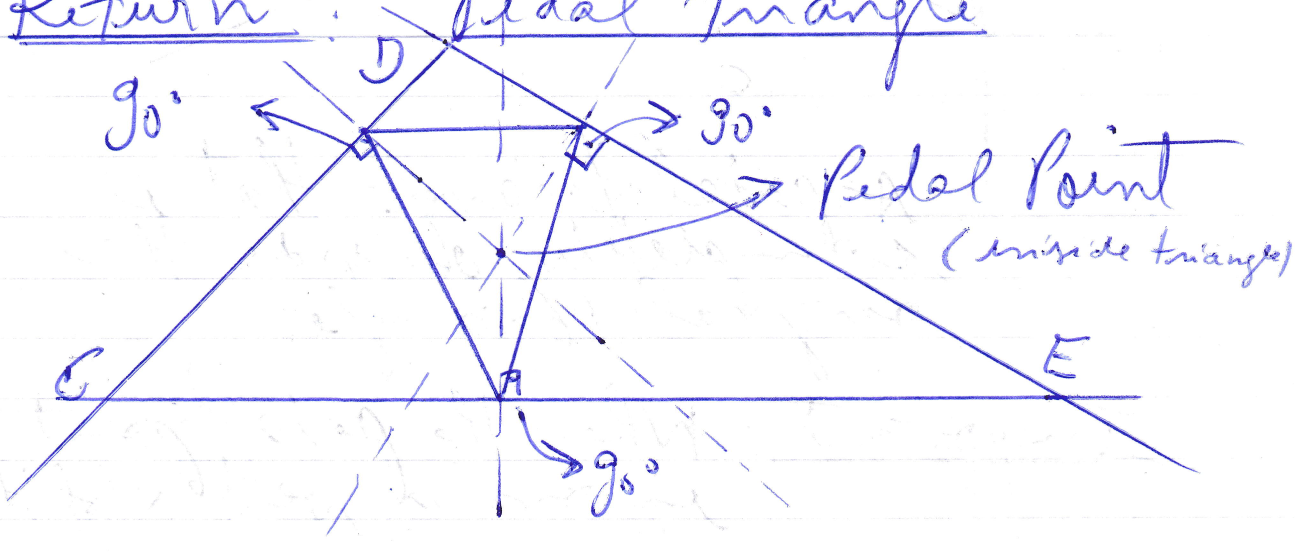
Obs.: Difference between Orthic triangle and Pedal Triangle.

Source: https://math.stackexchange.com/questions/3146011/difference-between-orthic-triangle-and-pedal-triangle

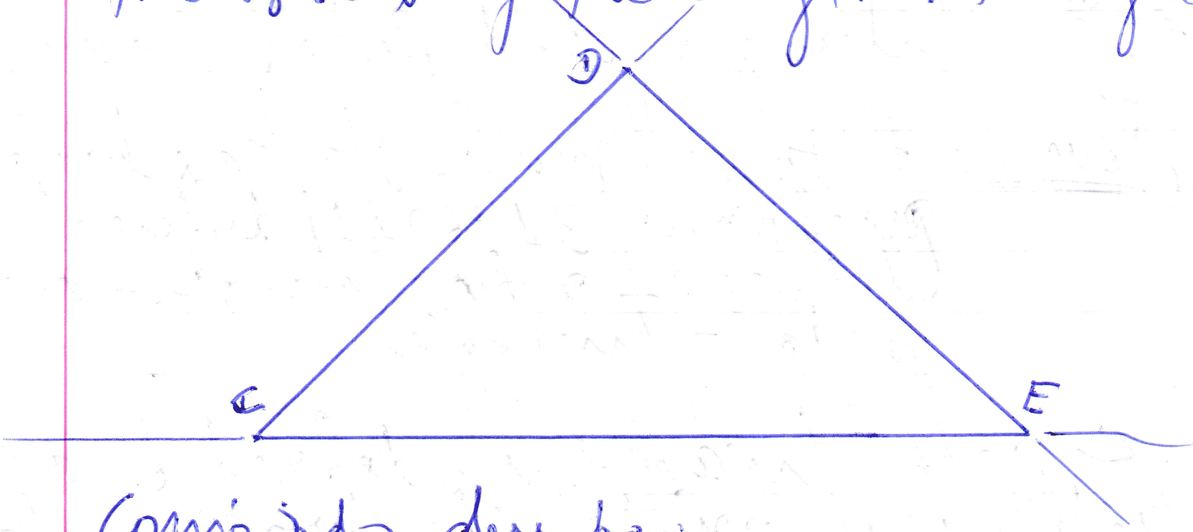
A pedal triangle is defined by an arbitrary point. (The vertices of the pedal triangle are where the feet of perpendiculars from that point meet the side-lines of the original triangle).

The orthic triangle is specifically the pedal triangle determined by the original triangle's orthocenter

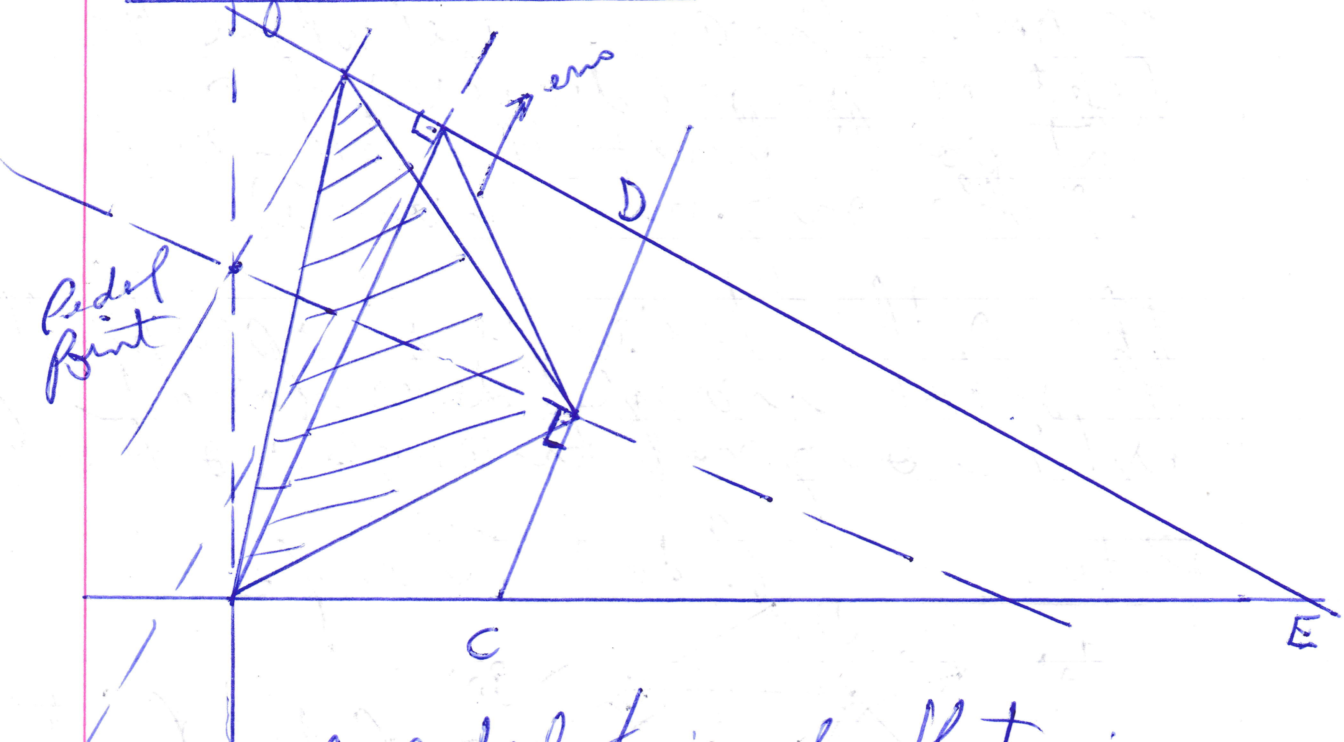
Return: Pedal Triangle



The pedal triangle has vertices that are the feet of the perpendiculars from the pedal point to each of the sides of the original triangle.



Corrigindo desenho:



A pedal triangle that is completely outside the original triangle.

Important: When the pedal point is on a vertex of the original triangle, the pedal triangle degenerates into the altitude of the original triangle.

Obs:

a) When the triangle is acute, the pedal triangle (altitude) is inside the original triangle.

b) When the triangle is right, the pedal triangle (altitude) lies along one of the side of the original triangle.

c) When the triangle is obtuse the pedal triangle (altitude), lies outside the original triangle.

Obs: Centroid of a triangle is the point where the three medians of a triangle meet.

Orthocenter of a triangle is the intersection point of the altitudes drawn from the vertices of the triangle to the opposite sides.

The Frégier Mapping
A Quadratic Transformation

Place of action is the projective enclosed Euclidean plane P^2.

We declare the (planar) Frégier mapping
$\gamma: P^2 \Rightarrow P^2$ to fixed points
O and F follows:

Connect a given point P_1 with O, draw the line g_2 orthogonal to $OP_1 =: g_1$ through O and intersect g_2 with line $FP_1 =: f$.

The intersection points $P_2 =: P_1^\gamma$ acts as Frégier image of P_1, see Fig. 5.

Let P_1 run through a line l, then $f \to g_1$ is a perspectivity.

As $g_1 \to g_2$ is an involutoric projectivity, the mapping

$f \to g_2$ is at least a projectivity.

It is well-known that projective pencil $\{g_2\}$ and $\{f\}$ generate a conic l^γ

this in mind we can already recognise γ as a

quadratic transformation.

As P_2 maps to P_1 again, γ obviously is involutoric.

We base the analytic description of γ on a cartesian coordinate frame and use homogeneous coordinates:

$O = (1, 0, 0)\mathbb{R}$, $F = (1, 0, 1)\mathbb{R}$,

$P_1 = (1, x_1, y_1)\mathbb{R}$, $P_2 = (1, x_2, y_2)\mathbb{R}$

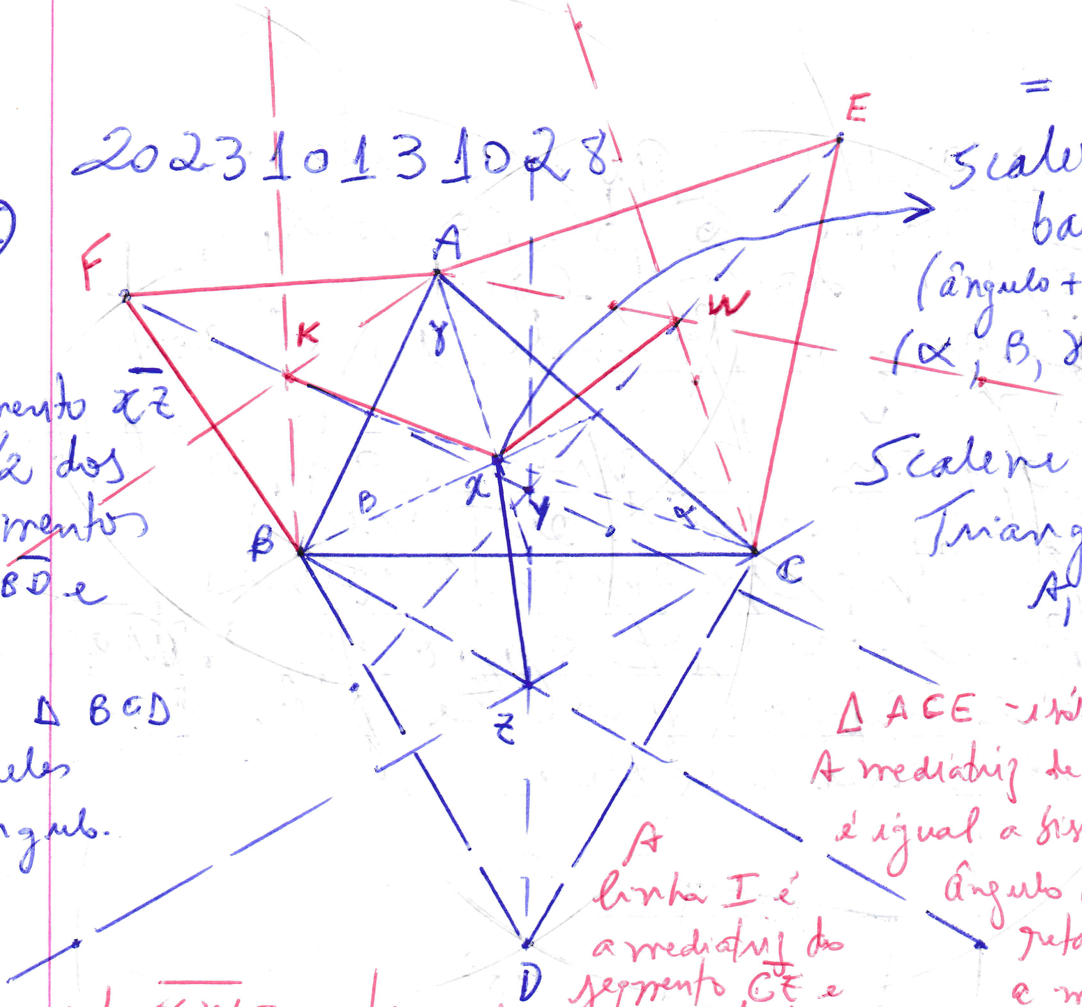
(I)



Scalene barycentre (ângulo + middle point) (α, β, γ)

Scalene Triangle A, B, C Δ.

Segmento $\overline{xz}$ é 1/2 dos segmentos $\overline{BC}$, $\overline{BD}$ e $\overline{CD}$.

Obs: Δ BCD isósceles triângulo.

Δ ACE - isósceles

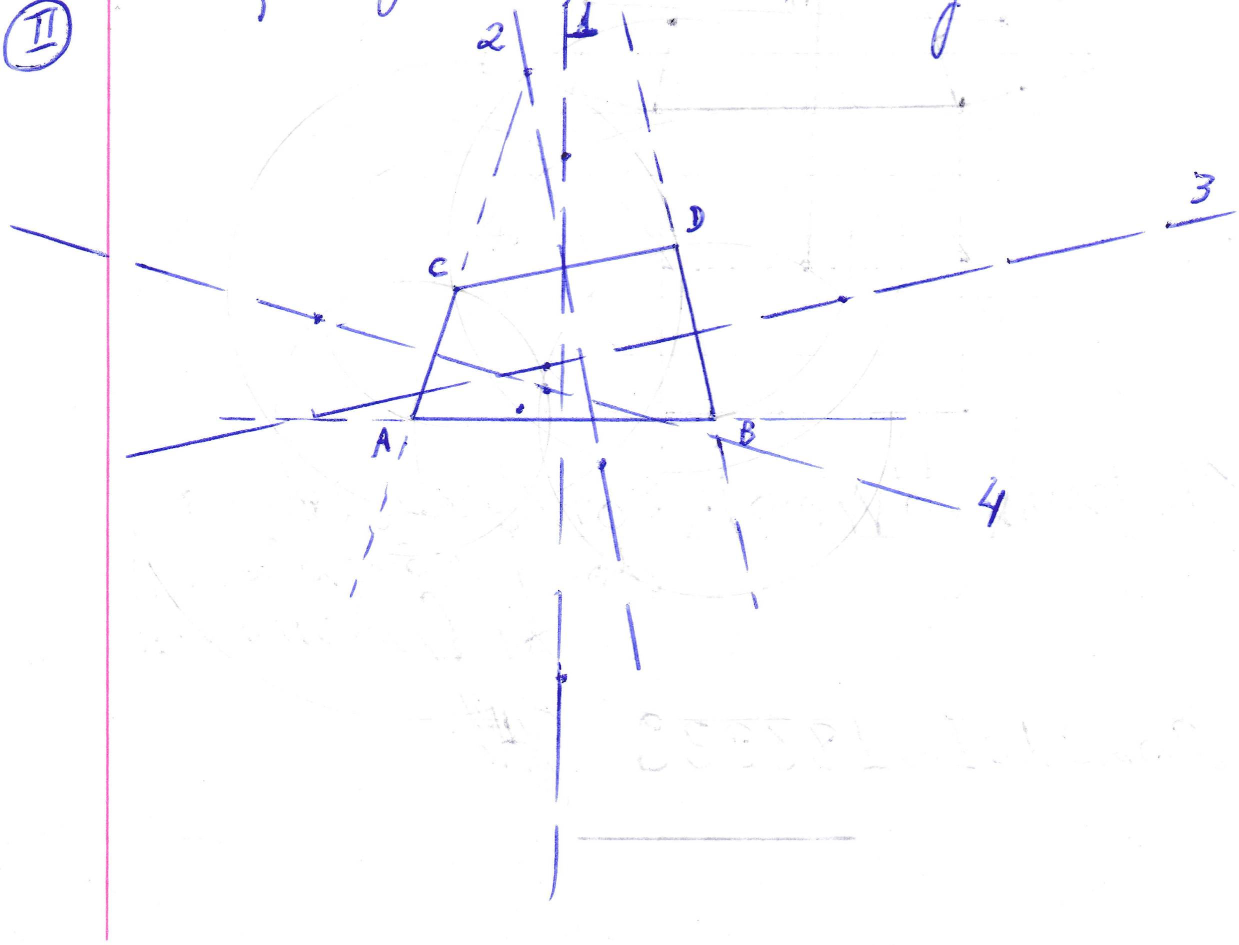
A mediatriz de um lado é igual a bissetriz do ângulo oposto à reta que se fez a mediatriz (perpendicular barycenter)

A linha I é a mediatriz do segmento $\overline{CE}$ e bissetriz do ângulo A do triângulo Δ ACE.

Segmento $\overline{XW}$ = $\overline{xz}$ = $\overline{Kx}$

Em vez do quadrado, usaremos triângulos.

(II)



Estudo: (quadrilátero). (II)

a) Segmento $\overline{AB}$ é cortado perpendicularmente pela linha 1. (perpendicular bisector) - mediatriz.

b) Segmento $\overline{CD}$ é cortado perpendicularmente pela linha 2. (perpendicular bisector)

c) Segmento $\overline{DB}$ → linha 3.

d) Segmento $\overline{AC}$ → linha 4.

Análise: (das linhas)

a) Linha 1 → não faz ângulo de 90° com nenhuma reta (2, 3, 4).

b) Linha 2 → faz ângulo de 90° com a linha 3.

c) Linha 4 → faz um ângulo maior que 90° com a linha 1.

Interessante:

A Linha 1 e a Linha 2 se interceptam no ponto da Mediatriz (perpendicular bisector) que cruza o segmento CD.

Voltando: Scalene Triangle Δ ABC. (I)

No triângulo escaleno (scalene triangle) Δ ABC, ou seja, os 3 lados deste triângulo apresentam diferentes tamanhos.

Na hipótese, em que realizamos a mediatriz, utilizando-se "perpendicular bisector" do segmento em questão, como por exemplo, $\overline{AB}$, $\overline{BC}$ e $\overline{AC}$.

No triângulo escaleno, os três lados de um triângulo são diferentes, mas ao fazer a "perpendicular bisector" de cada lado do triângulo, nós obteremos os seguintes pontos F, D, E, que farão partes de 3 triângulos equiláteros.

Análise:

a) Triângulo escaleno (scalene triangle) → ∆ ABC.

b) "Perpendicular bisector" (mediatriz) criar os seguintes triângulos equiláteros:

b1) Segmento $\overline{AB}$ cria-se o ponto F. Obteremos ∆ ABF (equilátero)

b2) Segmento $\overline{BC}$ cria-se o ponto D. Obteremos ∆ BCD (equilátero)

b3) Segmento $\overline{AC}$ cria-se o ponto E. Obteremos ∆ ACE (equilátero)

c) No caso do ∆ ABF, ao realizarmos as mediatrizes dos respectivos lados do triângulo equilátero (perpendicular bisector), concluiremos que:

c1) A mediatriz de um lado é igual a bissetriz do ângulo oposto ao segmento em que se fez a mediatriz, constituindo-se "perpendicular barycenter".

Explicando: No triângulo equilátero as mediatrizes (perpendicular bisector) corresponde a "perpendicular barycenter", pois o "barycenter" se obtém ligando-se o "middle point" com o ângulo oposto, dividindo-se este ângulo ao meio.

Importante: No triângulo escaleno (scalene triangle), as mediatrizes dos segmentos $\overline{AB}$, $\overline{BC}$ e $\overline{AC}$ são

obtidas no ponto diferente do ponto "scalene barycenter", que no caso é o ponto x, enquanto o outro ponto é o y.
c2) Ao realizarmos as mediatrizes do triângulo equilátero Δ ABF, obteremos o ponto K, este ponto é a intersecção dos 3 bissectores dos ângulos ABF. ✓
A distância entre o ponto K e o ponto "scalene barycenter" é igual aos outros 2 triângulos equiláteros Δ BCD e Δ ACE.
d) No caso do Δ BCD, ao realizarmos as mediatrizes dos referidos segmentos $\overline{BC}$, $\overline{BD}$ e $\overline{CD}$, ou seja, "perpendicular bijéctor", obteremos na intersecção destes segmentos o ponto Z.
A distância entre $\overline{xz}$ é igual aos segmentos Kx e $\overline{Wx}$.
e) No caso do Δ ACE, ao realizarmos as mediatrizes dos referidos segmentos $\overline{AC}$, $\overline{AE}$ e $\overline{CE}$, ou seja, "perpendicular bijéctor", obteremos na intersecção destes segmentos o ponto W.
A distância entre $\overline{xW}$ é igual aos segmentos $\overline{Kx}$ e $\overline{Zx}$.
Estudar (não sei se é aplicável a todos os triângulos escalenos).
O segmento $\overline{BC}$ tem 6 cm, ao ligarmos os pontos K, W, Z ao ponto x, obteremos 3 segmentos com o mesmo comprimento: $\overline{xZ}$, $\overline{xW}$ e $\overline{xK}$ com 3 cm cada um, mas testes devem ser feitos

com outros comprimentos de reta, que no caso é o segmento BC (número par), fazer com número ímpar 7 etc)

X115 is the fourth intersection of Steiner inellipse and nine-point circle.

Obs:

nine-point-circle →

Important:

The symmedian point K is the Frégier point of X115 with respect to the Steiner inellipse.

It shows up that the symmedian point K (= X6) is the Frégier point of the center of the Kiepert hyperbola (= X115) with respect to the Steiner inellipse.

Reversely said:

Is the Frégier point the symmedian

point K with respect to the Steiner inellipse, then the "Ex-Fregier point" is the center of the Kiepert hyperbola (=X115).

Analise:

a) Center of the Kiepert hyperbola.

202310150900

Kiepert Hyperbola is a hyperbola and triangle conic that is related to the solution of Lemoine's problem and its generalization to isosceles triangles constructed on the sides of a given triangle.

The vertices of the constructed triangles are given in trilinear coordinates by

$$A' = -\sin\phi : \sin(C+\phi) : \sin(B+\phi)$$
$$B' = \sin(C+\phi) : -\sin\phi : \sin(A+\phi)$$
$$C' = \sin(B+\phi) : \sin(A+\phi) : -\sin\phi$$

where ϕ is the base angle of the isosceles triangle.

Kiepert (1869) showed that the lines connecting the vertices of the given triangle and responding peaks of the isosceles triangles concur.

Obs: Concurrent → two or more lines are said to be concurrent if they intersect in a single point. Two lines concur if their trilinear coordinates satisfy

$$\begin{vmatrix} l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \\ l_3 & m_3 & n_3 \end{vmatrix} = 0$$

Three lines concur if their trilinear coordinates satisfy

$$l_1 \alpha + m_1 \beta + n_1 \gamma = 0$$

$$l_2 \alpha + m_2 \beta + n_2 \gamma = 0$$

$$l_3 \alpha + m_3 \beta + n_3 \gamma = 0$$

in which case the point is

$$m_2 n_3 - n_2 m_3 : n_2 l_3 - l_2 n_3 : l_2 m_3 - m_2 l_3.$$

Three lines are concurrent if their coefficients satisfy

$$\begin{vmatrix} A_1 & B_1 & C_1 \\ A_2 & B_2 & C_2 \\ A_3 & B_3 & C_3 \end{vmatrix} = 0.$$

Trilinear Coordinates:

Given a reference triangle ΔABC, the trilinear coordinates of a point P with respect to ΔABC are an ordered triple of numbers, each of which is proportional to the directed distance from P to one of the side lines.

Trilinear coordinates are denoted $\alpha : \beta : \gamma$ or (α, β, γ) and also are known as homogeneous coordinates or "trilinears".

Trilinear coordinates were introduced by Plücker in 1835.

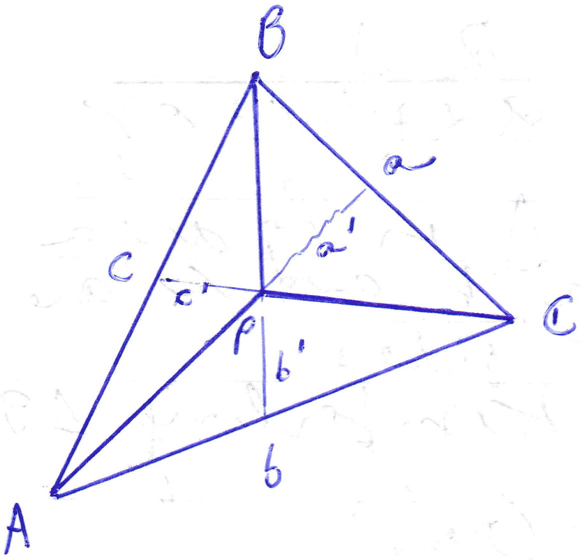
Since it is only the ratio of distances that is significant, the triplet of trilinear coordinates obtained by multiplying a given triplet by any nonzero constant describes the same point, so

$$\alpha : \beta : \gamma = \mu\alpha : \mu\beta : \mu\gamma.$$

For simplicity, the three polygon vertices, A, B, and C of the triangle are commonly written as

$$1:0:0,\quad 0:1:0,\quad \text{and } 0:0:1,$$

respectively.



Trilinear coordinates can be normalized so that they give the actual directed *distances* from P to each of the sides. To perform the normalization, let the point P in the above diagram have trilinear coordinates
$\alpha : \beta : \gamma$ and lie at distances
a', b', and c'
from the sides
BC, AC, and AB, respectively.
Then the distances
$a' = K\alpha$, $b' = K\beta$, and $c' = K\gamma$
can be found by writing Δ_a for the area of ΔBPC, and similarly for Δ_b and Δ_c.

We then have $\Delta = \Delta_a + \Delta_b + \Delta_c$

$$= \frac{1}{2}aa' + \frac{1}{2}bb' + \frac{1}{2}cc'$$

$$= \frac{1}{2}(ak\alpha + bk\beta + c\beta\gamma)$$

$$= \frac{1}{2}K(a\alpha + b\beta + c\gamma)$$ so

$$K \equiv \frac{2\Delta}{a\alpha + b\beta + c\gamma}$$

where Δ is the area of ΔABC and a, b, and c are the lengths of its sides
(Kimberling 1998, pp. 26-27).

Book: (ref.)

Kimberling - "Central Points and Central Lines in the Plane of a Triangle"
Math. Mag. 67, 163-187, 1994.

Kimberling - "Triangle Centers and Central Triangles"
Congr. Numer. 129, 1-295, 1998.

To obtain trilinear coordinates giving the actual distances, take $k = 1$, so we have the coordinates
$a' : b' : c'$.

These normalized trilinear coordinates are known as exact trilinear coordinates.

The trilinear coordinates of the line

$$ux + vy + wz = 0$$

are $u : v : w = a d_A : b d_B : c d_C$,

where d_i is the point-line distance from polygon vertex i to the line.

Obs: Point-Line Distance – 2 Dimensional

✡

The distance between a point with exact trilinear coordinates $(\alpha', \beta', \gamma')$ and a line

$l\alpha + m\beta + n\gamma = 0$ is

$$d = \frac{|l\alpha' + m\beta' + n\gamma'|}{\sqrt{l^2 + m^2 + n^2 - 2mn\cos A - 2nl\cos B - 2lm\cos C}}$$

(Kimberling 1998, p. 31)

Converter para o espaço curvo (distância será diferente) – aplicar

M.U.S.

Análise:

b) Symmedian Point.

In geometry, the Lemoine point, Grebe point or symmedian point is the intersection of the three symmedian

(medians reflected at the associated bisectors) of a triangle.

Symmedian Point

The point of concurrence K of the symmedians, sometimes also called the Lemoine point (in England and France) or the Grebe point (in Germany).

Symmedians

Symmedians are three particular lines associated with every triangle. they are constructed by taking a median of the triangle (a line connecting a vertex with the midpoint of the opposite side), and reflecting the line over the corresponding angle bisector (the line through the same vertex that divides the angle there in half).

The angle formed by the symmedian and the angle bisector has the same measure as the angle between the median and the angle bisector, but it is on

the other side of the angle bisector.

Important:

a) No triângulo Δ ABC, ao fazermos os ângulos bisectors, nós encontramos um ponto I (concur at the incenter)

b) Ao fazermos no mesmo triângulo Δ ABC, as medianas (Medians), nós obteremos o ponto G (concur at the centroid)

Medians → line connecting a vertex with the midpoint of the opposite side.

c) No mesmo triângulo, ao fazermos a reflexão (reflecting) da mediana obteremos Symmedians (concur at the symmedian point L) que se interceptam no ponto L.

The three symmedians meet at a triangle center called the Lemoine point

Ross Honsberger has called its existence

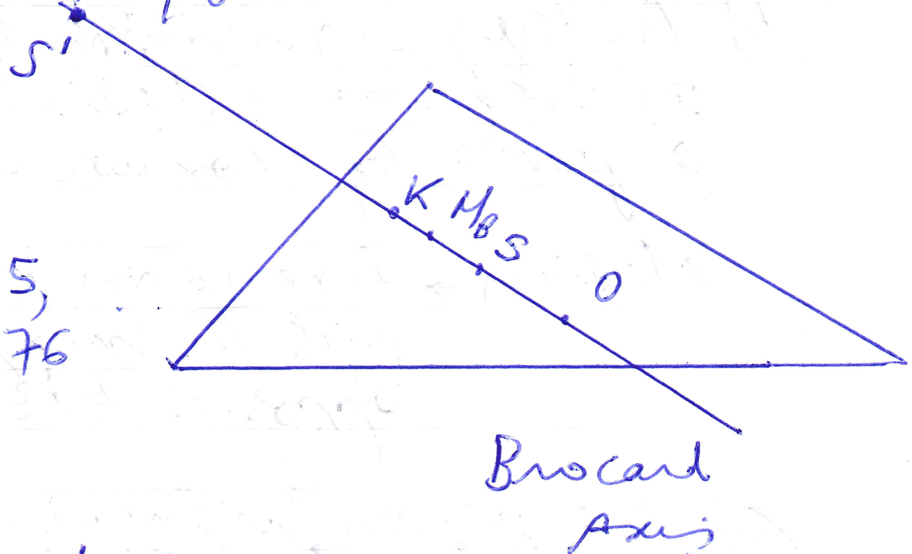
"one the crown jewels of modern geometry".

Chapter 7: The Symmedian Point. (1995)

→ Episodes in Nineteenth and Twentieth Century Euclidean Geometry (1995).

Voltando (return):

Symmedian Point



~~Hon~~
Honsberg 1995, p.76

The symmedian point lies on the Brocard axis (The Brocard axis is the line K O passing through the symmedian point K and circumcenter O of a triangle, where the segment OK is the Brocard diameter (Kimberling 1998, p.150).
The Brocard axis is perpendicular to the Lemoine axis and is the isogonal conjugate (the isogonal conjugate X^{-1} of a point X in the plane of the triangle ΔABC is constructed by reflecting the lines AX, BX, and CX about the angle bisectors at A, B, and C. The three

reflected lines then concur at the isogonal conjugate (Honsberger 1995, pp. 55-56).

(... Brocard axis is perpendicular to the Lemoine axis and is the isogonal conjugate of the Kiepert hyperbola.)

... The symmedian point lies on the Brocard axis and the Fermat axis. (Fermat axis is the central line connecting the first and second Fermat points! It has line function

$$l = a(b^2-c^2)(a^2-b^2-bc-c^2)(a^2-b^2+bc+c^2).$$

corresponding to Kimberling center.

Obs: 1) First Fermat Point

The first Fermat point X (or F_1) (sometimes simply called "the Fermat point", Torricelli point, or first isogonic center) is the point X which minimizes the sum of distances for A, B and C in an acute triangle,

$$|AX| + |BX| + |CX|.$$

It has equivalent triangle center functions

$$\alpha_{13} = \csc\left(A + \frac{1}{3}\pi\right)$$

$$\alpha_{13} = bc[c^2a^2 + (c^2+a^2-b^2)^2]$$
$$[a^2b^2 - (a^2+b^2-c^2)^2]$$
$$[4\Delta - \sqrt{3}(b^2+c^2-a^2]$$

and is Kimberling center X_{13} (Kimberling 1998, p. 67).

obs: It also arises in Napoleon's theorem.

obs) 2: Second Fermat Point

The second Fermat point X' or F_2 (also known as the second isogonic center) can be constructed by drawing equilateral triangles on the inside of a given triangle and connecting opposite vertices. The three diagonals in the figure then intersect in the second Fermat point, which has triangle center function

$\alpha = \csc\left(A - \frac{1}{3}\pi\right)$ and is

Kimberling center X_4. (141
= Kimberling 1998, p. 68).

Return:

... the symmedian point lies on the Brocard axis and the Fermat axis. It lies of the Brocard circle and is the center of the cosine circle. It also lies on the Jerabek hyperbola (The Jerabek hyperbola is a circumconic that is isogonal conjugate of the Euler line. (Kimberling 1998, p. 237).

↳ see:

Euler line (The line on which the orthocenter H, triangle centroid G, circumcenter O, de Longchamps point L, nine-point N, and a number of other important triangle center lie)

Obs: Longchamps point (L) is the reflection of the orthocenter H about the circumcenter O of a triangle. It has triangle center function

$$\alpha = \cos A - \cos B \cos C,$$

and is Kimberling center X_{20} (Kimberling 1998, p. 70).

return : Euler Line

... The Euler Line is perpendicular to the Longchamps lines and orthic axis.

return : Symmedian Point

... It also lies on the Jerabek hyperbola and the Thomson cubic.

(the Thomson cubic $Z(X_2)$ of a triangle ΔABC is the locus the center of circumconics whose normals at the vertices are concurrent. It is a self-isogonal cubic with pivot point at the triangle centroid, so its parameter is $x = bc$ and its trilinear equation is given by

$$bc\alpha(\beta^2+\gamma^2)+ca\beta(\gamma^2-\alpha^2)+ab\gamma(\alpha^2-\beta^2)=0$$

(Cundy and Parry 1995; Kimberling 1998, p. 240).

It is sometimes called the

seventeen-point cubic
(Casey 1893, p. 460;
Kimberling 1998, p. 240).

return: Symmedian Point

Its distances from K to the sides of the triangle are

$$KK_i = \frac{1}{2} a_i \tan \omega.$$

where
ω is the Brocard angle.

Análise:

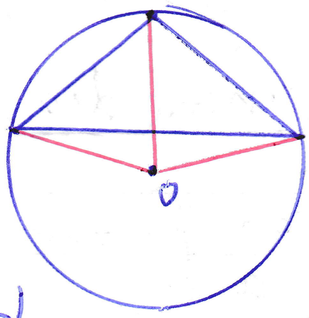
c) Steiner point (Fregier Theorem → / Heiss.)

obs: Steiner Circle
is the central circle with center at the nine-point center X_5 and radius

$$R_5 = \frac{3}{2} R,$$

where R is the circumradius
(the circumradius of a cyclic polygon is a radius of the circle inside which the polygon can be inscribed. Similarly the circumradius of a polyhedron is the radius of a

circumsphere touching each of the polyhedron's vertices, if such a sphere exists).

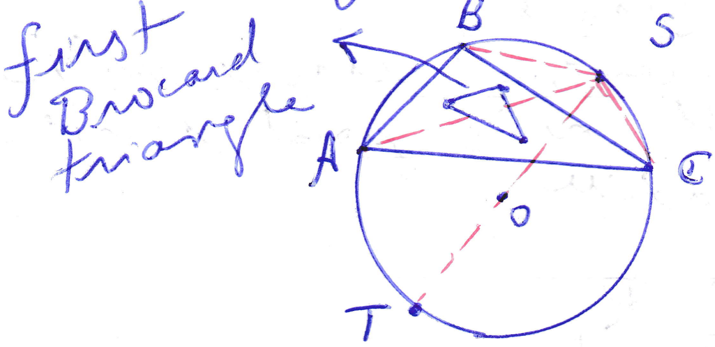


return: Steiner Circle

It is the circumcircle of the Steiner deltoid.

Steiner Points:

there are (at least) three different types of points known as Steiner points.



The point S of concurrence of the three lines drawn through the vertices of a triangle parallel to the corresponding sides of the first Brocard triangle is called the Steiner point (Honsberger 1995).

It lies on the circumcircle opposite the Tarry Point T and has equivalent triangle center functions

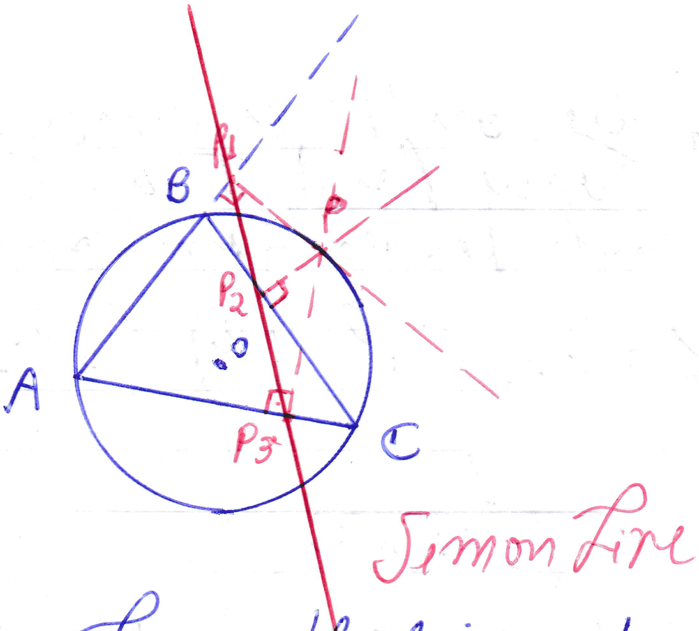
$$\alpha = bc(a^2-b^2)(a^2-c^2)$$

$$\alpha = \frac{1}{a(b^2-c^2}$$

obs: It also lies on the Steiner circumellipse.
It is Kimberling center X99.
The Brianchon point
(the point of concurrence of the joins of the vertices of a triangle and the points of contact of a conic of the triangle (Veblen and Young 1938, p. 111); Eddy and Fritsch 1994))

For the Kiepert parabola is also the Steiner Point (Eddy and Fritsch 1994).
The symmedian point K is the Steiner point of the first Brocard triangle (Honsberger, 1995, pp. 120-121).

The Simson Line (Importantíssimo)
↳ Research.



The Simon Line is the line containing the feet P_1, P_2, and P_3 of the perpendiculars from an arbitrary point P on the circumcircle of a triangle.

This line was attributed to Simson by Poncelet, but is now frequently know as the Wallace-Simson line since it does not actually appear in any work of Simson (Johnson 1929, p. 137; ~~Coxeter a~~ Coxeter and Greitzer 1967, p. 41; de Guzmán 1999).

Inverse statement:

The locus of all points P in the plane of a triangle $\triangle ABC$ such that the feet of perpendiculars from the three sides of the triangle is collinear is given by the circumcircle of $\triangle ABC$, is sometimes called the Wallace-Simson theorem (de Guzmán, 1999).

Important: The Simson line bisects the line HP, where H is the orthocenter
(Honsberger 1995, p.46).

Moreover, the midpoint of HP lies on the nine-point circle (Honsberger, 1995, pp. 46-47).

The Simson lines of two opposite point on the circumcenter of a triangle are perpendicular and meet on the nine-point circle
(also called Euler's circle or the Feuerbach circle, is the circle that passes through the perpendicular feet H_A, H_B, and H_C dropped from the vertices of any reference triangle ΔABC on the side opposite them.

Euler showed in 1765 that it also passes through the midpoints M_A, M_B, M_C of the sides of ΔABC.

By Feuerbach's theorem, the nine-point circle also passes through the midpoints E_A, E_B, and E_C of the segments ✡ that joint the vertices and the orthocenter H. These points are commonly referred to as the Euler points.

These three triples of points make nine in all, giving the circle its name.

O texto é longo mas de um modo geral, todos estes pontos serão úteis para manter a integridade dos cálculos, mas aplicável à uma superfície curva.

De acordo com o avançar da pesquisa, estes pontos serão projetados de forma ortogonal sobre uma superfície curva ou serão descritos na própria superfície curva.

Eu não preciso de tantos referenciais para fundamentar a minha pesquisa. O que interessa é comprovar a nova mudança de paradigma pois de um ponto de vista objetivo, os cálculos estão equivocados em virtude de terem sido obtidos com base em superfície plana.

Source: https://triangle-geometry.jimdofree.com

Importante:

Usar estes pontos como referencial para se manter a consistência dos gráficos, mas o que interessa é a lógica global do objetivo que se pretende obter.

Desejamos unir estes conceitos com Ligne Droite - Papelier e posteriormente vincular com o livro:

Sortais - La géométrie du triangle - Exercices résolus - (1997).pdf
→ 220 páginas - René Sortais

Pág. 08 (12) → Droite et cercle d'Euler.

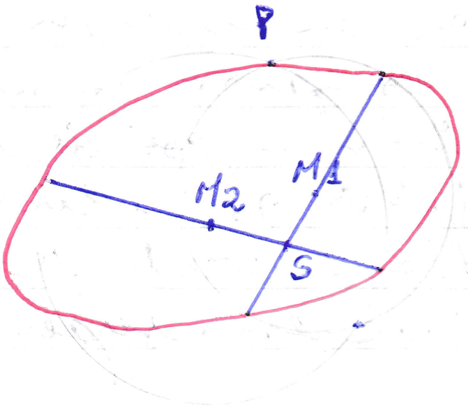
Return to Frégier theorem

Fig. 02 → Frégier point S and Ellipse (or another conic section).



Neste exemplo, nós precisamos começar com uma ellipse e depois calcular o ponto S. (Frégier Point), posteriormente, nós inserimos os círculos.

Com esta representação, nós conseguimos interligar 2 círculos com tamanhos (raios) diferentes com uma ellipse.

Important:

Poncelet's closure theorem → also know as Poncelet's porism, states that whenever (a qualquer momento) a polygon is one conic section and circumscribes another one, the polygon must be part of an infinite family of polygons that are all inscribed in and circumscribe the same two conics.

Conic Section: The conic sections are the nondegenerate curves generated by the intersections of a plane (~~perpendicular~~) with one or two nappes of a cone.
For a plane perpendicular to the axis of the cone, a circle is produced.
For a plane that is not perpendicular to the axis and that intersects only a single nappe, the curve produced is either an ellipse or a parabola (Hilbert and Cohn-Vossen 1999, p.8)
The curve produced by a plane intersecting both nappes is a hyperbola (Hilbert and Cohn-Vossen 1999, pp.8-9).

return: Poncelet's Porism →

Hyperbola (Gray 1997, p. 45) is a conic section defined as the locus (a locus is the set of all points (usually forming a curve or surface) satisfying some conditions. The locus of points in the plane equidistant from a given point is a circle, and the set of points in three-space equidistant from a given point is a sphere) .. of locus of all points P in the plane the difference of whose (cujos) distances $r_1 = F_1P$ and $r_2 = F_2P$ from two fixed points (the foci F_1 and F_2) separated by a distance $2c$ is a given positive constant k,

$$r_2 - r_1 = k$$

(Hilbert and Cohn-Vossen 1999, p. 3)

Letting P fall on the left x-intercept requires that

$$k = (c+a) - (c-a) = 2a$$

so the constant is given by $k = 2a$.

Important: Rectangular hyperbola ⟹

The special case of the rectangular hyperbola corresponding to a hyperbola with eccentricity $e = \sqrt{2}$, was first studied by Menaechmus.

IMPORTANT:

The hyperbola is the ~~sp~~ shape of an orbit of a body on an escape trajectory (i.e. a body with positive energy), such as some comets, about a fixed mass, such as the sun.

obs:

i.e. (id est) → "that is"

e.g (exempli gratia) → "for example"

Return: conic section (Important)

Kepler was the first to notice that planetary orbits were ellipses.

(Ellipse is a curve that is the locus of all points in the plane the sum of whose distances r_1 and r_2 from two fixed points F_1 and F_2 (the foci) separated by a distance of $2c$ is a given positive constant $2a$ (Hilbert and Cohn-Vossen 1999, p. 2).

This results in the two-center bipolar coordinate equation

$r_1 + r_2 = 2a.$

→ major radius

where a is the semimajor axis and the origin of the coordinate system is at one of the foci.

The corresponding parameter b is known as the semiminor axis

↳ minor radius

The ellipse is a conic section and a Lissajous curve.
(parametric curve)

return : **KEPLER** was first to notice that planetary orbits were ellipses, and Newton was then able to derive the shape of orbits mathematically using calculus (?), under the assumption that

gravitational force

goes as the inverse square of distance.

IMPORTANT :

CONIC SECTION may more formally be defined as the locus of a point P that moves in the plane of a fixed point F called the focus and a fixed line d called the ...

... conic section directrix (is the line which, together to define a conic section as the locus of points whose (cujo) distance from the ffocus is proportional to the horizontal distance from the directrix), with

(with F not on d) such that the ratio of the distance of P from F to its distance from d is a constant e called the eccentricity

r being the constant of proportionality.

If the ratio: ✡

r = 1, the conic is a parabola,

r < 1, it is an ellipse, and

r > 1, it is a hyperbola.

(Hilbert and Cohn-Vossen 1999, p. 27)

return: ... called the eccentricity ✡

If e=0, the conic is a circle

If 0<e<1, the conic is an ellipse,

If e= 1, the conic is a parabola, and

If $e > 1$, it is a hyperbola.

A conic section with conic section directrix at $x=0$, focus at $(p, 0)$, and eccentricity $e > 0$ has Cartesian equation

$$y^2+(1-e^2)x^2-2px+p^2=0$$

(Yates 1952, p.36), where p is called the focal parameter

Plugging in p gives

$$y^2+(1-e^2)x^2-\frac{2a(1-e^2)}{e}x+\frac{a^2(1-e^2)^2}{e^2}=0,$$

for an ellipse,

$$y^2=4a(x-a),$$ for a parabola, and

$$y^2+(1-e^2)x^2-\frac{2a(e^2-1)}{e}x+\frac{a^2(e^2-1)^2}{e^2}=0$$

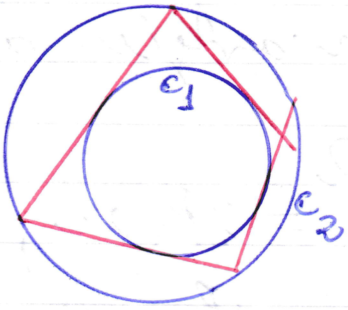
for a hyperbola.

Eff: The polar equation of a conic section with focal parameter p is given by

$$r = \frac{pe}{1 + e\cos\theta}.$$

Return: Poncelet's Porism

Poncelet Transverse



Let a C_1 lie inside another circle C_2. From any point on C_2, draw a tangent to C_1 and extend it to C_2.

From the point, draw another tangent etc. For n tangents, the result is called an n-sided Poncelet Transverse.

If, on the circle of circumscription there is one point of origin for which a four-sided Poncelet transverse is closed then the four-sided transverse will also close for any other point of origin on the circle (Dörrie 1965).

Obs: If the conic is taken as a circle (Casey 1888, pp. 124-126), then a polygon which has both an incenter and a circumcenter (and for which the transversals would therefore close) is called a bicentric polygon

(A polygon which has both a circumcircle (which touches each vertex) and a incircle (which is tangent to each side).

All triangles are bicentric with

$$R^2 - x^2 = 2Rr,$$

where R is the circumradius,
r is the inradius, and
x is the separation of centers.

For bicentric quadrilaterals, a result sometimes known as FUSS'S problem, the circles satisfy

$$2r^2(R^2+x^2) = (R^2-x^2)^2$$

(Dörrie 1965, Salazar 2006) or, in another form,

$$\frac{1}{(R-x)^2} + \frac{1}{(R+x)^2} = \frac{1}{r^2}$$

(Davis; Durége 1861; Casey 1888, pp. 109-110; Johnson 1929; Dörrie 1965).

Important: ✡

Para estabelecer parâmetros para a minha pesquisa, nós devemos observar os seguintes ~~pa~~ aspectos:

a) constant of proportionality:

$r = 1$ → parabola,

$r < 1$ → ellipse, and

$r > 1$ → hyperbola.

b) constant e (eccentricity)

$e = 0$, the conic is a circle,

$0 < e < 1$, the conic is ellipse,

$e = 1$, the conic is parabola, and

$e > 1$, the conic is hyperbola.

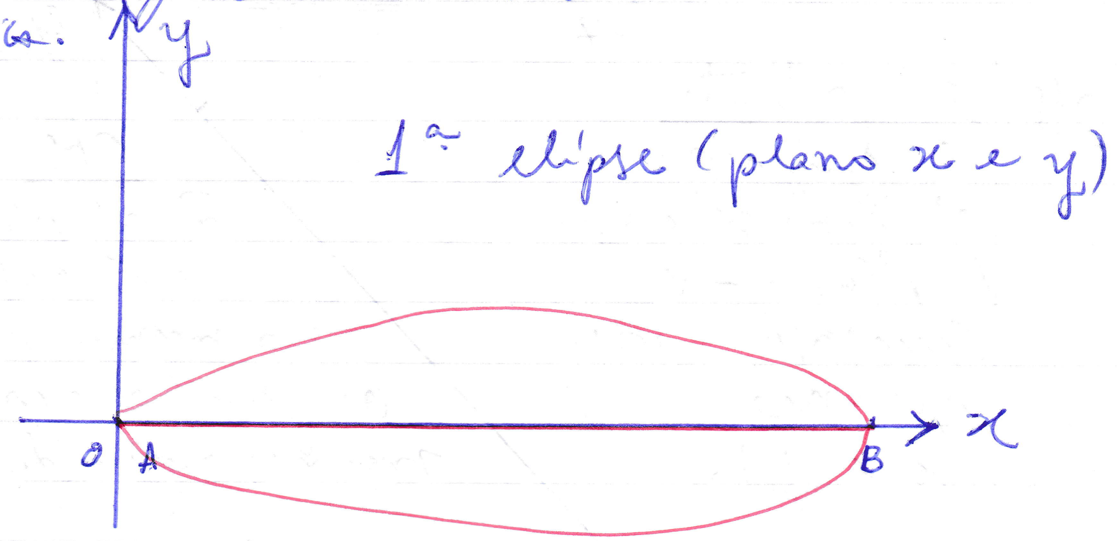
20231017214242

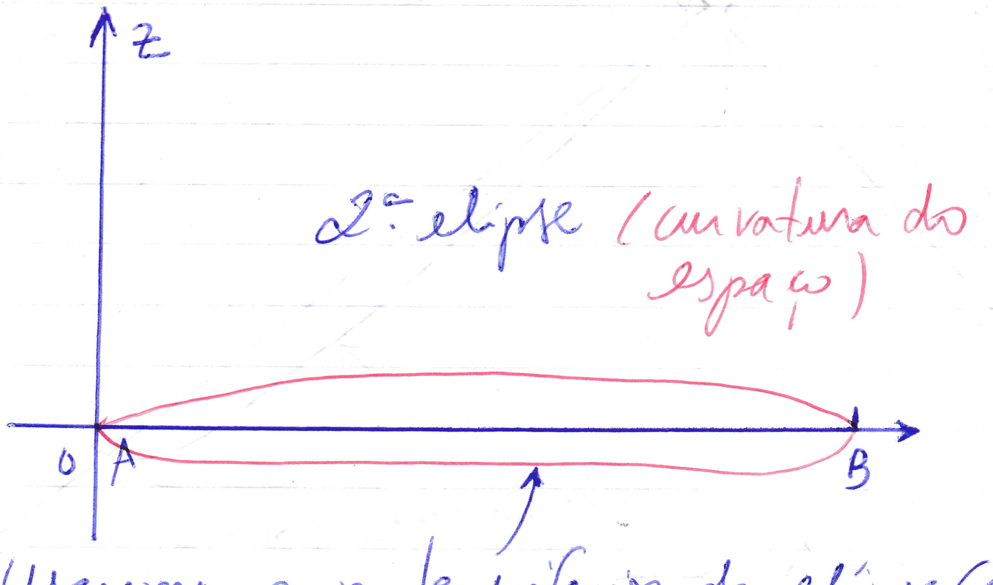
Solução para calcular a curvatura do espaço sobre a órbita elíptica dos planetas. (Uma delas). Estudar com profundidade.

Eu fiquei pensando em uma forma metódica para calcular a curvatura gerada pelas forças fundamentais do Universo sobre as órbitas elípticas e eu irei usar os mesmos procedimentos utilizados para analisar uma órbita elíptica.



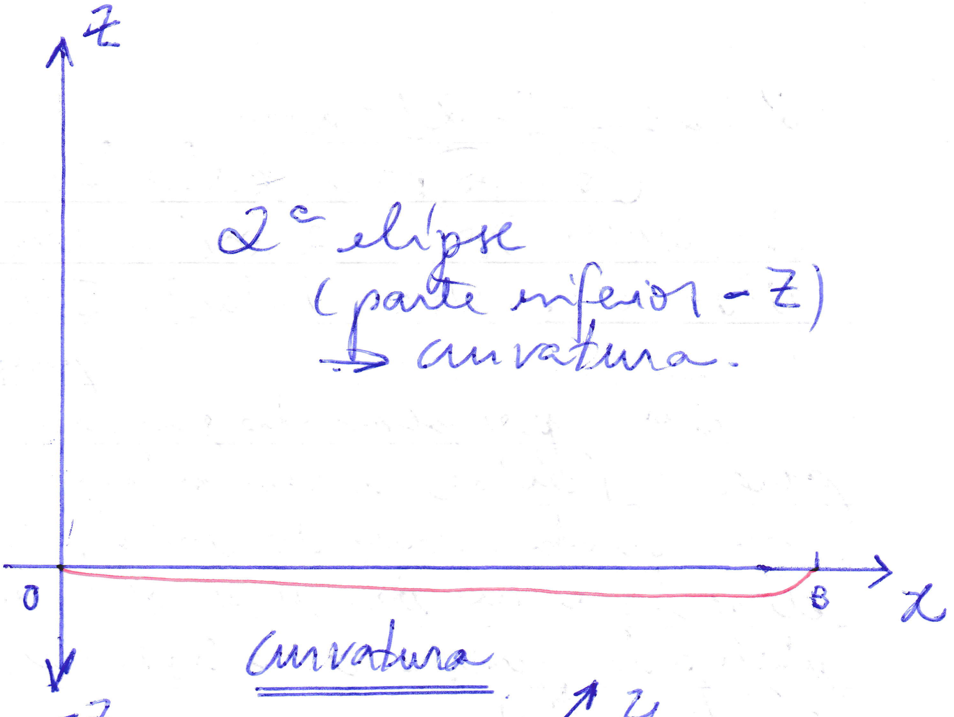
y
1ª elipse (plano x e y)
x
0
A
B

A 2ª elipse estará no eixo z, mas com um tamanho menor



z
2ª elipse (curvatura do espaço)
0
A
B

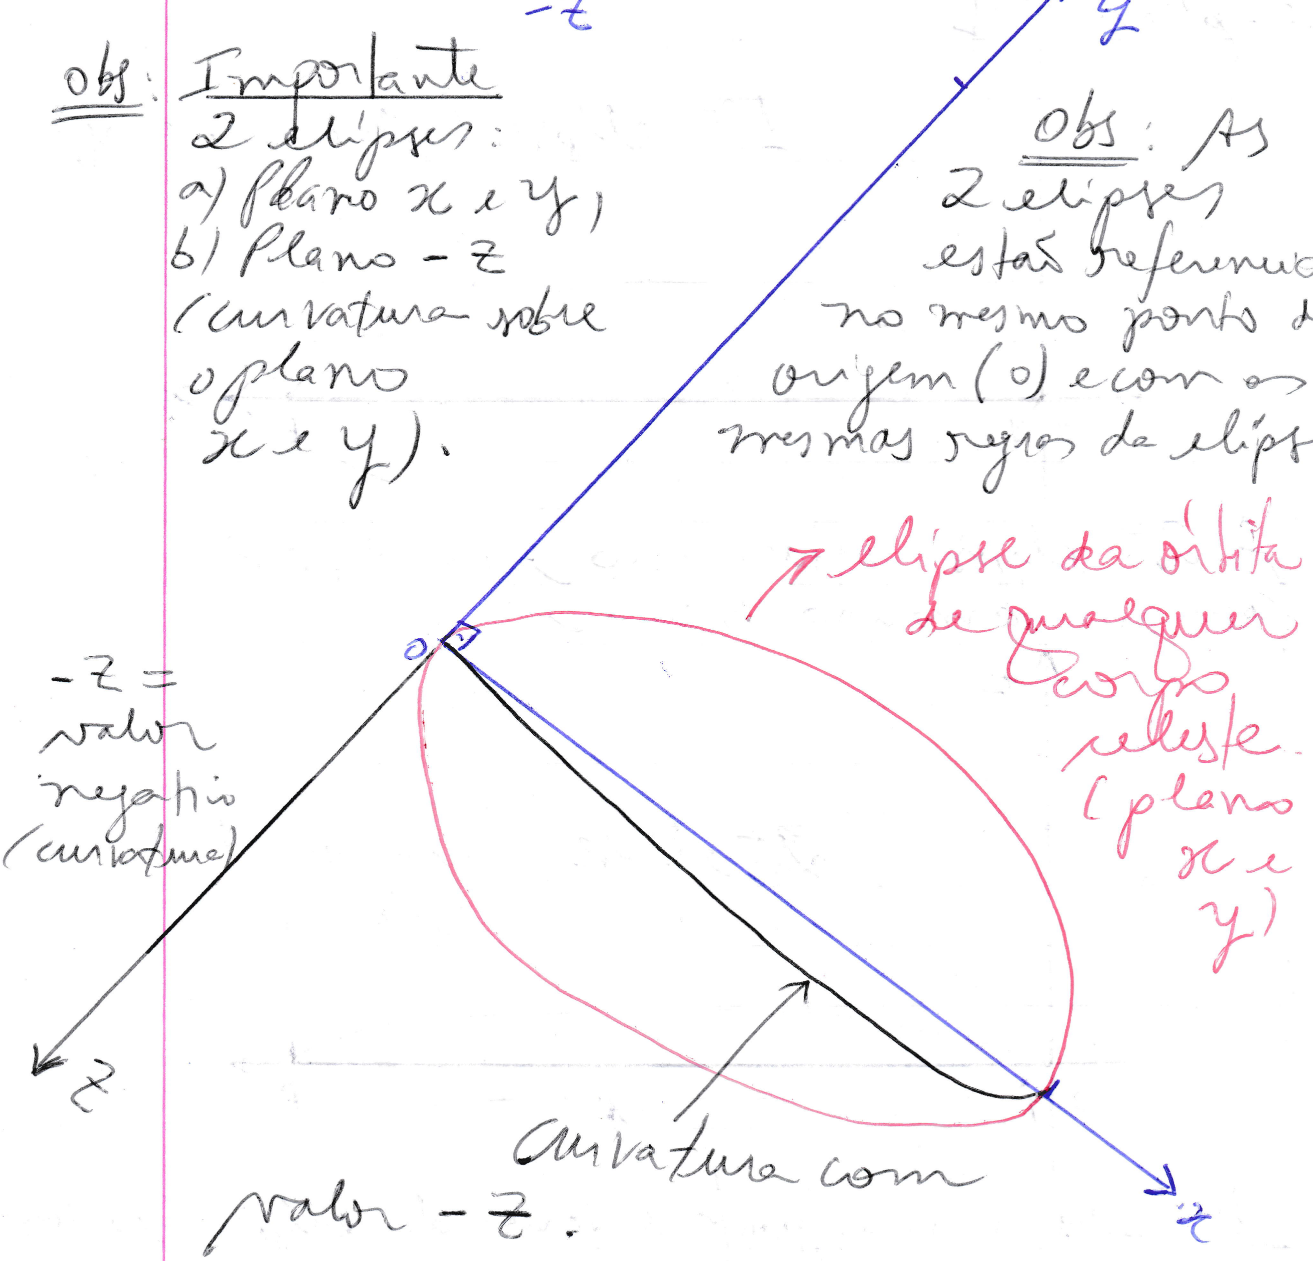
obs: Usaremos a parte inferior da elipse (curvatura) corte longitudinal



2ª elipse
(parte inferior - z)
⇒ curvatura.

obs: Importante
2 elipses:
a) plano x e y,
b) plano - z
(curvatura sobre
o plano
x e y).

obs: As
2 elipses
estão referenciados
no mesmo ponto de
origem (0) e com as
mesmas regras da elipse.



→ elipse da órbita
de qualquer
corpo
celeste.
(plano
x e
y)

-z =
valor
negativo
(curvatura)

curvatura com
valor - z.

Esta 2ª elipse será projetada (sobre) de forma ortogonal sobre um plano para o cálculo do novo número Pi (M.U.S.)

Vejamos, nós teremos 3 coordenados de valores números referentes à elipse, ou seja, x e y com a elipse orbital de um corpo celeste e z, ou seja, no eixo z mas com valor negativo em virtude da curvatura do espaço.

A obtenção destes 3 valores usarão as mesmas regras de elipse:

a) constant of proportionality

b) constant e (eccentricity).

Obs: A 2ª elipse terá um valor menor pois trata-se da curvatura do espaço.

Important: O valor negativo no eixo z poderá ser representada por uma equação que represente aquela curvatura.

Esta curvatura abrange toda a elipse da órbita do corpo celeste e a projeção ortogonal sobre um plano permitirá o cálculo do novo número do Pi (M.U.S.).

Important: Este aspecto será de fundamental importância para a chegagem dos cálculos obtidos, pois devemos utilizar este mecanismo nas duas elipses (x e y) e ($z \rightarrow -z$).

Primeiro, devemos escolher um ponto P sobre a elipse (x, y) e obter Frégier Point (S) e apartir do ponto P, nós deveremos criar dois círculos que se intercepta no ponto P. (círculos diferentes)

Não se esqueça de marcar os dois centros dos círculos (M1 e M2), pois estes pontos serão utilizados para marcarmos dois segmentos, ambos passando pelo ponto S, criando-se assim, o segmento ou reta que passa pelos pontos SM1 e SM2, sendo que ambos os segmentos estarão contidos nos respectivos círculos de tamanhos diferentes, M1 círculo menor e M2 círculo maior.

Important:

a) SM1 e SM2 devem ter o mesmo tamanho do diâmetro dos seus respectivos círculos.

b) SM1 e SM2 deverão atingir a elipse em ambos os pontos do segmento.

Interessante:

Eu tive uma idéia interessante, e se nós criarmos os dois círculos cujos dois pontos de intersecção fiquem justamente sobre a elipse em que nós obtemos o ponto Frégier Point (S) apartir do ponto P.

O primeiro ponto é o ponto P aleatório sobre a elipse.

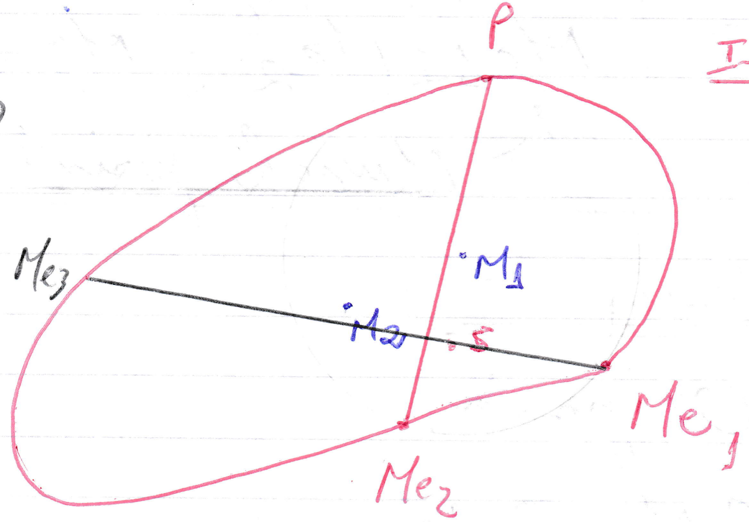
O segundo ponto sobre a elipse

é o ponto Musich (M_e), ou seja,

Me = Musich elipse.

Desta forma, nós temos mais um referencial de checagem dos cálculos. Vejamos:

Alinhar os pontos Me1 S e M2, and Me3



Important: Alinhar os pontos P M1 S e Me2

obs: Este é um tipo de configuração que eu criei.
(checar com cuidado!!!!)

obs: No primeiro exemplo, os dois círculos não há tanta convergência (colinear) dos pontos.

Nós podemos observar que:

SM_1 tem o diâmetro do primeiro círculo e os duas extremidades (estão) do segmento estão sobre o círculo, mas não está sobre nenhum ponto de intersecção entre os círculos. Observamos que somente o ponto P é uma intersecção entre os dois círculos M_1 e M_2, mas não estão sobre o outro ponto Me.

O segmento que passa pelos pontos S M_2 tem o diâmetro (acabou a caneta) do círculo M_2 e as duas extremidades estão sobre a elipse.

Obs: Checar os pontos Me_1, Me_2 e Me_3.
↳ Musich point.

Interessante:

Os pontos:

a) P M_1 S Me_2 → é uma reta com 4 pontos.

b) Me_1 S M_2 Me_3 → é uma reta com 4 pontos

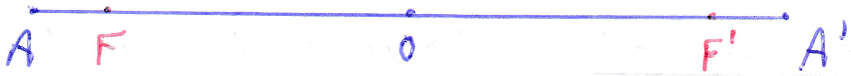
Obs: São duas retas para dar maior consistência aos cálculos e com o ponto Me_1 (Musich point) nós teremos uma maior estabilidade nos cálculos entre os dois círculos e estas duas retas (checar os cálculos).

20231017231700

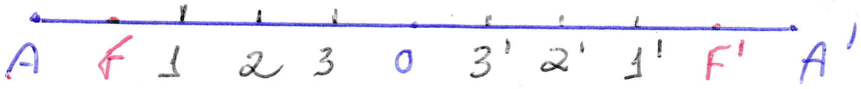
20231018153500

Construção Geométrica da Elipse utilizando-se régua e compasso:

- Trace o eixo maior
- Extremidades são os vértices A' e A', marcando os focos F e F' e o centro O.



A partir de F e F', trace arcos de tamanhos iguais marcando os pontos 1, 2, 3 e 4 e 1', 2', 3' e 4', ajuste de acordo com a reta



Agora, com a ponta seca do compasso ✪ em F e (arcos ou raios) A1', A2', A3'.... e depois com centro em F' e arcos A'1, A'2, A'3... trace os arcos. IMPORT: Compasso A1', depois mova para F e trace arco F! ✩

obs.: Estes procedimentos sempre no segmento $\overline{AA'}$.

Com centro em F e raios A1, A2, A3... e depois com centro em F' e raios A'1', A'2', A'3'..., trace arcos de modo a interceptarem os primeiros.

A curva que passa pelas intersecções e pelos vértices A e A' é a elipse de centro O e focos F e F'.

O segmento de reta ortogonal ao eixo AA' ~~que~~ passa pelo centro O, é o eixo menor, cujas extremidades são as interseções com a elipse formando seus vértices B e B'.

Important:

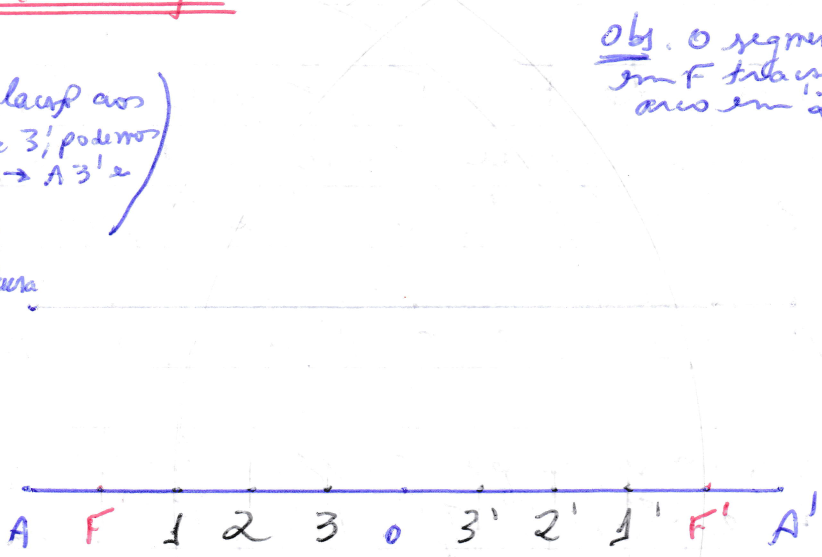
Neste exemplo, a base desta elipse é o Focus, ou seja, a sua unidade de medida. Nós devemos ajustá-la para adequá-la à realidade de nossa pesquisa.

Construção: 10 unidades ou 12 unidades.

obs: (Com relação aos pontos 3 e 3', podemos o ponto A → A3' e A' → A'3.)
→ wrong
muda-se a curvatura.

obs. O segmento A3' guarda em F traços apenas o arco em 2 (A2).

3 e 3' ficam de fora.



Neste caso, erros na realização do arco em 3 e 3' e ainda F. (Ficar atento!!)

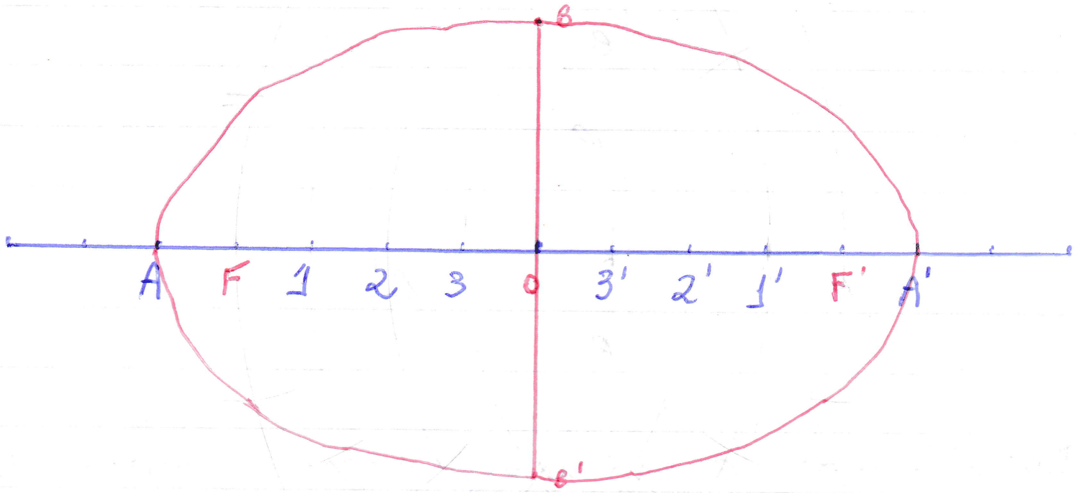
Important:

O segmento A A' deve estar contido numa reta maior para que possamos traçar os arcos de forma correta. Havendo mais pontos de referência, melhores serão os resultados.

Nova construção na próxima página:

Segmento com 14 unidades:

AO em F traça o arco A3' e A'O em F' traça o arco A'3. ⊛
Na intersecção dos arcos 3 e 3', obteremos 2 pontos B e B' (reta ortogonal)



Important

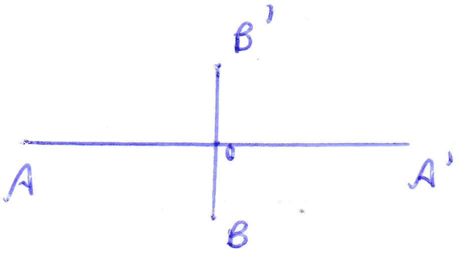
A distância entre A F e A' F' é uma unidade que nós poderemos ajustá-la para adequar-se à excentricidade da referida elipse.

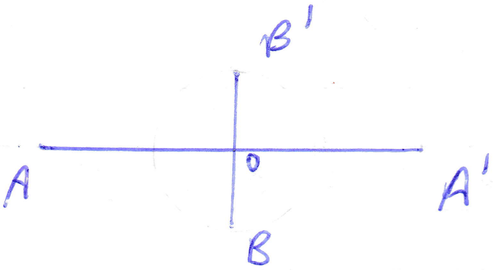
Segunda Forma de Construção de uma Elipse.

A construção desta elipse depende de seus dois eixos.

Important: Ajustando-se esses 2 eixos, ✡ nós teremos a excentricidade. (calcular depois)

Descrevemos dois círculos de centro O com diâmetros iguais aos eixos AA' e BB'.





Dividimos a circunferência maior e menor em N partes iguais. Por conveniência, nós vamos dividi-las em 16 partes iguais, realizando-se as bissetrizes entre os eixos e depois repetimos o processo.

Em seguida, traçamos retas perpendiculares ao eixo AA' pelos pontos que dividem a circunferência maior. ①

Depois, traçamos retas perpendiculares ao eixo BB' pelos pontos que dividem a circunferência menor ②

Os pontos (x_n, y_n) gerados a partir das interseções destas retas determinam a elipse.

Aumentando as retas da elipse:

B1 e B2 usados para bissetrizes

A
BIV, BV, BVI
B'
BVII, BVIII, BIX
A'
BX, BXI, BXII

> pontos que determinam a elipse.

obs: Fazer estas 2 simulações do ponto de vista antrométrico.

Important:

Estas construções foram feitas utilizando-se régua e compasso de forma gráfica e com erros e imprecisões nas definições dos referidos pontos que determinam a elipse.

Agora, nós devemos fazê-lo de forma aritmética, calculando-se os pontos e as suas distâncias, as bissetrizes devem ser obtidas por meio da determinação do ponto (x, y) que dividem cada quadrante da elipse.

Tudo tem que ser demonstrado de forma inequívoca.

20231018183700

20231018210000

A título de informação científica, Ⓐ complementar ao que eu já venho estudando eu encontrei na internet https://zenodo.org/records/1447218, a publicação com o título:

"Signal Time Travel Dilation
TEM Model Time Machine
Creation Theory 10/04/2018
→ Lance E. Wenner

Nome do arquivo:
Wenner-Time-Dilation-Ref-10-04-2018.pdf

Obs: Estudar com Tony Yuan 7-2.pdf
(Gravitational Waves).

Pág. 6- VI.

Gravity Time Length Well

Light (electromagnetic wave time path bending) while passing near a large mass like a Planet is also a time dilation effect rather that light speed change, which is again against ✡ Einstein [1], or some other invisible unknown lensing medium in the vacuum of space.

A mass warps the time length of its surrounding space an amount progressively more the larger the mass within limites per Einstein GR [1].

Tensor Calculus of momentum pressure in GR general relativity of the EINSTEIN [1] dual (4X4) matrix equation includes the fourth dimension time energy.

Ref.: 1) Synge - Tensor Calculus - (1949).pdf
→ 334 pages.

2) The Geometry of Total

Curvature on Complete open surfaces-2003.pdf
→ Katsuhiro Shiohama...
→ 296 pages.

Obs: Pág. 41 — chapter 2
the classical results of
Cohn-Vossen and Huber

↳ referência:

Hilbert, D. and Cohn-Vossen, S,

the Conic Sections, and their
surfaces of Revolution"!

3) The Geometry of Four-Manifolds-
1997.pdf
→ Donaldson/Kronheimer
→ 458 pages.

Obs: Usar este livro para analisar
fourth dimension time energy.

return: Pág. 6

This demonstrates all curved path
space-time gravity
(all earth size gravity for
example)
is mostly time length well charge
effect (time dilation).

Increasing the mass increases
the stress-energy tensors,
hence
bending its space-time curve path
more
(other mass taking less time
length to arrive) thereby,
due to the smaller time arc
at same distance
reducing geodesic path length
of the other mass heading somewhat
toward it (not attraction but
falling more toward larger mass
in less time).

A time length well
Theory for Earth gravity
does therefore not violate
general relativity
but agrees with and its effective
limits of, very large mass

bending actual 3d space,

more than 4d time, once

becoming a very large size like
a neutron star.

IMPORTANT:

→ LESS ENERGY ✡

Less Energy → see Entropy.

Since taking less time, mass or light (EMW) ✡

use less energy

following a space-time curved space (takes more energy to turn away), ✡ therein not violating the conservation of energy Newton [4] law either.

Velocity time length special relativity (SR) change is a different time dilation mode, from general relativity (GR) gravity time length change.

(SR) Increased velocity dilates time longer,

(GR) increased mass dilates objects heading toward it time shorter, both within the limits of Minkowski [8] 4 dimensional space-time for SR and GR.

Pág. 09 – Fig. (13) →

Waveguide delay time formula vs. Einstein SR vacuum Earth length compared indicating similar time curve relations.
Confirms time delay per frequency in a

angular waveguide

Fig.(14) Demonstrates the surfaces thickness (to reflect off) and their waveguide effect to delay wavelengths at different time intervals which in fact splits the light into different frequencies (wavelengths).

(*) The surface material determines the waveguides depth and angle of reflection required to obtain a full color light spectrum. (ver Newton → sobre o seu trabalho sobre as cores).

IMPORTANT: In an equilateral triangle the shape distance keeps all the different output light frequencies arriving at the same time called in phase. In other shapes, glass time delays light, rather than (em vez de) falsely bending or changing light speed etc again as previously discussed.

Arquivo: ellipse-20231022-01.ggb

Roteiro de ensaio

1) Crie os seguintes pontos:

a) F1 = Point(x Axis)
→ (-4, 0)

b) F2 = Point (x Axis)
→ (4, 0)

c) A1 = Point(x Axis)
→ (-5, 0)

d) A2 = Point(x Axis)
→ (5, 0)

e) A = Point(y Axis)
→ (0, 3)

f) O = Intersect(x Axis, y Axis)
→ (0, 0)

obs: Important:

Esta configuração de pontos é muito interessante pois facilita os cálculos.

Vejamos: Os pontos focus F1 e F2 estão na posição (-4,0) e (4,0) e portanto, estão na posição de número par.

Usando-se o sistema cartesiano, mantendo-se uma unidade como padrão de distanciamento entre os pontos e para que os pontos A1 e A2 estejam mantendo a distância de uma unidade dos pontos focus F1 e F2, nós precisaremos escolher o ponto A (y Axis) → (0, 3). Com este posicionamento nós criaremos uma elipse. O interessante, neste caso, é que estamos realizando uma adequação entre os números pares (eixo x) e números ímpares (eixo y), observando-se o distanciamento de uma unidade como padrão.

Posteriormente, nós criaremos o ponto B (yAxis) → (0,-3)

2) Agora criaremos os círculos menor e maior com base no ponto O como origem e o diâmetro do tamanho das retas A1A2 e AB. Vejamos:

a) Círculo menor - AB

c : Circle(O, A)

→ $x^2+y^2=9$

obs: Important: Na aba de configuração do Geogebra chamada Style escolha: (se quiser)

1) Line Thickness: mínimo. 3
2) Line Opacity: mínimo. 20

b) Círculo maior

d : Circle(O, A2)

→ $x^2+y^2=25$

obs: 1) Line Thickness: 3
2) Line Opacity: 20

3) Em seguida, nós criaremos os pontos:

a) C = Intersect(d, yAxis, 2)
→ (0,5)

b) D = Intersect(d, yAxis, 1)
→ (0,-5)

Vou ajustar para pontos em vez de intersecção pois facilita a execução

Portanto: Voltamos

Criação B = Point(yAxis)
→ (0, -3)

Em seguida, criaremos:

a) C = Point(yAxis)
→ (0 5)

b) D = Point(yAxis)
→ (0, -5)

Agora, nós criaremos os círculos:

a) Círculo menor:
c: Circle(O, A)
→ $x^2+y^2=9$

b) d: Circle(O C)
→ $x^2+y^2=25$

Retornando um pouco

Criaremos os pontos:

a) E = Point(xAxis)
→ (-3, 0)

b) F = Point(xAxis)
→ (3, 0)

Agora (sim):

a) c: Circle(O A)
→ $x^2+y^2=9$

b) d = Circle(O C)
→ $x^2+y^2=25$

3) **Nova Fase**:

Angle Bisector → important:

Para nós criarmos Angle Bisector, nós poderemos fazer de duas formas:

a) Criaremos os pontos:

a1) G = Point(y Axis)
$\rightarrow (0, 1)$

a2) H = Point(x Axis)
$\rightarrow (1, 0)$

a3) I = (1, 1) ⇒ Point

↳ Aqui está o ponto que facilitará a construção.

Vejamos:

Criaremos

f : Line(0, I)
$\Rightarrow -x + y = 0$

obs: Esta é a função do 1° Quadrante.

Para agilizar:

Criaremos o ponto

$J = (-1, 1)$

Em seguida:

g = Line(0, J)
$\rightarrow -x - y = 0$

obs: Esta é a função do 2° Quadrante.

Interessante:

O que foi feito facilita a construção da elipse.

Agora, vamos construir de outra forma, utilizando-se Angle Bisector, da seguinte maneira:

a) 1º Quadrante:

Voltando um pouco, nós criamos os pontos

a1) G = Point(y Axis)
$\rightarrow (0, 1)$

a2) H = Point(x Axis)
$\rightarrow (1, 0)$

Após: Angle Bisector

b1) f: Angle Bisector(H, O G)
$\rightarrow -0.707106781186547x + 0.707106781186547y = 0$

obs: Esta função é igual
$-x + y = 0$

b) 2º Quadrante:

Criaremos o ponto I

I = Point(x Axis)
$\rightarrow (-1, 0)$

Em seguida: Caso mantenha o f(b1)

g: Angle Bisector(I, O G)
$\rightarrow 0.70710678\ldots x + 0.70710678\ldots y = 0$

Obs: Esta função é igual à

$-x - y = 0.$

Important:

Nós manteremos a versão mais simplificada, pois facilitará a didática para os futuros estudantes desta pesquisa e de matemática e física.

Em resumo:

Após a criação do círculo maior (O, C).

d: Circle(O, C)

$\rightarrow x^2 + y^2 = 25$

Nós criaremos, dois pontos:

a) O ponto $G = (1, 1)$
→ que dividirá o 1º Quadrante.

b) O ponto $H = (-1, 1)$
→ que dividirá o 2º Quadrante.

Em seguida, nós criaremos as linhas:

a) f: Line(O G)
$\Rightarrow -x + y = 0$

b) g: Line(O H)
$\Rightarrow -x - y = 0$

Obs: Desta forma os quatros quadrantes estão divididos ao meio.

Importantíssimo:

Antes de criarmos as linhas f e g, nós devemos criar 4 pontos para ajudar na 2ª operação de Angle Bisector e são os seguintes:

a) $I = (3, 3)$

b) $J = (-3, 3)$

c) $K = (-3, -3)$

d) $L = (3, -3)$

Estudo Aprofundado:

Um aspecto interessante, com o ponto $I = (3, 3)$ nós dividimos o 1º Quadrante ao meio.
Para nós fazermos a próxima

Angle Bisector, primeiro vamos fazer um estudo mais detalhado:

Ponto F = Point(x Axis)
$\rightarrow (3, 0)$

Deste ponto, nós iremos (criara) criar um novo círculo

e: Circle(F, I)
$\rightarrow (x-3)^2 + y^2 = 9$

✓

Obs: antes disso, nós esqueço de criar o ponto

M = Point(x Axis)
$\rightarrow (6, 0)$

Depois de criar este ponto, nós criaremos o círculo e.

Em seguida, nós criamos o segmento h

$$\boxed{\begin{array}{l} h = \text{Segment}(I, M) \\ \rightarrow 4.242640687119286 \end{array}}$$

Obs: Este segmento é $3 \times \sqrt{2}$!!! (interessante!!!)

$\boxed{\text{IMPORTANTÍSSIMO.}}$

O triângulo retângulo formado pelos vértices OIM Δ OIM, com ângulo reto em $\boxed{I}$, cujos catetos OI e IM são iguais, apresentando o mesmo comprimento

$$\boxed{3\sqrt{2}}$$

e cuja hipotenusa $\boxed{\text{OM é 6 unidades.}}$

Atenção:

g: Angle Bisector(F, O, I)
$\rightarrow$ 0.3826... x + 0.9238... y = 0

Esta reta intersecta o cateto IM do triângulo retângulo Δ OIM, no ponto

$$\boxed{N = \text{Intersect}(g, h) \rightarrow (\underbrace{4.242640...}_{(3\sqrt{2})\ \hookrightarrow x}, \underbrace{-1.757359...}_{\hookrightarrow y})}$$

Este novo triângulo Δ ONM,

que é um triângulo obtuso
e também é um triângulo escaleno
Ângulos:

$$\begin{cases} O = 22{,}5° \\ M = 45° \\ N = 112{,}5° \end{cases}$$

Comprimentos: Segmentos

O triângulo t_1

t_1 = Polygon(M, O, N)
$\longrightarrow$ 5.272077...

Segmentos:

m = Segment(O, N, t_1)
$\longrightarrow$ 4.5922011...

n = Segment($\underset{(M)}{M}$, O, t_1) ($\underline{M}$, O, t_1)
$\longrightarrow$ 6

o = Segment(N, M, t_1)
$\longrightarrow$ 2.485281...

Portanto: Triângulo escaleno
com ângulo obtuso.

Interessante:

6 Segmento

h = Segment(I, M) → comprimento

→ 4.242640...

$(= 3\sqrt{2})$

e o ponto

N = Intersect(g, h)

$\rightarrow (\underbrace{4.242640...}_{(x)}, \underbrace{1.757359...}_{(y)})$

este valor é igual ao segment (I, M)

$(3\sqrt{2})$

obs: Os comprimentos são diferentes.

ON > IM.

IMPORTANTÍSSIMO:

Partindo-se do Ponto N (?), cujo valor não é exato.

N = Intersect(g, h)

Nós iremos traçar uma Perpendicular Line no ponto A2,

$$\boxed{\begin{array}{l} i: \text{PerpendicularLine}(A2, \text{xAxis}) \\ \rightarrow x = 5 \end{array}}$$

obs: Este passo desvendará nos caminhos.

Esta perpendicular irá interceptar

f: Line(O, G)
$\rightarrow -x + y = 0$

no ponto ~~A~~ P

P ~~Q~~ = Intersect(f, i)
$\rightarrow (5, 5)$

Obs: Criar este ponto quando da criação dos primeiros pontos.

Exemplos de pontos complementares
(a serem construídos)

P = (5, 5) → 1º Quadrante

Q = (−5, 5) → 2º Quadrante

Obs: Estes dois pontos já dividem os 4 quadrantes, mas devemos marcar os outros 2 pontos para facilitar a construção.

R = (−5, −5) → 3º Quadrante.

S = (5, −5) → 4º Quadrante.

Continuando:

Após construímos a perpendicular sobre o ponto A2 e marcando ponto P=(5,5), este ponto intercepta tanto a linha f como a linha i.

obs:

f: Line (0, G)
→ $-x + y = 0$

i: Perpendicular Line (A2, x Axis)
→ $x = 5$

Portanto: O Ponto P=(5,5) pode ser obtido traçando-se este ponto no 1º Quadrante ou fazendo-se a intersecção da linha f com a linha i (perpendicular ao ponto A2 no eixo X).

Posteriormente:

Marcamos o ponto:

T = Intersect (g, i)
→ (5, 2.0710678....)
(x) (y)

e o ponto

U = Intersect (i, h)
→ (5, 1)

Importantíssimo:

U = Intersect(i, h)
→ (5, 1)

obs: Este ponto deve ser marcado quando da criação dos primeiros pontos da construção.

Lembrando:

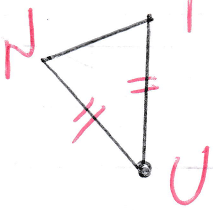
h = Segment(I, M)
→ 4.242640...
($3\sqrt{2}$) → comprimento

obs:

I = (3, 3)
M = (6, 0)

A interceptação da linha i com a linha h e também com a linha g, criará um triângulo isósceles

(isosceles triangle)
invertido



Criaremos o triângulo Δ NTU

t_1 = Polygon(N, T, U)
→ 0.4055915...

n = Segment(T, U, t_1)
→ 1.0710678...

t = Segment(U, N, t_1)
→ 1.0710678...

u = Segment(N, T, t_1)
→ 0.8197598...

} n = t

Obs: o Ponto U = (5, 1), o ângulo interno de U é igual 45°

Important:
O triângulo Δ MA2U é um triângulo retângulo e a sua hipotenusa é $\boxed{\overline{UM}=\sqrt{2}}$

Obs:
A2 M = 1
A2 U = 1
U M = $\sqrt{2}$

Obs: Em um círculo com centro em U = (5, 1), os pontos N e T estarão sobre o círculo.

ff:
Circle(U, N) → $(x-5)^2+(y-1)^2=1.147186...$

obs: Se fizermos um círculo com centro $V = (5,1)$ e raio $A2 = (5,0)$

$\rightarrow (x-5)^2 + (y-1)^2 = 1$

obs: Neste caso, os pontos N e T estarão fora do círculo.

Important:

Pontos:

$I = (3,3)$

$V = (5,1)$

A1

A distância entre estes pontos é

$I = \text{Segment}(V, I)$

$\rightarrow 2.82842712\ldots$

$= 2\sqrt{2}$

Nós devemos criar os seguintes pontos

$V = (1,5)$

$W = \text{Point}(y\,\text{Axis})$

$\rightarrow (0,6)$

Interessante: Vejamos →

(6 Segmento (I, W)

$J = \text{Segment}(I, W)$

$\rightarrow 4.24264068\ldots$

$(= 3\sqrt{2})$

Preste atenção:

$K = \text{Segment}(N, I)$

$\rightarrow 1.757359\ldots$

Mas se nós somarmos

$\overline{UN} + \overline{NI} = \overline{UI}$

Obs: $I = \text{Segment}(U, I)$

$\rightarrow 2.8284271\ldots$

$(= 2\sqrt{2})$

Portanto:

$UN + NI = 2\sqrt{2}\ (UI)$

$IV = UI\ (2\sqrt{2})$

Obs: $\overline{UV} = 4\sqrt{2}$

Vamos prestar atenção.

Isto vai facilitar a minha pesquisa.

$\Rightarrow$

Fazendo AngleBisector do ângulo

A2 O T, nós obtemos

f: AngleBisector(A2, O, T)
↳ 0.195090... x +
0.980785... y = 0

Obs: O mais interessante que o ponto exato que divide este ângulo e o ponto U

$$\boxed{U = (5, 1)}$$

WRONG!!!
Ajuda a dividir o ângulo

Important:

Não divide.

Este ponto (divide) o 1º Quadrante em 8 partes iguais e por Consequente também divide o 3º Quadrante e o ponto é

Z = (−5, −1) → criar este ponto

Agora vamos ligar os ponto Z U

FILE:
elipse-20231022-09.ggb.

f = Segment(Z, U)
↳ 10.198039027...

20231022202233

20231023083000.

Esta fase de criação deste ponto será posteriormente!

$A_1 = (6, 4)$

r = Line $(0, A_1)$

$\rightarrow -2x + 3y = 0$

Retornando:

Nós vamos criar os pontos dos outros quadrantes (2°, 3° e 4°).

a) $A_1 = (-1, 5)$

b) $B_1 = (-5, 1)$

c) $C_1 = (5, 1)$

> Estes pontos são referências para dividir os demais quadrantes (1/8 de um quadrante). (Ajudam)

Até este ponto (correto)

Agora, nós iremos criar os outros pontos de referência:

(CHECAR)

a) $D_1 = (6, 4)$

b) $E_1 = (-6, 4)$

c) $F_1 = (-6, -4)$

d) $G_1 = (6, -4)$

> Outras divisões nos quadrantes (2°, 3° e 4°) → 1/8 de um quadrante. (Ajudam) → checar!!!

Vamos continuar as divisões dos quadrantes:

Fazendo os "espelhamentos":

A) D_1 em relação P, obteremos o ponto $H_1 = (4, 6)$ ✓

Vejamos:

a) Ponto $P = (5, 5)$

b) Ponto $D_1 = (6, 4)$

c) Ponto $H_1 = (4, 6)$

Interessante:

A distância entre os pontos $\overline{D_1 P}$ e $\overline{PH_1}$ são iguais à $\sqrt{2}$.

Agora, nós viemos criar os outros pontos:

B) Ponto $J_1 = (-4, 6)$

obteremos:

a) $E_1 = (-6, 4)$

b) $Q = (-5, 5)$

c) $J_1 = (-4, 6)$

C) Ponto $J_1 = (-4, -6)$, nós obteremos:

a) $F_1 = (-6, -4)$

b) $R = (-5, -5)$

c) $J_1 = (-4, -6)$

D) $K_1 = (4, -6)$, nós obteremos:

a) $G_1 = (6, -4)$

b) $S = (5, -5)$

c) $K_1 = (4, -6)$.

Interessante:
Cada bloco destes 3 pontos, nós obteremos 2/8 de um quadrante.

Portanto:

a) $H_1 P D_1$ = 2/8 do 1° Quadrante;

b) $I_1 Q E_1$ = 2/8 do 2° Quadrante;

c) $F_1 R J_1$ = 2/8 do 3° Quadrante e

d) $G_1 S K_1$ = 2/8 do 4° Quadrante.

---

* Checar o ponto $U = (5, 1)$ → não divide o quadrante em 1/8.
(11,30° → correto 11,25°)

Vamos checar os outros pontos:

Por exemplo: $D_1 P H_1$

→

Os pontos D_1 e H_1 estão errados.

Vamos criar outros mecanismos de checagem.

RETORNO :

Usaremos somente pontos precisos e não fazer Angle Bisector
↳ usa números imprecisos.

↓
correto.

Veremos :

Arquivo mais atualizado

ellipse-20231023-03.ggb

Novos Cálculos :

ellipse-20231023-04.ggb ⇐

Paramos no ponto U

U = Intersect(i, h)
→ (5, 1).

Para confirmar a intersecção, criamos o ponto

Z = Intersect(h, i)
→ (5, 1).

Para ajudar nos cálculos:

Criaremos os pontos:

a) $A_1 = (-1, 5)$
b) $B_1 = (-5, 1)$
c) $C_1 = (-5, -1)$
d) $D_1 = (-1, -5)$
e) $E_1 = (1, -5)$
f) $F_1 = (5, -1)$

> Estes pontos serão úteis para os cálculos de Angle Bisector.

Important:

Nós usaremos apenas Angle Bisector para dividi ao meio os 1º, 2º, 3º e 4º Quadrantes.

Vejamos:

$L = (3, -3)$
$I = (3, 3)$

> criar uma linha ligando estes pontos.

$g = \text{Segment}(L, I)$
$\Rightarrow 6$

Criar os seguintes pontos:

a) H_1 = Point(d)
→ (4, -3)

b) I_1 = Point(d)
→ (4, 3).

ligar estes pontos.

r = Segment(H_1, I_1)
→ 6

Vamos marcar os pontos sobre a elipse.

J_1 = Intersect(p, q, 2)
→ (3, 2.4)

K_1 = Intersect(p, r, 2)
→ (4, 1.8)

continuando:

L_1 = Intersect(p, r, 1)
→ (4, -1.8)

M_1 = Intersect(p, q, 1)
→ (3, -2.4)

Agora, nós vamos fazer o mesmo procedimento do outro lado (2º e 3º Quadrantes)

Os pontos:

J = (-3, 3)]
K = (-3, -3)]> ligar estes pontos

s = Segment(K, J)
→ 6

N_1 = Point(d)
→ (-4, 3)

O_1 = Point(d)
→ (-4, -3)
]> ligar estes pontos

a = Segment(O_1, N_1)
→ 6

P_1 = Intersect(p, s, 2)
→ (-3, 2.4)

Q_1 = Intersect(p, a, 2)
→ (-4, 1.8)

R_1 = Intersect(p, a, 1)
→ (-4, -1.8)

S_1 = Intersect(p, s, 1)
→ (-3, -2.4)

File de referência:

ellipse-20231023-05.ggb.

Criar o Frégier Point:

Crie o ponto T_1 sobre a elipse (ponto aleatório)

Crie outro ponto aleatório no outro lado da elipse: U_1

Após crie o segmento que ligue o ponto U_1 T_1.

Em seguida, use o comando Perpendicular Line sobre o ponto T_1. Esta linha interceptará a elipse no outro lado, use o comando Intersect que unirá esta linha perpendicular à elipse.

Em seguida, crie uma linha que ligue (Segment) V_1 U_1 e em seguida marque o Polygon (T_1, U_1, V_1).

Neste momento, nós criamos o primeiro triângulo retângulo.

Para criar o segundo triângulo retângulo, nós devemos criar outro ponto:

W_1 sobre a elipse

Depois, com o comando Segment, ligar os pontos T_1 W_1.

Use o comando Perpendicular Line sobre esta linha no ponto T_1.

Esta linha intercepta a elipse no ponto Z_1, crie uma linha ligando os pontos W_1 e Z_1, marque em

Use seguida o Polygon:
Polygon(T_1, W_1, Z_1).

Em seguida use o comando

Intersect em relação aos dois triângulos retângulos, criando-se assim, o ponto

Frégier Point (point D_2)

File: ellipse-20231023-padrão-Frégier-Point.ggb.

Criação de 2 círculos que se interceptam sobre a elipse em 2 pontos:

Primeiro:

Crie a linha D_2T_1, sendo D_2 o ponto Frégier Point.

I_1 : Line(D_2, T_1)
$\rightarrow -4.1342\ldots x + 0.924011\ldots y = -4.61\ldots$

Após crie o ponto que intercepta esta linha com a elipse no ponto
($H2$ = Intersect(p, I_1, 2)
$\rightarrow (0.44923\ldots, -2.987866)$.

Agora, partiremos para CIRCLE

Use o comando:

Circle through 3 Points

Ligando os seguintes pontos:

a) c_1: Circle(T_1, H_2, Z_1)

$\rightarrow (x - 1.0888275...)^2$
$(y + 0.0863965...)^2 =$
$8.827609...$

b) d_1: Circle(T_1, W_1, Z_1)

$\rightarrow (x + 0.7275995...)^2 +$
$(y + 0.4830656...)^2 =$
$16.96827 84...$

Important:

Os 2 círculos se cruzam em 2 pontos (T_1 e Z_1) sobre a ellipse.

Obs: Checar se as linhas correspondem aos diâmetros dos referidos círculos.

File:

ellipse-20231023-10.ggb.

Off: Calcular os centros destes círculos com geometria e fazer simulação somente sobre estes círculos e linhas, analisando os seus alinhamentos.

20231023183200

20231024083000

Estudo sobre dois círculos que se interceptam em dois pontos e o ponto Frégier Point:

Agora: 20231024163100:

Simulei dos 0830 às 1631 e obtive o arquivo:

ellipse-20231024-06-dois-circulos-MAIS-PROXIMO---3X3-PONTOS.ggb

obs: Descrevê-lo posteriormente.

Ponto: J

J = Interseção(f, Eixo x)
→ (1.76, 0)

Este ponto é interessante (estudar)

obs: O interessante desta simulação é que o ponto H e K há a interseção de 3 figuras geométricas.

— 2 círculos

— 1 elipse

Do outro lado, há também a interseção do círculo maior com a elipse.

Veja outro arquivo:

ellipse-20231024-06-dois-circulos-MAIS-PROXIMO---3X3-Pontos-Ponto1-76.ggb

Continuar as simulações dos dois círculos.

20231024175600

20231025081800

Eu criei uma forma de unir dois círculos que se interceptam em dois pontos e os quatro pontos criados que correspondem ao dois diâmetros destes dois círculos estão sobre a elipse.

Passos para criar esta simulação

obtida na data de
20231025120000
estes passos estão armazenados no arquivo:

Ellipse-20231025-01-2-
circulos-ellipse-07.ggb

Source: Data-Novo Vivo-010-2023/
Geogebra-2023.

Obs: Estes últimos quatro dias foram de intensa pesquisa com o uso de computador.

Passos de criação:

1) A = Intersect(x Axis, y Axis)
$\rightarrow$ (0, 0)

2) I = Point(x Axis)
$\rightarrow$ (-8, 0)

3) J = Point(x Axis)
$\rightarrow$ (8, 0

4) B = Point(y Axis)
$\rightarrow$ (0, 6)

5) D = Point(x Axis)
$\rightarrow$ (0, -6)

6) c: Ellipse(I, J, B)
$\rightarrow 9x^2 + 25y^2 = 900$

7) C = Point(c)
$\rightarrow$ (3.94..., 5.51...)

Obs: Este ponto é aleatório e será utilizado para a criação dos dois triângulos retângulos para a obtenção do ponto Fregier Point

8) f: Perpendicular Line
(I, x Axis)
$\rightarrow x = -8$

Obs: no ponto I (foci I), line through I perpendicular x Axis

9) Intersect
(c, f)
$\rightarrow$ E = (-8, -3.6)
$\rightarrow$ F = (-8, 3.6)

Obs: Estes dois pontos intersectam a perpendicular sobre a elipse

10) g = Segment
(E, C)
$\rightarrow$ 15.026...

11) h: Perpendicular
(C, g)
$\rightarrow$ 11.94... x - 9.11... y = -97.404...

12) G = Intersect
(c, h, 2)
→ (9.533..., −1.8109..)
obs: Perpendicular
sobre o ponto C e
intercepta a elipse c.

13) i = Segment
(E, G)
→ 17.62464...

14) j = Segment(F, C)
→ 12.100070...

15) k: Perpendicular
(C, j)
→ −11.94...x − 1.912...y =
−57.713...

16) H = Intersect
(c, k, 2)
→ (5.624..., −4.96...)

17) I = Segment
(F, H)
→ 16.090947...

18) K = Intersect
(i, 1)
→ (1.857...,
−2.594...)

obs: Este ponto K
é o Fregier Point.

19) m: Line(C, K)
→ 8.10...x − 2.09009...y =
20.48333999...

20) L = Intersect(g, 1)
→ 2.82401..., 0.3476...)
obs: Dispensável mas
tem um valor referencial.

21) M = Intersect
(c, m, 2)
→ (0.98..., −5.97...)

22) Com o comando
CIRCLE THROUGH 3 POINTS
criaremos
d: Circle(C, H.M)

$$\to (x-2.1477118\ldots)^2 + (y+0.14655060\ldots)^2 = 35.26702036\ldots$$

Important:
O Ponto C é um
ponto aleatório.
O Ponto H é a
perpendicular sobre
o ponto C do segundo triângulo.

Este ponto H também intercepta a ellipse c.

INCRÍVEL:

Este ponto H fazendo-se um segmento até o ponto K (Frégier Point)

Usando-se o segmento CM que é o diâmetro do primeiro círculo e usando-se a função

Perpendicular Bisector,

nós descobrimos o centro deste círculo no ponto que esta perpendicular intercepta o segmento CM.

Obs: Para checar se é mesmo o centro, eu utilizei o sistema das duas cordas sobre o círculo, eu fiz Perpendicular Bisector destas duas cordas e elas se encontraram no mesmo ponto.

Outro jeito é usando um compasso para marcar a perpendicular sobre este segmento.

Portanto:

23) n: Perpendicular Bisector(M, C)

→ $-2.9606\ldots x - 11.4832\ldots y = -4.67\ldots$

24) N = Intersect(m, n)

→ $(2.4676\ldots, -0.22903\ldots)$

25) e : Circle(N, C)

$\rightarrow (x - 2.4676...)^2 + (y + 0.2290...)^2 = 35.1578...$

Importantíssimo:

Com este círculo nós podemos eliminar o círculo anterior (C, H, M) → criado por meio dos três pontos, ou seja, este novo círculo (N, C) encontra ou intercepta a elipse em dois pontos $\boxed{C \text{ e } M}$

Portanto, há 4 pontos na mesma linha (colineares)

→ $\boxed{\text{C, N, K (Frégier Point) e M}}$

Obs:

O Ponto H quando ligado ao Ponto K (Frégier Point), encontra o ponto F ("foci") que a perpendicular sobre o foci I (−8, 0).

26) p : Circle(F, H, C)

$\rightarrow (x + 1.187723...)^2 + (y + 0.680483...)^2 = 64.72964422...$

27) g: Perpendicular Bisector(F, H)
→ g: -13.62455...x + 8.5609663...y = 10.35661077...

28) O = Intersect(g, l)
→ (-1.187723..., 0.68048...)

Source:

Ellipse-20231025-01-2-circulos-e-ellipe-07.ggb

Important:

O segmento:

a) CM = diâmetro do primeiro círculo (menor)

b) FH = diâmetro do segundo círculo (maior)

Important:

4 pontos em cada linha (colineares)

a) C N K M,

b) F O K H.

obs!!! Estou feliz!!! Eu tive a benção de DEUS.

Voltando aos estudos de 20231017

Os pontos C (aleatório) e K (Frégier Point) são padrões desta simulação.

Agora, os pontos

a) H → é o ponto Me1.

b) M → é o ponto Me2.

c) F → é o ponto Me3.

Obs: Me = Munich Ellipse

Importante:

Newton calculated the force of gravitational attraction between two balls, such as planets and the sun. To do this, he had to create, together with

Gottfried Wilhelm von Leibniz

and other scientists, the foundation of what is now called

integral and differential calculus.

The law of gravitation was first tested in the experiments of the British Henry Cavendish in 1798. They were carried out almost simultaneously with

Coulomb's experiments,

which I will discuss later, and on very similar equipment.

✡ ⇒ The forces of mutual gravitational attraction of two massive balls were a huge number of time less than the forces of electrical interaction in Coulomb's experiments, and their measurement required great skill from the experimenter.

Mathematical Work.pdf

Pág. 539(548) - Historical Remarks
On Gauss-Bonnet.

Let M be a two-dimensional oriented Riemannian manifold and D a compact domain on M, bounded by a sectionally smooth curve C. The Gauss-Bonnet formula says:

$$\sum(\pi-\alpha)+\int_C \kappa_g \, ds+\iint_D K\, dA = 2\pi\chi(D)$$

where $\chi(D)$ is the Euler characteristic of D and the members at the left-hand side are respectively the exterior angles at the corners, the integral of the geodesic curvature, and the integral of the Gaussian curvature.

These are respectively the point, line, and surface curvatures, so that the formula expresses the total curvature in terms of a topological invariant.

The most important special case of the formula is the theorem on the angle sum of a rectilinear triangle in the euclidean space.

Pág. 548 (557) – What is Geometry?

IMPORTANT:

Pág. 549 (558) –

Euclid realized that the PARALLEL POSTULATE was not as transparent as his other axioms and postulates.

Efforts were made to prove it as a consequence.

Their failure led to the discovery of non-Euclidean geometry by C. F. GAUSS, John Bolyai, and N. I. Lobachevski in the early 19th century.

Pág. 551 (560) →

A fundamental notion is "CURVATURE" in its different forms. Its simplest manifestation

is the circle in plane Euclidean geometry.

① IMPORTANT: O problema está no círculo pois este é representado de forma equivocada. Tanto no plano euclidiano como no "non-plane" euclidiano, nós observamos uma inconsistência matemática.

Nós devemos adequá-los à uma nova realidade que se impõe, ou seja, estas figuras geométricas devem ser prescritas de acordo com os novos parâmetros estabelecidos pela nova Matemática e consequentemente, a uma nova Geometria que se fez presente com a readequação dos princípios matemáticos antigos aos novos, estabelecidos pelo

M.U.S.

→ Mathematical Uniforme Space.

Uma nova matemática para uma nova realidade, realidade esta antiga e até agora, desconhecida pelo mundo da Matemática antiga.

Retornando:

Pág. 59(90') → Coulomb's Experiments.

⇒ Relação de forças entre as estruturas.

In mathematical terms it measures the non-commutativity of covariant differentiation.

It is remarkable that suitable algebraic combinations of curvature give topological invariants.

To illustrate this we wish to state the

Gauss-Bonnet theorem.

Let D be a domain with a sectionally smooth boundary on a two-dimensional Riemannian manifold.

Then the Gauss-Bonnet theorem is

the formula

$$\sum(\pi-\alpha)+\int_{\partial D}\kappa_g\,ds+\iint_{D}K\,dA=2\pi\chi(D),$$

Obs: Checar a fórmula correta

Let $X(u,v)$ be an orthogonal parametrization of a neighborhood on an oriented surface S in $\mathbb{R}^3$, and let $w(t)$ be a smooth field of unit vectors along the curve

$\alpha(t) = X(u(t), v(t))$ on S.

Then

$$[Dw/dt] = \frac{1}{2}(EG)^{-\frac{1}{2}}\{G_u\, dv/dt - E_v\, du/dt\} + d\varphi/dt,$$

where $\varphi(t)$ is the angle from X_u to $w(t)$ in the given orientation.

d) The Gauss-Bonnet theorem
→ 10 pages.

Pág. 5 → Definition 3. 5.

The geodesic curvature K_g of a curve is a measure of the amount of deviance of the curve from the shortest arc between two points on a surface.

Definition 3. 6.

The Gaussian curvature K of a surface is an intrinsic measure of the curvature of a surface at a point.

Retornando:

$$\sum(\pi-\alpha)+\int_{\partial D} K_g\, ds+\iint_{D} K\, dA = 2\pi\chi(D),$$

where the first term is the sum of the exterior angles at the corners, the second term is the integral of the geodesic curvature along the sides, the ~~(third)~~ third term is the integral of the Gaussian curvature over D, and $\chi(D)$ is the Euler characteristic of D.

Pag. 553 (562)-

The above provides the geometrical basis of gauge field theory in physics.

Here M is a four-dimensional Lorentzian manifold, so that the Hodge $*$-operator is defined, and we define the codifferential

$$\delta = * d * \qquad (17)$$

M.U.S.

There is discrepancy of terminology and notation, as given by the following table:

mathematics	physics
connection ω	gauge potential A
curvature Ω	strength F

Maxwell's theory is based on a $U(1)$-bundle over M, and his field equations can be written

$$dA = F, \quad \delta F = J, \qquad (18)$$

where J is the current vector.
Actually, Maxwell wrote the first equation as

$$dF = 0, \qquad (19).$$

which is a consequence.

Intrinsically define curves.

Pág. 1027 (1043) -
the Nature of Space

History of discrete space

In discussing the notion of curved spaces,

Bernhard Riemann

remarked in 1854 that it would be easier to give a general mathematical definition of distance if

space were discrete.

PLANCK LENGTH:

$\text{Sqrt}[\hbar G/c^3] \cong 2 \times 10^{-35}$ meters

since at this scale dimensional analysis suggests that quantum effects should be comparable in magnitude to gravitational ones.

Important: Pag. 1154 (1170) →

Geometry → Euclid gave axioms for basic geometry around 300 BC which were used with fairly little modification for more than 2000 years. In the 1830s, however, it was realized that the system would remain consistent even if so-called

PARALLEL POSTULATE

was modified to allow space to be curved.

Alexandrov - Intrinsic Geometry of Convex Surfaces - 2005/

a) Alexandrov - Selected Works Part I.. - 1996.pdf

Pág. 01(12) - Chapter I

On Infinitesimal Bending of Nonregular Surfaces
→ 1936

Study of continuous length - preserving deformations of a surface is sensible not only for regular surfaces:

It suffices that on a surface there be enough curves for which the concept of length is meaningful.

Lebesgue[1] defined the corresponding class of the so-called rectifiable surfaces (la famille des surfaces rectifiables) as follows.

A surface S,

$$x=f(u,v),\ y=\varphi(u,v),\ z=\overset{(\psi)}{\psi}(u,v).$$

given over a domain D in the plane (u,v) is said to be rectifiable, if to each rectifiable curve on D there corresponds a rectifiable curve on S.

IMPORTANT:

For a surface homeomorphic to a sphere,

we naturally take a sphere of unit radius as the domain of parameters. Then, every (convex) Convex surface is rectifiable, as seen if a sphere in the interior of the surface is mapped onto it in (de tal modo) such (em tal) a way that a point of the sphere is sent to the point on the surface lying on the same radius.

a) 20231028 - Posamentier - The Secrets of Triangles A Mathematical Journey-(2012).pdf

Pág. 128 - The angle bisector not only bisects the angle, it also partitions the opposite side proportionally to the two adjacent sides. That is, for FIGURE 5-3, we have AD as the bisector of angle BAC, which then gives us

$$\boxed{\frac{c}{b} = \frac{m}{n}}$$

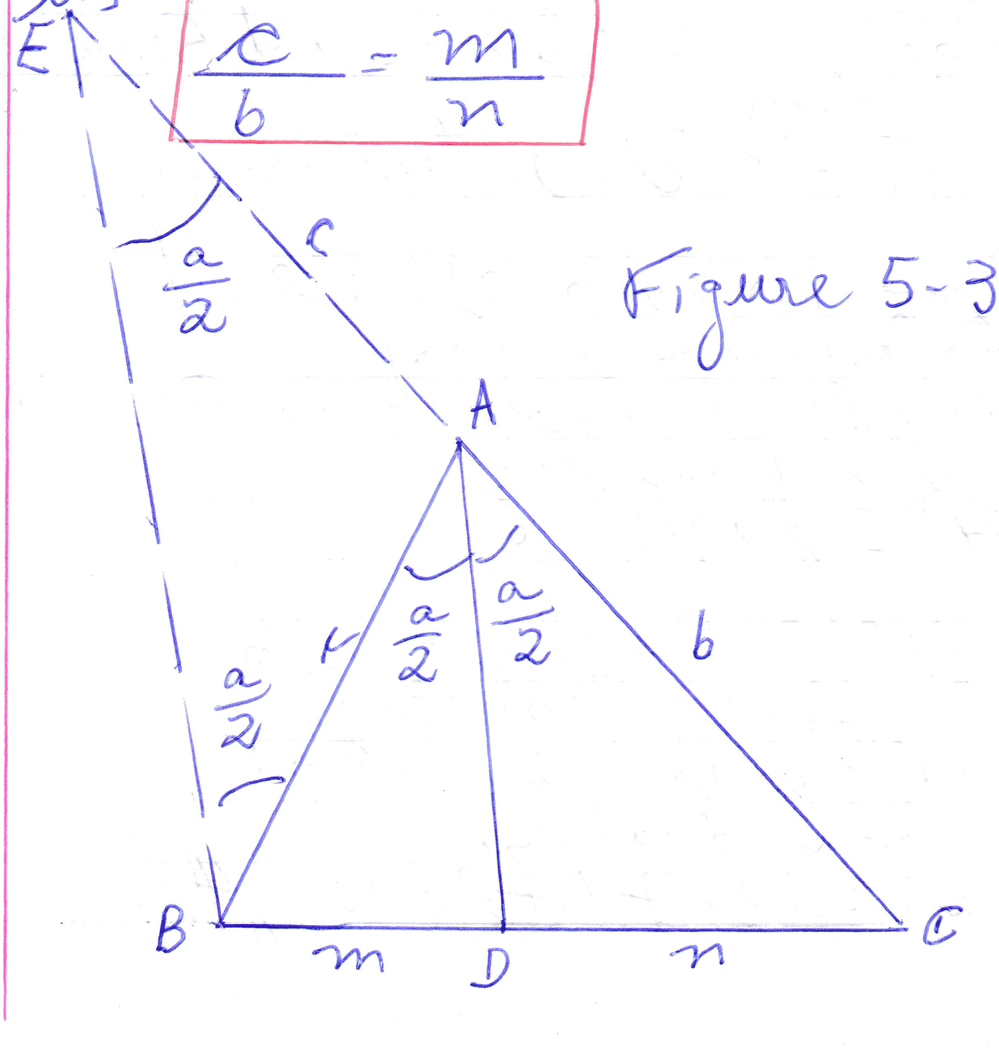

Figure 5-3

Pag. 129

To show why this is true is a bit tricky, as we must bring in some auxiliary lines:

We construct BE parallel to AD and intersecting CA (extended) at point E.

All the angles marked with $\frac{a}{2}$.

are equal.

Therefore, since triangle AEB is isosceles, AE = AB = c.

For triangle BCE, we have

$$\frac{AE}{CA} = \frac{BD}{CD}, \text{ or } \frac{c}{b} = \frac{m}{n}.$$

While it is relatively easy to find the length of and altitude of a triangle (usually using the Pythagorean theorem), it is not so trivial to find the length of an angle bisector of a triangle.

There is a very helpful relationship that can be used to find the length of an angle bisector

Pag. 130 — In FIGURE 5-4, we have triangle ABC, with AD, the bisector of ∠ BAC, which we will call t_a. We begin our development by extending AD beyond D to meet the circumscribed circle of triangle ABC at E.

We then draw BE.

Since $\angle BAD = \angle CAD$, and $\angle E = \angle C$

(both angles inscribed in the same arc),

$\triangle ABE \sim \triangle ADC$, and

$$\frac{AC}{AD} = \frac{AE}{AB}, \text{ or}$$

$$AC \cdot AB = AD \cdot AE = AD(AD+DE) =$$

$$AD^2 + AD \cdot DE$$

However, $AD \cdot DE = BD \cdot DC$, since they are intersecting chords of the same circle.

Substituting equation (II) into equation (I), we obtain $AD^2 = AC \cdot AB - BD \cdot DC$, which is what we sought to develop.

Yet in simpler terms, using the letter designations in

FIGURE 5-3, we can write this relationship as

$$t_a^2 = bc - m \cdot n, \text{ or}$$

$$t_a = \sqrt{bc - mn}$$

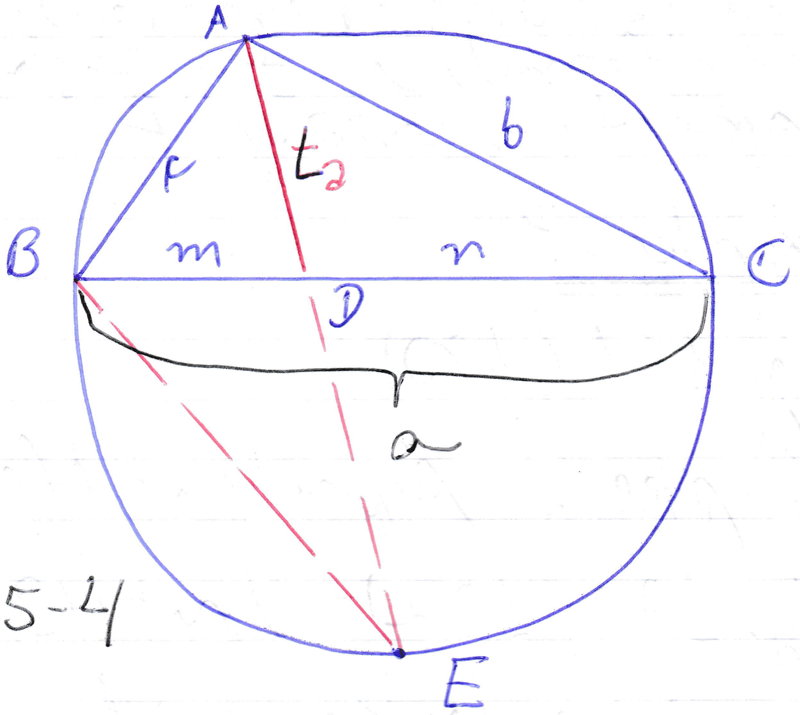

Figure 5-4

For the ambitious reader we provide yet another formula for finding the length of the angle bisector of a triangle given only the three sides:

$$t_a = \frac{2\sqrt{bcs(s-a)}}{b+c},$$

$$t_b = \frac{2\sqrt{cas(s-b)}}{c+a},$$

$$t_c = \frac{2\sqrt{abs(s-c)}}{a+b}, \text{ where}$$

$$s = \frac{a + b + c}{2}.$$

$$y = \frac{1}{\sigma\sqrt{2\pi}} e^{\frac{-(x-\mu)^2}{2\sigma^2}}$$

In this formula μ (mu) is the mean or midpoint of the curve, π is the approximate constant 3.14159, e is the approximate constant 2.718282, and σ (sigma) is the standard deviation.

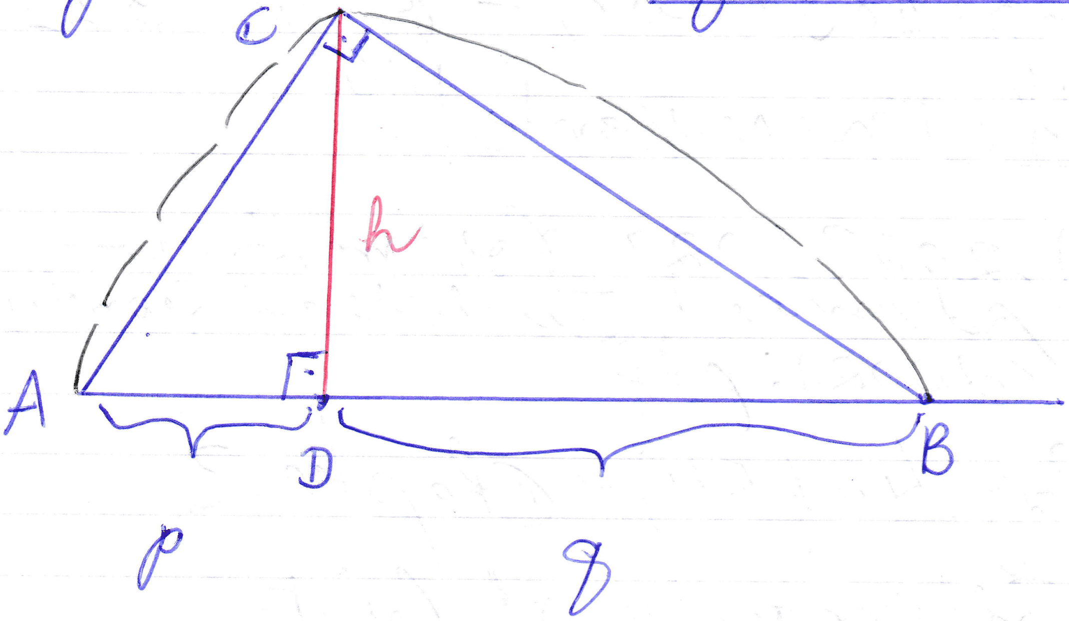
Pág. 184 (203) - The Geometric Mean.

The geometric mean of two numbers a and b is $\sqrt{ab}$, and of three number, a, b, and c is $\sqrt[3]{abc}$.

Therefore, for the above situation the geometric mean of the 3 interest rates is

$$\sqrt[3]{(0.1)(0.4)(0.5)} \simeq 0.27$$

Pág. 185 (204) - Figure 3.10



From the triangle similarity, $\Delta ADC \sim \Delta CDB$, we get the proportional relationship

$\frac{AD}{CD} = \frac{CD}{BD}$, or $\frac{p}{h} = \frac{h}{q}$.

this gives us $h = \sqrt{pq}$, which is one reason why h is considered the geometric mean between p and q.

ORTHOGONAL COORDINATE SYSTEM

It is only in the special case of an orthogonal coordinate system - for which e_ξ and e_η are

everywhere mutually perpendicular

Obs: Estudar com profundidade esta afirmação.

checar

⇒ Eu tenho as minhas dúvidas !!!

Aprofundar com cautela !!!

Cont. (retornando ao texto)

everywhere mutually perpendicular - that this term is absent (the simplest example is, of course, Cartesian coordinates).

Similarly, given two vector

u an v with curvilinear ~~Coordi~~ components

(u^ξ, u^η) and (v^ξ, v^η) at a prescribed point (ξ, η), we can form their dot product
(product)

$$u.v = u^\xi v^\xi + u^\eta v^\eta + (u^\xi v^\eta + u^\eta v^\xi)\, e_\xi . e_\eta,$$

and thus determine the angle θ between them from

$$\cos\theta = \frac{u.v}{|u|\,|v|}, \qquad (7.43)$$

where $|u|$ is given in terms of (u^ξ, u^η) by an expressions analogous to (7.42).

We can also avoid the normalization (7.40) and use the metric tensor directly to compute angle between vectors: we replace the numerator in (7.43) by

(R)

$$[u^\xi, u^\eta] \begin{bmatrix} r_\xi . r_\xi, & r_\xi . r_\eta \\ r_\xi . r_\eta & r_\xi . r_\eta \end{bmatrix} \begin{bmatrix} v^\xi \\ v^\eta \end{bmatrix},$$

and similarly $|u|$ and $|v|$ are replaced by the square roots of the scalar values obtained by multiplying the metric on the left and right by the components of u and v, respectively.

Figure 8.28 illustrates lines of curvature on a "triaxial ellipsoid"

(all three semi-axes are of unequal length)

⇑ OBS:

checar a viabilidade de utilização quando projetados ortogonalmente em um plano.

– in this case, the lines of curvature are all closed loops. They form an orthogonal net, except at the umbilics situated on the section containing the smallest and largest semi-axes. These curves were first accurately drawn – in plane projection – by

Gaspard Monge in his 1807

treatise "Application de l'Analyse à la Géométrie".

...

– the surface "patches" delineated by the lines of curvature would
⇒ define the ~~sp~~ shapes of the roof tiles, and

he proposed that chandeliers be suspended from two umbilical points - see [367, p. 269].

The lines of curvature shown in Fig. 8.28 admit an elegant geometrical interpretation.

For constants a, b, c and three different instances

λ, μ, ν

(such that $0 < \lambda < c^2 < \mu < b^2 < \nu < a^2$)

of the parameter η in the equation

$$\frac{x^2}{a^2-\eta} + \frac{y^2}{b^2-\eta} + \frac{z^2}{c^2-\eta} - 1 = 0 \quad (8.100).$$

Pag. 197 (209) - Chapter 9

Algebraic Geometry

Hence, to describe an algebraic space curve,

two polynomial equations

$g(x, y, z) = h(x, y, z) = 0$ in

the three Cartesian coordinates (x, y, z)

must be specified.

But this simply amounts to formulating the space curve as the set of points common to the two surfaces

$g(x, y, z) = 0$ and

$h(x, y, z) = 0$ — i.e.,

as the intersection of those surfaces.

This fact incurs difficult theoretical issues, concerning the conditions under which two algebraic surfaces will intersect in a

single "irreducible" space curve

or in a composite of such curves.

Gravitational instantons
→ splace Einstein equations is a consistent background of the EFS model preserving certain fraction of the supersymmetry.
The field configuration is given by

$$ds^2 = \frac{dr^2}{1-\frac{a^4}{r^4}} + \frac{r^2}{4}\left(d\theta^2 + \sin^2\theta\, d\phi^2\right) + \frac{r^2}{4}\left(1-\frac{a^4}{r^4}\right)\left(d\psi + \cos\theta\, d\phi\right)^2,$$

$$F = \frac{2}{r^4}(e^3 \wedge e^0 + e^1 \wedge e^2) = \dot{F},$$

$\phi = 0$; $a = 0$; $g_1 = g_2$

with the above choice of background fields, the supersymmetry variations give the projector conditions,

$$(1 - \gamma_5)\epsilon = 0, \quad (\alpha^3 + \dot{\alpha}^3)\epsilon = 0$$

With these projectors the killing spinor equations look really simple, namely,

$$\partial_\mu \epsilon = 0$$

So the killing spinors are independent of b_z, θ, ϕ, ψ.

Because of the twin supersymmetric conditions, the solution preserves

$\boxed{\frac{1}{4}}$ of the supersymmetry.

The Curvature of Space

Curvature and Intrinsic Geometry of a Surface in the Works of Euler.

By the curvature of a curve at a point we mean the limit of the ratio of the angle $\Delta\alpha$ between the tangents at the endpoints of an arc to the length Δs of that arc as the latter contracts to the point; that is, the limit

$$K = \frac{d\alpha}{ds} = \lim_{\Delta s \to 0} \frac{\Delta\alpha}{\Delta s}. \qquad (8.1)$$

K is also the reciprocal of the radius of curvature at the point in question, that is, the radius of the

$\boxed{\text{osculating}}$ $\boxed{\text{circle}}$

at that point. (the osculating circle at a point P of a curve is defined as the limit of circles determined by three points on the curve as they tend to P).

Osculating → first ⇒ Leibniz

① Leibniz → "New reflections on the nature of the angles of tangency and osculating and their use in mathematical practice to replace complex figures with simpler ones → 1686

The concepts of the curvature of a curve and of the osculating (literally "kissing" from the Latin osculans) circle were already known to Leibniz. ①

Leibniz also suggested the possibility of caracterizing the curvature of a surface by means of an osculating sphere. ②

② In a letter to Johann Bernoulli, dated July 29, 1698.

Euler → "Investigations of the curvature of surfaces" – 1767.

(Pag. 1-22 – vol. 28)

Euler called a normal section of a surface $z = f(x, y)$ perpendicular to the xOy plane a principal section. By varying the angle φ

between a normal section and the principal section Euler found that at each point of the surface there is a maximal radius of curvature f and a minimal radius of curvature g, that their planes are perpendicular to one another, and

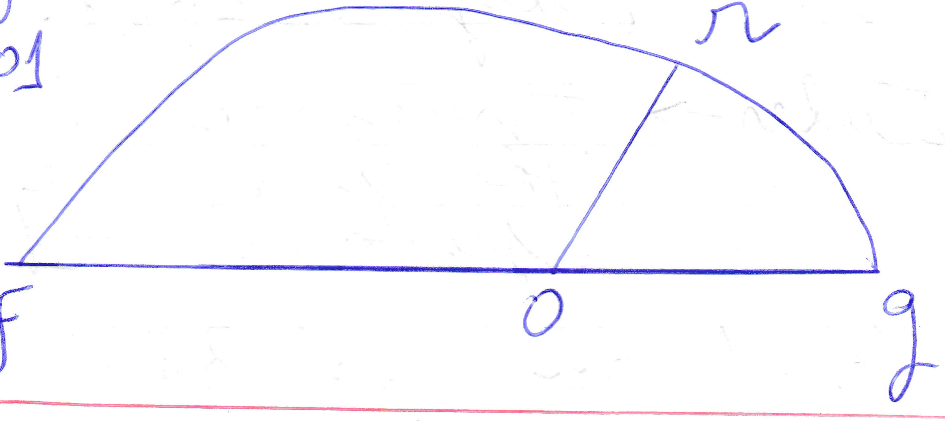
Pág. 281 (293) →

that the connection between an arbitrary radius of curvature

$$r = r(\varphi)$$ and the

radii of curvature f and g is given

Fig. 101



by

$$\boxed{r = \frac{2fg}{f+g-(f-g)\cos 2\varphi}}$$

Pág. 135(147) - Chapter 5
Relativity and Electrodynamics

5.1 - Lorentz Transformation

Since Maxwell's equations involve derivatives with respect to space and time, they are clearly dynamical laws!

... Galilean transformation

$$x = x' + v t', \quad (5.1)$$

Pág. 137(149) -

Lorentz in 1904 established the mathematical result that Maxwell's equations can be true in all inertial frames if they are connected to each other by what we now call the

Lorentz transformation

$$x = \gamma(x' + v t'), \qquad (5.6)$$

$$y = y', \qquad (5.7)$$

$$z = z', \qquad (5.8)$$

$$t = \gamma\left(t' + \frac{v}{c^2} x'\right), \qquad (5.9)$$

where

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}} \qquad (5.10)$$

Obs: Einstein pode ter deduzido desta equação.

Note that $x' = 0$, $t' = 0$ corresponds to $x = 0$, $t = 0$, implying that time is set to zero in both the frames at the instant when the origins of the two frames coincide.

The revolutionary implication of (5.9) was the time measured by different observers can be different.

→ 549 pages.
Pag. 107(108) - Chapter 6
Gravity as Geometry
Pag. 125(126) - 6.5/
Spacetime is Curved

In the presence of a gravitational field, spacetime remains flat, but clocks run at a rate that is a factor $(1+\phi/c^2)$ diferent from their rates in empty spacetime, where ϕ is the gravitational potential at the location of the clock.

Clocks run faster where ϕ is positive and slower where ϕ is negative.

Pag. 126(127) - 6.6.
Newtonian Gravity in Spacetime Terms
(Field Metric)

$$ds^2 = -\left(1+\frac{2\phi(x^i)}{c^2}\right)(c\,dt)^2+\left(1-\frac{2\phi(x^i)}{c^2}\right)(dx^2+dy^2+dz^2) \qquad (6.20)$$

Pág. 135(136) - Chapter 7
The Description of Curved Spacetime

$$ds^2 = -dt^2 + dx^2 + dy^2 + dz^2 \quad (7.1)$$

in the $c = 1$ units.

Pág. 137(138) - Box 7.1

The Penrose Diagram for Flat Space

Pág. 138(139) → 7.2 Metric

To describe a general geometry use a system of four coordinates x^α, to label the points and specify the line element giving the distance, ds^2, between nearby points separated by coordinate intervals dx^α. That line element will have the form

$$ds^2 = g_{\alpha\beta}(x)\, dx^\alpha dx^\beta, \quad (7.8)$$

where $g_{\alpha\beta}(x)$ is a symmetric, position-dependent ① matrix called the metric.

Obs: ① When dealing with functions of the coordinates, we routinely use the abbreviations $f(x^\alpha)$, or $f(x)$, for $f(x^0, x^1, x^2, x^3)$ where there is no danger of confusion.

For example, the metric for flat spacetime (WRONG !!!) in polar coordinates (7.4) is

$$g_{\alpha\beta}(x) = \begin{array}{c|cccc} & 0 & 1 & 2 & 3 \\ \hline 0 & -1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 \\ 2 & 0 & 0 & r^2 & 0 \\ 3 & 0 & 0 & 0 & r^2 \sin^2\theta \end{array} \qquad (7.9)$$

Diagonal metrics such as this can be specified more compactly by writing $g_{\alpha\beta}(x) = \mathrm{diag}(-1, 1, r^2, r^2\sin^2\theta)$.

Obs: Este cálculo esta errado poi vocês estão descrevendo uma superfície plana (que não é plana) em coordenadas polares.

Pág. 445 (444) – Chapter 21
Curvature and the Einstein Equation

$$\begin{pmatrix}\text{a measure of local} \\ \text{spacetime curvature}\end{pmatrix} = \begin{pmatrix}\text{a measure of} \\ \text{matter energy density}\end{pmatrix} \qquad (21.1)$$

This relation, called the Einstein equation (or Einstein's equation), is field equation of general relativity in the way that Maxwell's equations are the field equations of electromagnetism.

Skew-Symmetric Linear Transformations and Electromagnetic Fields.

2.1. Motivation via the Lorentz Law

A charged particle in M is a triple (α, m, e), where
(α, m) is a
material particle and e is a nonzero real number called the
charge of the particle.

Lorentz World Force Law (or Lorentz 4-Force Law) which expresses the rate at which the particle's world momentum changes at each point on the worldline as a linear function of the particle's World velocity:

$$\frac{dP}{d\tau} = eFU, \qquad (2.1.1).$$

where

$U = U(\tau)$ is the particle's world velocity,

$P = mU$ its world momentum

and,

at each point, $F : M \to M$ is a linear transformation defined in terms of the classical

"eletric and magnetic 3-vectors $\vec{E}$ and $\vec{B}$"

at that point (2.1.1) is an abbreviated version of the somewhat (um pouco) more accurate and considerably more cumbersome (pesado)

$$\frac{dP(\tau)}{d\tau} = e\,F_{\alpha(\tau)}(U(\tau)),$$

where

$F_{\alpha(\tau)}$ is the appropriate linear transformation at $\alpha(\tau) \in M$.

→ 296 pages.

Pág. 08(20) – 1.3
The Riemannian curvature tensor

Newton's first law states that the motion of a particle is in a straight line at constant speed if no force acts upon it.

Geodesics on a Riemannian manifold are understood to be subject to Newton's first law: it is considered that the straightness of a geodesic is equivalent to the existence of a parallel velocity vector field along it.

Lemma 1.3.1. Let $z(t) = \xi^i(t) X_i \circ \gamma(t)$ be a vector field along a curve γ, where $\gamma(t) = (x^1(t), \ldots, x^n(t))$ in a coordinate neighborhood U. Then the map

$$t \mapsto \left(\frac{d\xi^i}{dt} + \Gamma^i_{kj} \xi^k \frac{dx^j}{dt} \right) X_i \circ \gamma(t)$$

is independent of the choice of local coordinates, and hence is a vector field along γ.

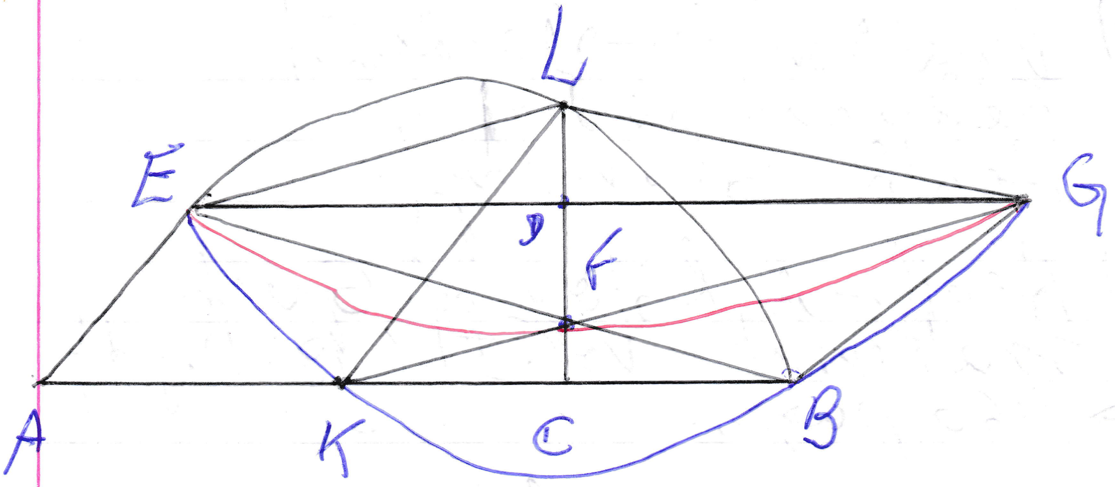
IMPORTANT:

Pág. 191(205) - We resume Eudemus's account.

Pág. 193(207) -



IMPORTANT:

A linha vermelha (concava)
→ negativa, apresenta uma
curvatura.
Calcular esta curvatura.

A case too where the outer (exterior) circumference is less than a semicircle was solved by Hippocrates, who gave the following preliminary construction.

Let there be a circle with diameter AB, and let its centre be K.

Let CD bisect BK at right angles; and let the straight line EF be so placed between CD and the circumference that it verges towards B [i.e. will, if produced, pass through B], while its length is also such that the square on it is $1\frac{1}{2}$ times the square on (one of) the radii.

Let EG be drawn parallel to AB, and let (straight lines) be drawn joining K to E and F.

Let the straight line [KF] joined to F and produced meet EG in G, and again let (straight lines) be drawn joining B to F, G.

It is then manifest that BF produced will pass through ["fall on"] E [for by hypothesis EF verges towards B] and BG will be equal to EK.

Interessante:

Simplicius proves this at length. the proof is easy.

The triangles FKC, FBC are equal in all ~~as~~ respects [Eucl. I. 4]. therefore, EG being parallel to KB, the triangles EDF, GDF are equal in all respects [Eucl. I. 15, 29, 26]. (right triangles). Hence the trapezium is isosceles, and BG = EK.

this being so I say that the trapezium EKBG can be comprehended in a circle.

a) 20231102- A Course in Metric Geometry-2001.pdf

Pág.07(16)- 1.2.3. Spheres

Example 1.2.25.- The n-spheres S^n is the set of unit vectors in R^{n+1}, i.e., $S^n = \{x \in \mathbb{R}^{n+1} : |x| = 1\}$.

The angular metric on S^n is defined by $d(x,y) = \arccos \langle x, y \rangle$.

In other words, the spherical distance is defined as the EUCLIDEAN ANGLE between unit vectors.

It equals the length of the shorter arc of a great circle connecting x and y in the sphere.

Another formula for this metric is

$$d(x,y) = 2 \arcsin \frac{|x-y|}{2}.$$

The metric on the circle described in Example 1.2.9 is a partial case of this example.

Pág.04(13)- Example 1.2.9. →

The unit circle, S^1, is the set of points in the plane lying at distance 1 from the origin:

Being a subset of the plane, the circle carries the restricted Euclidean metric on it. We define an alternative metric by setting the distance between two points as the length of the shorter arc between them.

For example, the arc-length distance between two opposite points of the circle is equal to $\boxed{\pi .}$ → wrong!!!

Obs: Metric is wrong too!!!

The distance between adjacent vertices of a regular n-gon (inscribed into the circle is equal

$$\boxed{\frac{2\pi}{n}} \rightarrow$$

Interessante: Exercise 1.2.10.

(a) Prove that any arc of length less or equal to π, equipped with the above metric, is isometric to a straight line segment.

(b) Prove that the entire circle with this metric is not isometric to any subset of the plane (regarded with the restriction of Euclidean distance onto this subset).

Pág. 03(12) – Example 1.2.3.

and Example 1.2.4.

$$|(x_1, y_1).(x_2, y_2)| = \sqrt{|x_1 x_2|^2 + (y_1 y_2)^2}$$

In particular, $R \times R = R^2$.

Angle Sum and the Defect of a Triangle

Definition:

Let $\triangle ABC$ be a triangle in a protractor (transferidor) geometry. The defect of $\triangle ABC$ is

$$\boxed{\delta(\triangle ABC) = 180 - (m(\angle A) + m(\angle B) + m(\angle C)).}$$

We already know that for a EUCLIDEAN GEOMETRY

$\boxed{\delta(\triangle ABC) = 0}$

for all triangles $\boxed{\text{(Theorem 7.2.9)}}$

⇝ será estudado mais tarde.

We have seen examples in which

$$\boxed{\delta(\triangle ABC) < 0}$$

(the Moulton Plane)

and in which

$$\boxed{\delta(\triangle ABC) > 0}$$

(the Poincaré Plane)

We also know that for a neutral geometry

$$\boxed{\delta(\triangle ABC) \geq 0}$$

(Theorem 7.2.8).

IMPORTANT: GAUSS recognized that in order to prove EPP is satisfied it was sufficient to prove that $\boxed{\delta(\triangle ABC) = 0}$ for one triangle.

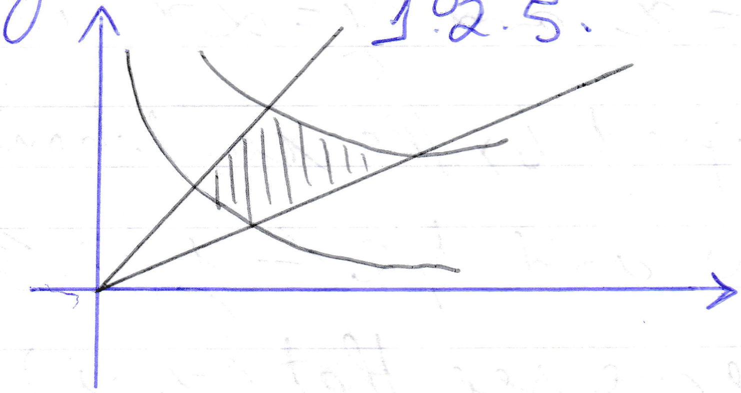
See:

Figure 1.2. Region in Example 1.2.5.



Obs:

Example 1.2.5

Let R be the region in the xy-plane that lies in the first quadrant (that is, $x \geqslant 0$ and $y \geqslant 0$) and is between the hyperbolas $xy = 1$, $xy = 2$, and bounded by the lines $2y = x$, $y = 2x$

(see Figure 1.2),
Specify R by a set of inequalities.

Solution: the region in the first quadrant that is between the hyperbolas $xy=1$ and $xy=2$ is specified by the conditions that

$$x>0 \text{ and } 1 \le xy \le 2.$$

Similarly the region in the Region in the first quadrant that is between the lines

$2y=x$ and $y=2x$ is

specified by the conditions that

$$x>0 \text{ and } 1/2 < y/x \le 1.$$

Hence we see that $(x,y) \in R$ if and only if

$$1 \le xy \le 2 \text{ and } 1/2 \le y/x \le 2$$

and $x>0$.

Pág. 374(395) -
The photon is an example of a massless relativistic particle with an energy, whose value depends on the reference frame.

Minkowski coordinates:

$$p^0 = \hbar \frac{\omega}{c}, \quad p^a = \hbar k^a, \quad a = 1, 2, 3$$

where $\omega > 0$ is the angular frequency of the particle's light wave and k^a are the three components of the wave vector in the frame.

Above $\boxed{k = \frac{h}{2\pi}}$ → wrong !!!,

Where h is Planck's constant (6.626 x 10^{-27} erg sec).

As

$$\sum_{a=1}^{3} (k^a)^2 = \left(\frac{\omega}{c}\right)^2$$

from electromagnetism, in this case we must have $g(P, P) = 0$ and so the photon is massless and its world lines are lightlike.

Clearly there is no Minkowski frame at rest with a photon, because $k^a = 0$ for $a = 1, 2, 3$ would force $\omega = 0$ and the four-momentum would not be casual.

Sometimes one reads that photons are "pure energy".

Pag. 800 (817) →

Kaufmann's method

Kaufmann's experiments show that the real constant mass of the electron is negligible (insignificante) compared with the apparent [electrodynamic] mass; it can be considered as zero, so that if it is mass which constitutes matter we can almost say the matter no longer exists... there are merely holes in the aether.

Poincaré.

Pág. 152(178)

Kaufmann found that e/m varied slightly with velocity, ~~descr~~ decreasing with increasing velocities.

Fig. 3.7. the points on the parabola refer to electrons deflected by parallel and anti-parallel (left side) fields.

IMPORTANTÍSSIMO:

Pág. 153(179) →

Ritz [08] (1911 - Gesammelte Werke - Oeuvres) queried the invariance of Kaufmann's parabola (3.7.17)

(3.7.17) – Kaufmann obtains the equation of a parabola

$$y = \frac{c^2 E}{\kappa H^2}\,\frac{m}{e}\,x^2$$ Pag. 152 (178)

the ratio,

$$\frac{y}{x} = \frac{c}{u}\,\frac{E}{H'} \qquad (3.7.18)$$

is, therefore, a measure of the deviation of the Lorentz force from zero [cf. Eq. (3.7.15) above].

... Kaufmann's parabola, (3.7.17), for it will only have that form if m is independent of the speed.
If the mass did increase with velocity, say, at some power greather than one, the parabola would tend to a straight line as that power increases.

Instead of (3.7.18) (as mine) Ritz tried ⓑ

$$\frac{y}{x} = \frac{\sqrt{(c^2-u^2}}{u}\,\frac{E}{H'} \qquad (3.7.19)$$

giving rise to a parabola,

$$y = \frac{mc^2E}{eKH^2}x^2 + K\frac{eE}{mc^2}, \quad (3.7.20)$$

shifted upward at the origin.

ⓑ Actually, Ritz wrote 2c for c, but that does not change anything "in a theory which considers only relative velocities."

20231104110000" continuação:

b) a-new-perspective-on-relativity...pdf
Pág. 341(367) - 7.1.

Centrifugal versus Gravitational Forces.

General relativity is based on the notion that gravity, rather than being a force acting between masses, is the curvature of space-time itself. The source of the (positive) curvature is mass itself, just like electric charge is the source. And just as free particles follow "straight lines in space-time"

Obs: Do ponto de vista teórico, nós podemos representar matematicamente uma linha reta, mas isto não condiz com a realidade do Universo, pois caso o Universo tenha começado com o Big-Bang, não há possibilidade do Universo ser plano em virtude da energia inicial que por si só interfere na formatação do Universo.

Um aspecto interessante do Universo, ele não pode ser infinito em virtude do próprio Big-Bang. É uma questão de lógica, o finito não pode conter o infinito, pois se ele começou, não é infinito e para que ele exista há a necessidade do espaço, este sim infinito, o nada é infinito e em cima deste nada o Universo pode surgir, se desenvolver e se expandir.

Deus criou o nada para que o Universo pudesse surgir.

Se Deus tivesse preenchido tudo, não haveria a necessidade do surgimento do Universo.

O espaço é algo infinito e que alguns chamam de aether.

O espaço do nada permite a criação de tudo.

Deus é tão magnânimo que permitiu que algo fosse criado para receber o homem, ou seja, o Universo foi criado pela benevolência de Deus para que o homem pudesse viver nele. Quando eu digo o homem, eu me refiro à vida e há infinitas formas de vida no Universo.

Portanto, o Universo existe porque há o espaço do nada que

permite que o Universo se expanda.

Retornando:

"straight lines in space-time"
They follow geodesics in the curved space-time of a gravitational field.

Pag. 342(368)-

We shall return to this lack of equivalence of between gravitational and centrifugal forces which cause acceleration in (Chapter 9), but we already have seen it in action in Sec. 2.2.3

Maxwell, in 1858, who proved that for an absolute instrument the optical length of any curve in the object space is equal to the optical length of its image, provided both spaces are homogeneous.

Refractive index

$$n(r) = \frac{1}{1+(r/a)^2} n_0 \qquad (2.2.4)$$

Where
r denotes the distance from a fixed point O, and n_0 and a are constants.

Retornando:

... action in Sec. 2.2.3 where Maxwell used this strategy in his classic treatment of inversion in elliptic space.

↳ órbita dos planetas.

IMPORTANTÍSSIMO:

If we take a flat space metric in the plane and consider a constant index of refraction, we will demonstrate that Fermat's principle is capable of yielding the phase of the oscillation of a Bessel function of the first kind in the periodic domain in the asymptotic short-wavelength limit.

This is identical to the WKB result, and it allows us to associate a wave phenomenon with a geodesic trajectory.

The only potential present is the repulsive centrifugal potential, and that keeps the trajectory open.

Pág. 438 (464) - WKB

Expression (9.2.7) is the phase of the phase of the Hermite polynomials in the short-wavelength (WKB) limit. ... Planck's constant

Retornando: Pag. 342 (368) -

In contrast to the generalization of special relativity, where gravity is considered to be the curvature of space-time instead of a bona fide force, the centrifugal force is built into the phase of the Bessel function in the periodic domain where the trajectory consists of straight-line segments that are tangent to a caustic circle, whose radius is determined by the magnitude of the angular momentum

↳ (see book: 20231103 - Biedenharn - Angular Momentum in quantum physics - (1981). djvu).

and the arc segment joining the points of tangency.

$$\sigma_{xx} = \frac{1}{8\pi}\left(E_y^2 - E_x^2\right),$$

Retornando: Search: bending

Pág. 343 (369) – The bending of light requires a coupling of the gravitational and centripetal potential that is commonly referred to as Schwarzschild's potential [cf. Fig. 7.6]. Here, it arises when we determine the extremum condition for Fermat's principle.

Pág. 448 (474) – The hyperbolic geometry that describes a uniformly rotating disc also describes the bending of light by a massive body when the transition is made from a constant to a non-constant surface of negative curvature.

Pág. 452 (478) – The geodesic still appear as straight lines to the Poincarites, whereas, to us Euclideans, they appear to be bent, and things vary in size depending on where we look. We also see things like the bending of light and the shifting of frequencies in a gravitational field.

Pág. 462 (488) – The bending of the geodesic is attributed to the rotation of the disc [Grøn 04]. But if the stereographic hyperbolic metric were applicable it would invalidate

Einstein's old result! (9.6.16)

$\boxed{9.6.16}$ → Integrating over a period,

$$h = \frac{2\pi r}{\sqrt{(1-r^2/k^2}} > 2\pi r \quad (9.6.16)$$

shows that the length of a hyperbolic circle of radius

sinh(h/k) is greater than that (do que um) of an Euclidean circle having a radius r [= k tanh (h/k). this is none other Einstein's old results!!!

Retornando:

... (9.6.16), and it would also be in conflict with his general theory.

There is no way out for (9.6.28) to hold,

$\boxed{9.6.28}$ → Pag. 461 (487) -

The Euclidean area of the ellipse is

(interessante!!!)

$$\pi \frac{(1-r^2/\kappa^2)^{3/2}}{\kappa^2} = \frac{\pi}{\kappa^2}\,\text{sech}^3\left(\frac{r}{\kappa}\right).$$

↳ Wrong !!! (ajustar)

If we use the hyperbolic definition of an angular momentum ⇐ for the stereographic inner product model that we found previosly in (9.2.5),

$$l_h = \frac{r^2\dot{\vartheta}}{1-r^2/\kappa^2}, \qquad (9.6.28)$$

then we must modify the equation for the radius of the trajectory,

$$\dot{r} = \pm c\left(1-\frac{r^2}{\kappa^2}\right)\sqrt{\left[1-\frac{\Delta^2}{r^2}\left(1-\frac{r^2}{\kappa^2}\right)\right]}, \qquad (9.6.29)$$

if and only if $\Delta = l_e/c$, where $l_e = r^2\dot{\vartheta}$, the Euclidean expression for the angular momentum.

Pág. 476 (502) - the curvature (9.10.11)

$\boxed{9.10.11}$, the curvature will be negative and constant. In general, the curvature is

$$K = -T_0^2\left(\frac{\lambda^2}{r_1^2}\, j_0^2 + j_0'^2\right). \quad (9.10.11)$$

Retornando:

The curvature (9.10.11) cannot distinguish between the diffusion equation (9.10.7) or a wave equation.

9.10.2 A matter of curvature

Geometries which are both homogeneous and isotropic have constant (Gaussian) curvature.

Gaussian curvature is a measure of a surface's intrinsic geometry or the invariance of a surface to bending without stretching.

As we know, there are three distinct simply connected isotropic geometries in any dimension:

Euclidean with zero curvature, elliptic with positive curvature, and hyperbolic with negative curvature.

cf. Search: curvature (184 ocorrências)

"Recently, Weinberg (2005, 2006) has extended the "in-in" formalism and used it to calculate higher-order Gaussian and Non-Gaussian correlations in cosmology.

These correlations depend on the whole history of inflation, not just on the behavior of fields when they exit from the horizon.

Pág. 196 (214) - 5.3.3.

ζ - function regularization

For example, in flat Euclidean space, the Laplacian

$-\nabla_\mu \nabla^\mu$ acting on scalars has eigenvalues

$\boxed{k^2 \geq 0.}$

In flat Minkowski spacetime,

$\Box = \nabla_\mu \nabla^\mu$ has eigenvalues $\boxed{-(k^0)^2 + k \cdot k}$

which have no definite sign.

The Feynman boundary conditions adopted in Minkowski spacetime quantum field theory ensure that the WICK rotation $k^0 \to ik^0$ may be ~~permo~~ performed leading to a result which is equivalent to using elliptic operators in a Euclidean spacetime.

A rigorous proof of the equivalence between Minkowski and Euclidean field theory may be given.[5]

Pág. 06(15)- Affine Geometry

The study of those properties of geometric figures that remain unchanged by an Affine Transformation is called affine geometry.

For example,

since an affine transformation preserves straight lines and RATIOs of distances between POINTs, the notions of PARALLEL lines, MIDPOINTS of LINE segments, and tangency are valid concepts in affine geometry.

The notion of a CIRCLE,

however (porem), is not.

(A circle can be transformed into an ELLIPSE via an affine transformation. The equidistance of points on the circle from the circle center need not be preserved).

Affine geometry was first studied by Swiss mathematician Leonhard Euler (1707-1783).

Only postulates

1, 2, and 5 of EUCLID'S POSTULATES

remain valid in affine geometry.

g2) Heath - Euclid's Elements - (2021).pdf → 692 pages.

Pag. 9 - Postulates.

1. Let it have been postulated to draw a straight-line from any point to any point.

2. And to produce a finite straight-line continuously in a straight-line.

5. And that if a straight-line falling across two (other) straight-lines makes internal angles on the same side (of itself) less than two right-angles, being produced to infinity, the two (other) straight-lines meet on that side (of the original straight-line) that the (internal angles) are less then two right-angles (and do not meet on the other side)[a]

Pag. 13(22) - Angle.

$1 \text{ grau} = \frac{2\pi}{360} \cong 0.017$ radian.

$1 \text{ rad} = \frac{360}{2\pi} \cong 57.3°$.

The full surface area of the sphere is 4π steradian.

Obs: Trisecting an angle.

Pag. 512(521) - Trisecting an angle.

Pag. 372(381) - Pappus's theorems.

Pag. 249(258) - Heron's formula

Area of a triangle

solely in terms of the side-lengths of the triangle.

$$\boxed{\text{area} = \sqrt{s(s-a)(s-b)(s-c)}}$$

where

a, b, and c are the sides of the triangle,

and $s = \frac{1}{2}(a+b+c)$ is its "semiperimeter".

Proved: Heron's formula →

if θ is the angle between the sides of length a and b, then the area of the triangle is given by area

$$\boxed{\text{area} = \frac{1}{2} ab \sin(\theta).}$$

The Law of Cosines asserts that

$$\boxed{c^2 = a^2 + b^2 - 2ab\cos(\theta).}$$

Solving for $\sin(\theta)$ and $\cos(\theta)$, and substituting into the standard identity from Trigonometry,

$$\boxed{\cos^2(\theta) + \sin^2(\theta) = 1},$$

yields, after some algebraic work, Heron's result.

Heron claims that if x approximates the square root of a number N, then

$$\frac{x + \frac{N}{x}}{2}$$ is a better approximation.

For example: $3 \Rightarrow \dfrac{3 + \frac{10}{3}}{2} \simeq 3.1667$

as an improved estimate.

Repeating the procedure yields

$$\frac{3.1667 + \frac{10}{3.1667}}{2} \cong 3.1623$$

as an even better approximation (In fact, $\sqrt{10} \cong 3.16227766$).

Then $(y - \sqrt{N}) = \frac{1}{2x}(x - \sqrt{N})^2$, which shows that if the error $x - \sqrt{N}$ is small, then the error $y - \sqrt{N}$ will be even smaller. (We are assuming here that x is a value greater than 1.).

cf. Newton's Method when applied to the function $f(x) = x^2 - N$.

Pág. 253 (262) – Hyperbola.

$$\sqrt{(x-c)^2 + y^2} = \left(\frac{c}{a}x - a\right)$$

valid for one branch of the figure at least.

Set $e = \frac{c}{a} = \frac{\sqrt{a^2+b^2}}{a} = \sqrt{1 + \frac{b^2}{a^2}}$.

This is called the Eccentricity of the hyperbola and has a value greater than 1.

The above equation can be rewritten:

$$\frac{\sqrt{(x-c)^2+y^2}}{x-\frac{a}{e}}=e.$$

See: hyperbolic functions

$$\cosh(t)=\frac{e^t+e^{-t}}{2}$$

$$\sinh(t)=\frac{e^t-e^{-t}}{2}$$

Pag. 255(264) - hyperbolic geometry (Lobachevskian geometry)

Hyperbolic geometry is a Non-Euclidean geometry in which the famous PARALLEL POSTULATE fails in the following manner:

"Through a given point not on a given line, there is more than one line parallel to that given line".

Pag. 257(266) - Identity ⇒ $3\arctan(1/4)+\arctan(1/20)+\arctan(1/1985)=\frac{\pi}{4}$ 20231107180000

Pág. 116(118)- 6.6.3 Terceiro Período
Newton e a Mecânica Celeste
Pág. 118(121)-

Em novembro de 1684, Newton enviou a Halley um manuscrito de nove páginas intitulado:

"De motu corporum in gyrum"
(Sobre o movimento dos corpos em uma órbita)
que, além de reafirmar a órbita elíptica dos planetas, continha uma demonstração matemática das três leis de Kepler.

Na curta exposição, Newton demonstrou que, se os planetas se movem numa órbita elíptica, eles precisam estar sob o controle do

quadrado de uma força inversa direcionada para um foco da elipse e...

Obs: Ponto chave para a solução do problema.

...e demonstrou, ainda, que, sob a influência do quadrado de uma força inversa, a órbita dos planetas descreve uma seção cônica.

Análise:

O termo: "o controle do quadrado de uma força inversa direcionada para um foco da elipse".

Nós devemos ter mente que por causa das forças fundamentais da Física, a força fraca, a força forte, e o eletromagnetismo são responsáveis pela geração da "gravidade" que na realidade não existe, havendo apenas os efeitos sobre o espaço e a matéria.

Em relação à matéria, esta por sua vez nada mais é que uma forma de energia.

Einstein em sua fórmula demonstrou isso:

$$E = mc^2$$

O interessante é que Nikola Tesla disse que tudo é energia. Desta forma, a pseudo-gravidade é gerada pelas três forças fundamentais da Física.

Em relação ao termo: "a força de atração entre os corpos é inversamente proporcional ao quadrado da distância entre eles".

De forma bem simplista, esta descoberta foi feita com base na observação das estrelas por outros astrônomos, mas nós podemos também deduzir de algo ainda mais simples decorrente do nosso cotidiano, por exemplo, um aluno sentado na última coluna de sala de aula e na última carteira, para ser ainda mais exagerado, na última coluna, na última fileira e na última carteira ou cadeira, bem no canto da sala, o que o aluno verá?

Ele verá que as carteiras mais próximas deles são maiores do que aquelas que estão no outro lado de sala de aula.

O tamanho das carteiras vai diminuindo a uma taxa fixa, ou seja, a carteira que está mais perto exerce uma força mais forte sobre o aluno do que aquela que está do outro lado. O mesmo acontece com os planetas e as estrelas. De um modo geral, a resposta está no tamanho da luz que se pode capturar, as carteiras mais próximas geram uma reflexão de luz maior por causa de sua proximidade enquanto as mais longínquas exercem uma menor reflexão de luz e portanto, uma pouca interferência por causa da distância.

Na Astronomia Moderna, a luz é uma fonte de dados, como tamanho da estrela, temperatura, distância do observador etc. Portanto, a resposta já estava exposta a um aluno que entra pela primeira vez em uma sala de aula, mas por causa da tenra idade não tem o preparo pra discernir o que já está lá exposto.

Pág. 120 (122) → No Universo, existem dois movimentos naturais: em repouso e em movimento uniforme (velocidade invariável) ao longo de uma linha reta.

Obs: O que é uma linha reta?
(straight line)

Nós devemos ter em mente que há várias acepções do que seja uma linha reta, não me refiro à questões moral, ética, comportamental, mas sim a linha reta real e a linha real teórica.

Este assunto será devidamente aprofundado em uma oportunidade futura em um capítulo separado.

... ao longo de uma linha reta.
Existem três possibilidades de mudança:
a) uma partícula em repouso pode começar a se mover;
b) uma partícula em movimento retilíneo uniforme pode reduzir ou

acelerar sua velocidade;
3) ou uma partícula mudar de direção
ao se desviar da linha reta.

Pág. 125 (127) - 6.7.1. Vácuo.

Pág. 320 (322) → Coulomb

apresentaria à Academia de Ciências três ~~de~~ Memórias (1786, 1787 e 1788) consagradas à distribuição de

ELETRICIDADE

em condutores e à variação da densidade elétrica de dois condutores em contato.

Verificaria Coulomb que a carga elétrica se situa na superfície externa de um condutor, e que sua distribuição estática depende de sua

CURVATURA,

e que o ar não era um isolante ideal.[421]

RETORNANDO: FOCO DA ELIPSE

A elipse na mecânica celeste é causada por causa das forças fundamentais da Física. Caso houvesse a ação da gravidade como uma força fundamental independente e portanto atuante no mundo físico, a gravidade geraria em razão da sua própria existência uma órbita circular perfeita e não elíptica.

Um outro aspecto a ser considerado, é a própria esfericidade do Sol que por sinal não é perfeita, mas poderia ser, caso a "massa" do Sol fosse maior.

A esfericidade perfeita dependerá das três forças fundamentais da Física e não da gravidade, ou seja, não g, depende exclusivamente da ação da "pseudo-gravidade".

Importante:

CURVATURE = ENERGY.

O Sol não é perfeitamente esférico por causa da energia representada pelas três forças fundamentais da Física, que curvam o espaço em volta da estrela e a própria estrela.

✡ ⇒ Com **M.U.S.** haverá a uniformização do espaço de forma matemática, em que nós teremos, a qual compreensão da realidade do mundo físico representado de forma matemática. Assim, um Universo curvo expressado constantemente em uma superfície plana.

O erro da pseudo-gravidade gera o comportamento dos fenômenos da mecânica celeste como periélio e o afélio, ou melhor, a descrição foi feita de forma errônea e não corresponde com a realidade observada.

Vejamos: Pág. 105 (107).

Em 1609, ao estudar a órbita de Marte, descobriu Kepler o primeiro princípio do movimento planetário; Marte descreve órbita elíptica, da qual um dos focos é ocupado pelo Sol.

Verificando que no periélio (ponto de menor afastamento do Sol) a velocidade angular do planeta é máxima, decrescendo depois para chegar a um mínimo afélio (ponto da órbita em que a distância do Sol é máxima), pode KEPLER demonstrar serem iguais as áreas varridas, em tempos iguais, pelo raio do vetor que liga o centro do planeta ao do Sol; ou, em outras palavras, uma linha que une o planeta ao Sol descreve áreas iguais em períodos de tempo iguais, durante a revolução do planeta. Tal descoberta, que corresponde ao segundo princípio do movimento planetário, significa que quanto mais perto do Sol, mais rápida a velocidade do planeta.

b) 1021 - História - da - Ciência - Vol. II - Tomo II ... pdf

Pág. 144 (146) - Em meados de 1830, Faraday era famoso e respeitado, além de reconhecido como o maior cientista experimentador da Inglaterra de seu tempo.

Depois de ter inventado o dínamo, ter descoberto a indução eletromagnética e ter avançado nas pesquisas da eletrólise, mas sem formação matemática e com pouco conhecimento teórico, Faraday, para explicar a configuração formada por limalhas de ferro ao redor de um imã (já observado por Pedro Peregrino no século XIII), sugeriria que as forças magnéticas atuariam como filamentos ou linhas de força que saíam de ímãs e circuitos.

A esse conjunto de linhas Faraday chamaria de "campo", em que as linhas de força magnética formariam o campo magnético e as de força elétrica, o campo elétrico.

→

IMPORTANT:

A introdução de tal concepção (de ação de campo) seria extremamente útil, porquanto explicava que os corpos agiam sobre os outros corpos tanto por contato quanto pela interação dos campos por eles produzidos.

Como tais idéias contrariavam a noção de ação à distância de Newton, aceita universalmente, e temendo que viesse a ser vítima de violentas críticas, Faraday depositou no cofre da Sociedade Real, em 1832, documento com essas idéias. As instruções eram para ser o envelope aberto somente após a sua morte, o que não o impediu de, em janeiro de 1844, explicar, em conferência na Sociedade Real, as linhas principais de suas idéias sobre o assunto.

Essas idéias pioneiras seriam retomadas por **MAXWELL**.

1839 → **GAUSS**

"Teoremas gerais sobre as forças atrativas e de repulsão que atuam de acordo com o inverso do quadrado da distância"

→

Leis de Heinrich Friedrich Lenz (1804-1865) sobre a ação térmica da corrente elétrica (1842/43), segundo os quais, uma corrente elétrica induzida flui numa direção tal que seja gerada uma oposição à mudança que a induziu

(se assim não fosse haveria uma violação da conservação de energia).

Pág. 71(73) – Para muitos autores, o marco inicial da Geometria diferencial seria a publicação da "Disquisitiones circa superficies curvas" (1827), na qual GAUSS definiu a

CURVATURA

da superfície num ponto (curvatura gaussiana ou curvatura total)

e formulou seu famoso THEOREMA EGREGIUM, pelo qual a curvatura total K é uma propriedade absoluta da superfície.

Pág. 72(74) → Riemann abordaria aí as propriedades das variedades topológicas num número arbitrário de dimensões, e, influenciado pela teoria das superfícies, de Gauss, e por seus próprios trabalhos de Física ~~na~~ Matemática, definiria

41

o quadrado da distância de dois pontos infinitamente vizinhos dessa variedade por uma forma quadrática, e mostraria como medir curvatura dessa variedade.

obs: Quadrado da distância um padrão físico que se repete em toda a Física.

Trabalhos de Beltrami e Bianchi sobre as superfícies de curvatura constantes

GABRIEL DARBOUX (1842-1917), sobre os sistemas triplos ortogonais (Leçons sur la théorie générale des surfaces, 1887/96, em 4 volumes).

Em branco

(propositalmente)

Pág. 78(80) - Eugenio Beltrami (1835-1900), professor em Bolonha, Pisa, Pavia e Roma, mostrou que a superfície gerada pela revolução de uma tratriz em torno de uma assíntota é uma pseudo-esfera por ter uma

(troca de caneta)

uma curvatura negativa constante

(a esfera tem curvatura positiva constante).

Se a reta entre dois pontos da pseudoesfera for definida como a geodésico por esses pontos, a geometria resultante terá as propriedades dos postulados de

Lobachevsky,

e com a curvatura total constante não nula será não euclidiana (conforme o teorema de Gauss).

Como o plano é uma superfície com curvatura constant nula, concluiu Beltrami que a

GEOMETRIA EUCLIDIANA

GEOMETRIA EUCLIDIANA

pode ser considerada como um intermediário entre as Geometrias de Lobachevsky e a de Riemann.

Pág. 108 (110) – Astrônomo Bessel fez a sua contribuição à Astrometria e do seu observatório em Königsberg, Bessel detectou, em 1838, com um heliômetro fabricado por Fraunhofer, que a estrela CISNE 61 descoberta por Giuseppe Piazzi, duas décadas antes, e admitida como a mais próxima da terra, por sua rápida rotação se movia, em comparação com duas outras estrelas vizinhas, aparentemente num movimento anual elíptico; essa paralaxe só poderia ser causada pelo movimento de translação da Terra.

A paralaxe, calculada em 0,3136" (bastante próxima da atual de 0,30" ± 0,003"), corresponde a uma distância da terra de 590 mil unidades astronômicas, ou de 10,4 anos-luz.

Pág. 137 (139) - O cientista alemão Helmholtz deu apoio à Teoria de Maxwell e incumbiu o jovem físico Heinrich Rudolf Hertz (1857-1894) de estudar o Electromagnetismo.

Hertz (entre 1885 e 1889) concluiu que as propriedades das ondas eram similares às da luz, o que o levou a concluir que as ondas de luz eram radiações eletromagnéticas, segundo as equações de Maxwell.

Estava dado o primeiro passo para o conhecimento do efeito fotoelétrico.

IMPORTANTÍSSIMO:

Pouco depois, o físico irlandês George Fitzgerald (1851-1901) sugeriria a hipótese, conhecida como da

CONTRAÇÃO, pela qual

o comprimento dos corpos materiais variaria, de acordo com seu movimento no éter de uma quantidade que dependia do

QUADRADO DA RAZÃO ENTRE →

QUADRADO DA RAZÃO
ENTRE SUA VELOCIDADE e a
VELOCIDADE DA LUZ.

Obs: Interessante!!!

Essa formulação seria aproveitada pelo físico holandês
Hendrik Antoon Lorentz

Em novembro de 1892, informou à Academia de Ciências de Amsterdã ter adotado a hipótese de Fitzgerald sobre a contração do comprimento num trabalho que seria publicado em 1892/93.

Lorentz sustentaria que a massa de qualquer partícula aumentaria à medida que ela atingisse velocidades cada vez maiores, e que a contração da distância acarretaria uma dilatação do tempo.

Obs: Importantíssimo!!!

Einstein tirou deste argumento a sua Teoria da Relatividade.

Começaria a surgir a noção da velocidade da luz como limite máximo no Universo[153].

Pág. 138(140) - 6.20.3 Eletrologia

A Eletrologia é a parte da Física que investiga os fenômenos elétricos e magnéticos e a interrelação entre seus respectivos campos. Seus amplos âmbitos foram unificados pelas famosas quatro Equações de Maxwell, de 1873, formulação matemática das leis empíricas constitutivas do Eletromagnetismo.

Pág. 140 (142) - Em 1827, Ampère escreveria "Teoria matemática dos fenômenos eletrodinâmicos, deduzida unicamente da experiência", obra que coroaria suas investigações sobre a Eletricidade e o Magnetismo e na qual explicaria os fenômenos pela hipótese de uma interação newtoniana entre elementos de corrente.

Idealizou, então, a célebre "regra da mão direita", pela qual a deflexão da agulha tomaria a direção dos dedos dobrados da mão direita quando esta segurasse o fio condutor, desde que mantivesse o polegar na direção da corrente elétrica.

Na obra, Ampère enunciou igualmente quatro importantes princípios do Eletromagnetismo:

i) as ações de uma corrente ficam invertidas quando se inverte o sentido da corrente;

ii) há igualdade nas ações exercidas sobre um condutor móvel por dois outros, fixos, situados a igual distância do primeiro;

iii) a ação de um circuito fechado, ou de um conjunto de circuitos fechados sobre um elemento infinitésimo de uma corrente elétrica é perpendicular a esse elemento; e

IV)

Obs.: Importante!!!

Estudar com profundidade e atenção a perpendicularidade pois a curvatura do espaço age tanto na "massa" (energia) quanto na eletricidade e eletromagnetismo.

Plane Loci → we infer that the following were two of the loci considered:

(1) the locus of points the difference of the squares of whose distances from two fixed points is CONSTANT is a straight line perpendicular to the line joining the points;

(2) the locus of points the ratio of whose distances from two fixed points is constant (and not equal to one) is a circle.

The latter locus is in fact, now know as the "Circle of Apollonius".

Pág. 136(158) - The Three-Line and Four-Line Locus

Apollonius → Book III :

The three- and four-line locus to which reference is made played an important role in mathematics from Euclid to Newton.

Given three lines (or four lines) in a plane, find the locus of a point P that moves so that the square of the distance from P to one of these is proportional to the

product of the distances to the other two

Obs: Estes cálculos serão alterados.

... (or, in the case of four lines, the product of the distance to two of them is proportional to the product of the distances to the other two), the distances being measured at given angles with respect to the lines. Through modern analytic methods, including the normal form of the

straight line,

it is easy to show that the locus is a conic section — real or imaginary, reducible or irreducible. If, for the three-lines locus, equations of the given lines are

$A_1x + B_1y + C_1 = 0,$

$A_2x + B_2y + C_2 = 0,$ and

$A_3x + B_3y + C_3 = 0,$ and if the angles at which the distances are to be measured are θ_1, θ_2, and θ_3, then the locus of $P(x,y)$ is given by

$$\boxed{\frac{(A_1x+B_1y+C_1)^2}{(A_1^2+B_1^2)\sin^2\theta_1} = \frac{K(A_2x+B_2y+C_2)}{\sqrt{A_2^2+B_2^2\sin\theta_2}} \cdot \frac{(A_3x+B_3y+C_3)}{\sqrt{A_3^2\,B_3^2\sin\theta_3}}.}$$

This equation is, in (generral) general, of second degree in x and y; hence, the locus is a conic section.

"The theorem of Cavalieri":

If two solids have equal altitudes, and if sections made by planes parallel to the bases and at equal distances from them are always in a given ratio, then the volumes of the solids also are in this ratio (Smith 1959, pp. 605–609).

"History of Mathematics" and "Source Book in Mathematics" (1959)

Pag. 304 (326)

Cavalieri concentrated on an extremely useful geometric theorem equivalent to the modern statement in the calculus.

$$\int_0^a x^n dx = \frac{a^n + 1}{n+1}.$$

IMPORTANT:

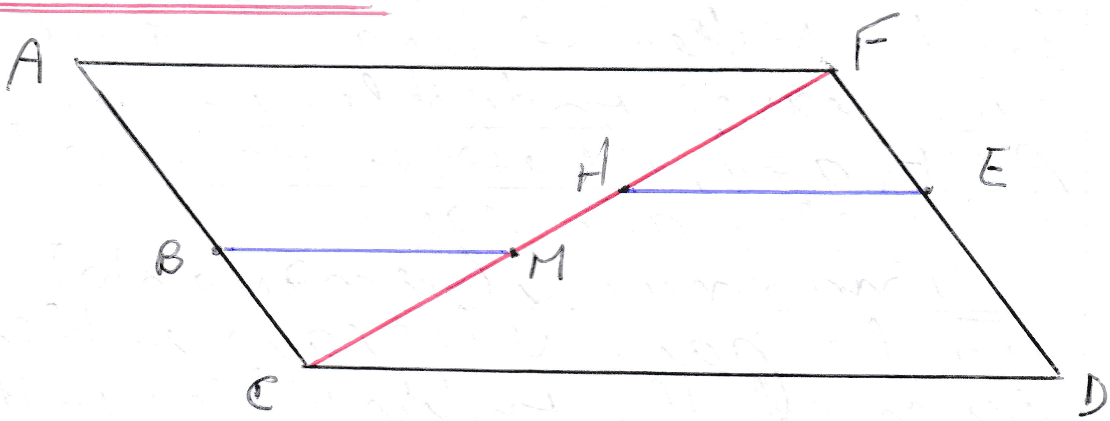

Fig. 15.2

The statement and the proof of the theorem are very different from those with which a modern reader is familiar, for Cavalieri compared powers of the lines in a parallelogram parallel to the base with the corresponding powers of lines in either of the two triangles into which a diagonal divides the parallelogram.

Let the parallelogram AFDC be divided into two triangles by the diagonal CF (Fig. 15.2) and let HE be an indivisible of triangle CDF that is parallel to the base CD. Then, on taking BC = FE and drawing BM parallel to the base CD, ~~then~~, it is easy to show that the indivible BM in triangle ACF will be equal to HE. Hence, one can pair all of the indivisibles of triangle CDF with equal indivibles in triangle ACF, and, therefore, the two triangles are equal.

Inasmuch (inquanto) as the parallelogram is the sum of the indivisibles in the two triangles, it is clear that the sum of the first powers of the lines in one of the constituent triangles is

half of the sum of the first powers of the lines in the parallelogram;

in other words:

$$\int_0^a x\,dx = \frac{a^2}{2}.$$

Through a similar but considerably more involved argument, Cavalieri showed that the sum of the squares of the lines in the triangle is one-third the sum of the squares of the lines in the parallelogram.

For the cubes of the lines, he found the ratio to be 1/4.

Pag. 314(336)- Classification of Curves.

Pag. 315(337)- Rectification of Curves.

Descartes added to the usual axioms of geometry one more axiom:

> Two or more lines (or curves) can be moved, one upon the other, determining by their intersection other curves.

→ 472 pages.

Pág. 48 (61) - CONSTANT GRAVITATIONAL

$$G = 6.67259 \times 10^{11}\, m^3\, kg^{-1}\, s^{-2}. \quad (3.5)$$

a) One day → 86400 s (SI)

b) mass of Sun → $m_\odot = 1.9891 \times 10^{30}$ Kg.

c) the mean distance between the center of mass Earth-Moon and the Sun, AU (Astronomical Unit), serves as length unit.

d) in these units the constant of gravitation is written as $\boxed{k^2}$, where k is referred to as the

$$\boxed{\text{GAUSSIAN CONSTANT.}}$$

Obs: Today, the AU is defined in such a way that the Gaussian constant K keeps the same numerical value, namely

$$\boxed{K = 0.01720209895 \sqrt{(AU)^3 m_\odot^{-1} d^{-2}}} \qquad (3.6)$$

as it already had at Gauss's epoch.

IMPORTANT:

The constant k is also approximately the mean (média) daily motion of the center of mass of the Earth-Moon system in its orbit around the Sun, expressed in rad/d, what corresponds to

$$\frac{180°}{\pi \cdot K} \approx 0{,}986°/d.$$

Cartesian coordinate system.

Coordinate system is defined by three orthogonal unit vectors

$$\boxed{e_i,\ i = 1, 2, 3},$$

originating from an origin O. For a right-hand system, we have

$$\boxed{e_3 = e_1 \times e_2},$$

where $e_1 \times e_2$ is the vector product of the two vector

$$\boxed{e_i;\ i = 1, 2}.$$

The set of the three unit vectors $e_i = 1, 2, 3$, is also called an orthonormal base in E^3.

A vector x pointing from the origin of the coordinate system to an arbitrary point in E^3 is called a position vector. Each position vector may be represented as a linear combination of the three base vector:

$$x = x_1 e_1 + x_2 e_2 + x_3 e_3 \qquad (3.8)$$

The Wave Nature of Material Particles.

Louis de Broglie in 1924 →

Wave Mechanics.

$$pr = nh/2\pi \quad (4)$$

↓

Equation
Pág. 192 (200)

De Broglie sought some reason for the quantization condition Eq. (4) that was used by Bohr. It occurred to him that if an electron behaved like a wave, then perhaps the allowed orbit in an atom were just those in which the circumference of the orbit equals an integral number of electron wave lengths.

Fig. 14 (a) – For circular orbits (orbit of radius $= r$ and $\lambda =$ wave length)

$$\boxed{n\lambda = 2\pi r}$$

obs: Since $\lambda = h/p$ for an electron?
⇒ $\lambda = h/p$ is the same relation that was used for photons in explaining the Compton effect.

Fig. 14 (c) – first three states. this was the birth of what came to be called wave mechanics. It started with de Broglie's postulate that an electron orbit was a reinforced wave the otherwise moved in that orbit like a particle in a Coulomb field.

Pag. 126 (143) - 6.5
/Harmonic Motion of a Classical Phase-Space Distribution

There is a particular intermediate initial width, which will turn out to be $\boxed{\sigma_{x0} = \sigma_0/\sqrt{2}}$, for which the classical phase-space distribution keeps its shape while oscillating as a whole.

This is the classical analog of the coherent state of quantum mechanics.

..."The ~~sp~~ phase-space probability density corresponding to a GAUSSIAN WAVE PACKET without correlation between momentum and position at the initial time

$\boxed{t = 0}$ is

Pág. 127(144) ⇒

$$p_i^{cl}(x_i, p_i) = \frac{1}{\underset{\Uparrow}{2\pi}\,\sigma_{x0}\,\sigma_{p0}} \exp\left\{-\frac{1}{2}\right.$$

error!!!

$$\left.\left[\frac{(x_i - x_{0i})^2}{\cancel{\sigma_{x_0}^2}\,\sigma_{x0}^2} + \frac{(p_i - p_{0i})^2}{\sigma_{p0}^2}\right]\right\}.$$

Here x_{0i}, p_{0i} are the initial expectation value and σ_{x0}, σ_{p0} are the initial widths of position and momentum, respectively.

The covariance ellipse of the bivariate Gaussian is caracterized by the exponential being equal to $-1/2$.

Pág. 128(145) – $\boxed{\text{Fig. 6.9}}$

Obs: Important!!!

We summarize our discussion by the following simple statements:

1) A classical phase-space distribution described by a bivariate Gaussian keeps its Gaussian shape.

2) Its center, which is the center of the covariance ellipse, moves on a circle around the center of the x, p plane with angular velocity ω.

3) The covariance ellipse keeps its shape but rotates around its center with the same angular velocity ω.

In figure 6.9 we illustrate the motion of the covariance ellipse for the three cases #

$$\boxed{\sigma_{x_0} < \sigma_{p0}, \quad \sigma_{x0} > \sigma_{p0}, \quad \sigma_{x_0} = \sigma_{p0}.}$$

The Equivalence Principle

4.2.1. - Everything Falls with the same acceleration.

"In contrast to eletric and magnetic fields the gravitational field exhibits a most remarkable property which is of fundamental importance for what follows. Bodies which are moving under the sole influence of a gravitational field receive an acceleration which does not in the least depend on the material or the physical state of the body"

Einstein.

Obs: Autor:

Primeiramente não há um contraste entre eletric and magnetic field, pois a "gravidade", ou seja, a pseudo-gravidade não existe, existindo apenas

os seus feitos decorrentes da eletricidade e magnetismo.

A atração dos corpos depende das três forças fundamentais da física, mas
Einstein inverteu a ordem

PROPOSITALMENTE,

Vejamos:

a) a aceleração não depende do material ou do estado físico do corpo, isto é uma meia-verdade pois não é do material ou estado físico do corpo, mas sim da energia contida naquela "massa".

A massa nada mais é que uma forma de energia.

Portanto, depende da massa (sim) envolvida na questão.

b) A massa que se refere Einstein decorre das forças fundamentais da física, pois ele descreveu os efeitos dessas forças sobre os próprios corpos ou "massas", ou seja, desta forma, a própria energia é a força que atua no próprio corpo ou massa.

Os efeitos não são uma força

autônoma independente, mas o reflexo das próprias forças fundamentais da física.

Confirmando o explicar:

Pág. 189 (206) → free-fall

"fifth force" ???

NO, let alone the fourth force.

Vejamos:

"... "More accurate measurements again confirmed the equality of free-fall accelerations in the gravitational field.

Obs: Neste caso, não há uma "gravitational field" e portanto, o free-fall não pode interferir no "gravitational field".

O mais grave de tudo, o pseudo "free-fall" não existe como força independente e decorre unicamente das três forças fundamentais da física.

Aprofundando: (Pag. 189 (206)

Fig. 4.4 → The Dicke experiment.

The Earth is in free fall around the Sun. ← text

← commentary

Obs: Não é verdade, as forças fundamentais da física continuam agindo sobre a Terra. A inércia da energia da própria Terra comportasse como uma "queda-livre"!

This should eliminate inertial forces in the Earth's frame.

Another way to see this is to say that centrifugal forces is exactly balanced by the gravitational attraction to the sun.

If different bodies have different free-fall accelerations in the same field this balance will not always occur.

In this experiment Dicke looked at a rotation of a torsion balance connected to one aluminium and one gold sphere on a 12 hour cycle as the Earth rotates.

The spheres have equal inertial masses.

Important: →

Broken line indicates rotation if gold falls with greater free-fall acceleration that aluminium.

Pág. 154 (178) - Chapter 4
The mean-value theorem; Applications of the first and second derivatives.

The Mean-Value Theorem:

If f is differentiable on the open interval (a, b) and continuous on the closed interval [a, b], then there is at least one number c in (a, b) for wich

$$\boxed{f'(c) = \frac{f(b) - f(a)}{b - a}}$$

→ is to say that the graph of f has at least one point $(c, f(x))$ at which the tangent line is parallel to the line l.

IMPORTANT:

Utilizar este conceito como um instrumento de checagam de minha pesquisa. Paralelo e diagonal ao mesmo tempo.

Vejamos:

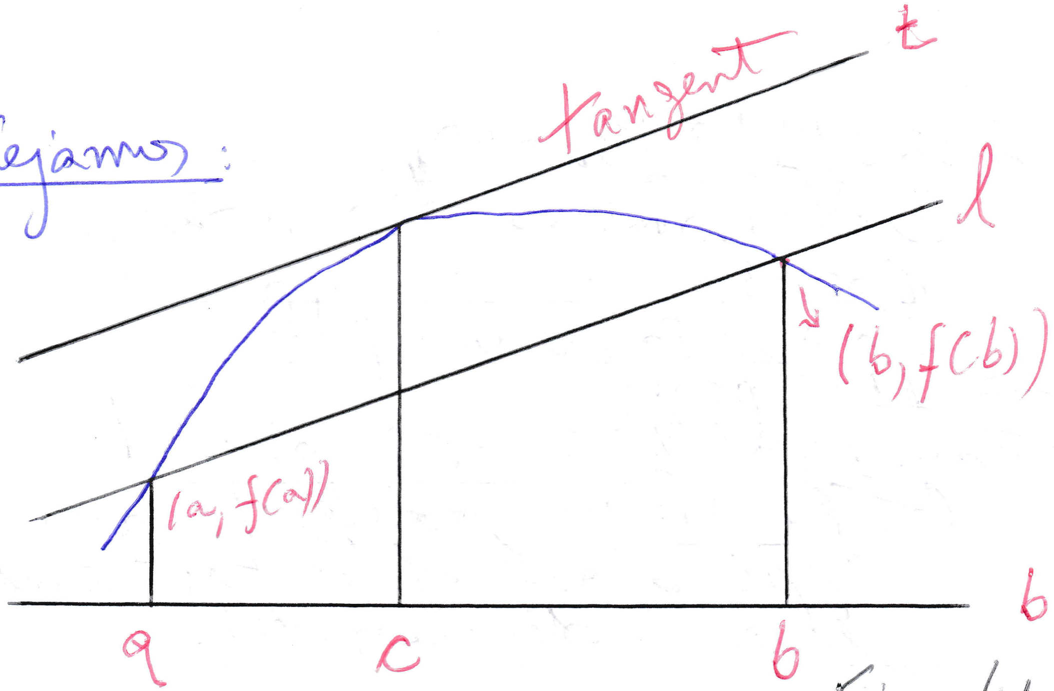

Figure 4.1.1

Análise:

A linha b (base) que contém a projeção dos pontos a, b e c sobre a abscissa x será utilizada como parte superior da curvatura espaço "tempo".

A função f (linha azul) como a curvatura do espaço elliptico da órbita de um planeta ou sistema solar.

A tangente t paralela a linha l será um referencial de checagem de projeção sobre a linha b (eixo x), mas devemos ficar atentos à linha l pois esta representa os dois pontos do nosso sistema de cálculo porque nós deveremos ter dois referenciais de estudo que deverão estar interligados entre si, que nós explanaremos a seguir:

a) Os pontos (a, f(a)) e (b, f(b)) deverão coincidir ou ser os pontos focais de elipse da órbita de um planeta ao redor de sua estrela ou do próprio sistema solar em questão.

Obs: Utilizar o sistema duplo elíptico único musichiano,

esboçado anteriormente com os dois círculos, ponto Frigier e os pontos $\underbrace{Me_1, Me_2, Me_3}$ – Musich points.

Obs: Esses pontos deverão ser alinhados entre si.

Vejamos:

1) P, M_1, S e Me_2.

2) Me_1, S, M_2 e Me_3.

Importante: Utilizar **Pappus's theorem** como checagem dos pontos colineares de modo a manter um referencial objetivo de uma linha reta (straight line).

Obs: Os pontos focais da ellipse são essenciais da a estabilidade dos cálculos e sua respectiva projeção ortogonal sobre o plano.

b) Os pontos $(a, f(a))$ e $(b, f(b))$ deverão representar, em outra simulação, as bordas ou limites da órbita do sistema solar.

Os pontos $(a, f(a))$ e $(b, f(b))$ estão sobre a linha l e são dois pontos que estão na função f. (linha azul).

A tangent t deverá coincidir com a concavidade inferior da curvatura do espaço. (sistema duplo elíptico curvo muschiano)!

Continuando o estudo sobre
Mean-Value Theorem

First we will show that if a function f has a nonzero derivative at some point x_0, then for
x close to x_0
$f(x)$ is greater than $f(x_0)$ on one side of x_0 and less than $f(x_0)$ on the other side of x_0.

Vejamos: Theorem 4.1.2.

Theorem 4.1.2.

Suppose that f is differentiable at x_0!

If $f'(x_0) > 0$, then

$$f(x_0 - h) < f(x_0) < f(x_0 + h)$$

for all positive h sufficiently small!

If $f'(x_0) < 0$, then

$$f(x_0 - h) > f(x_0) > f(x_0 + h)$$

for all positive h sufficiently small.

Proof:

- $f'(x_0) > 0$

by the definition of the derivative,

$$\lim_{k \to 0} \frac{f(x_0 + k) - f(x_0)}{k} = f'(x_0).$$

- With $f'(x_0) > 0$, we can use $f'(x_0)$ itself as ϵ and conclude that there exists $\delta > 0$ such that

→

if $0 < |k| < \delta$, then

$$\left| \frac{f(x_0+k)-f(x_0)}{k} - f'(x_0) \right| < f'(x_0)$$

For such k, we have

$$-f'(x_0) < \frac{f(x_0+k)-f(x_0)}{k} - f'(x_0) < f'(x_0)$$

and thus

$$0 < \frac{f(x_0+k)-f(x_0)}{k} < 2f'(x_0).$$

In particular

$$(*) \quad \frac{f(x_0+k)-f(x_0)}{k} > 0.$$

We have shown that $(*)$ holds for all numbers k which satisfy the condition $0 < |k| < \delta$.

If $0 < h < \delta$, then

$$0 < |h| < \delta \text{ and}$$

$$0 < |-h| < \delta.$$

Consequently,

$\Rightarrow$

$$\frac{f(x_0+h)-f(x_0)}{h} > 0 \text{ and}$$

$$\frac{f(x_0-h)-f(x_0)}{-h} > 0.$$

The first inequality show that $f(x_0+h)-f(x_0) > 0$ and therefore $f(x_0) < f(x_0+h)$.

The second inequality shows that $f(x_0-h)-f(x_0) < 0$ and therefore $f(x_0-h < f(x_0)$.

IMPORTANT:

Next we prove a special case the mean-value theorem, known as

$$\boxed{\text{ROLLE'S THEOREM}}$$

(1691)

In Rolle's theorem, we make the additional assumption that

$f(a)$ and $f(b)$ are both 0.

(See Figure 4.1.2) →

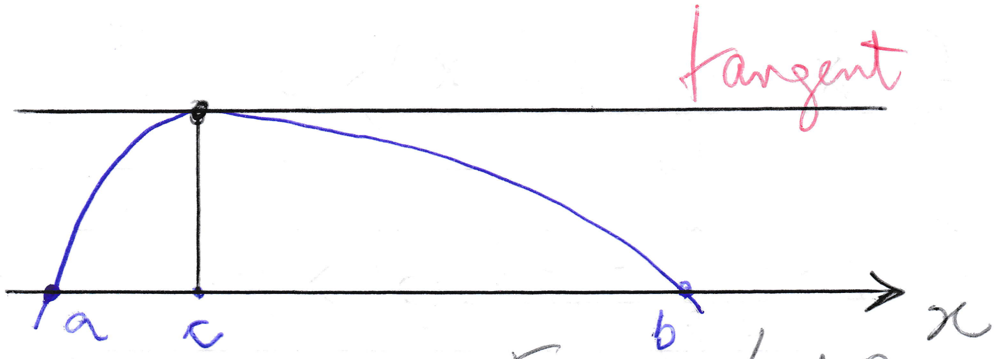

Figure 4.1.2.

Obs: Utilizar esta configuração para criar um referencial de checagem sobre a curvatura do espaço (bending light).

In this case, the line through $(a, f(a))$ and $(b, f(b))$ is horizontal. (It is the x-axis). The conclusion is that there is a point $(c, f(c))$ at which the tangent line is horizontal.

THEOREM 4.1.3
ROLLE THEOREM

Suppose that f is differentiable on the open interval (a, b) and continuous on the close interval $[a, b]$. If $f(a)$ and $f(b)$ are both 0, then there is at least one number c in (a, b) for which

$$\boxed{f'(c)=0}$$

PROOF: If f is constantly 0 on $[a, b]$, then $f'(c) = 0$ for all c in (a, b).

If f is not constantly 0 on $[a, b]$, then f takes on either some positive values or some negative values.

Since f is continuous on $[a, b]$, f must take on a maximum value at some point c of $[a, b]$ (Theorem 2.6). This maximum value, $f(c)$, must be positive. Since $f(a)$ and $f(b)$ are both 0, c cannot be a and it cannot be b. This means that c must lie in the open interval (a, b) and therefore $f'(c)$ exists. Now $f'(c)$ cannot be greater than 0 and it cannot be less than 0 because in either case f would have to take on values greater than $f(c)$. (This follows from theorem 4.1.2.). We can conclude therefore that $f'c) = 0$.

Livro: A Nova Física
Da Metafísica desinvertida.

Obs: A interpretação relativística de que a "energia é matéria radiante e matéria é energia condensada" expressa muito bem o materialismo absoluto trazido por Einstein e a idéia errônea de que a energia vem da matéria.

Tesla já havia realizado inúmeras

invenções de vulto, que corresponde à ausência total de matéria, ou seja, o vácuo é feito de energia.

A tecnologia de Tesla usava ressonância de ondas eletromagnéticas que ele denominava "ondas eletromagnéticas longitudinais".

Alguns ramos não ortodoxos de física denominam a energia do vácuo responsável pela tecnologia de Tesla de "energia escalar", um termo que se refere a uma forma de energia "não vetorial", ou seja, não originária da dimensão do espaço-tempo e portanto não definível por parâmetros temporais e espaciais, como são a energia potencial e a energia cinética.

Keppe: (concluiu)

1) A matéria advém da energia e ambas não são equivalentes.

A energia (escalar de Tesla, ou essencial de Keppe) é hierarquicamente superior e sempre existe onde não há matéria (partículas), porém nem sempre há matéria – ou poderá haver – onde há energia. A matéria simplesmente capta energia essencial e desprende energia secundária segundo a ressonância de sua estrutura interna.

A

Análise:

O nada gera a energia, portanto o vácuo é a energia que cria os demais. Caso não houvesse o nada, nada teria sido criado. O nada cria o vácuo que é uma forma de energia "primordial" que permitirá a criação da matéria.

O nada existe por causa de Deus e existe antes do vácuo, o vácuo é conseqüência do nada. Aqui eu não estou falando nem de filosofia, teologia ou religião, mas apenas querendo demonstrar que o nada, criado por Deus, permitiu a criação de tudo, pois caso Deus não fizesse isso, ou seja, Ele ocupando tudo, não haveria espaço para a criação do nada e consequentemente do vácuo.

A afirmação de Keppe de que a energia sempre existe onde não há energia decorre, para mim, do nada pois o vácuo já é uma manifestação da energia criadora do nada.

O vácuo decorre do nada e o nada é muito maior que o vácuo, pois para existir o vácuo há a necessidade de existência do nada.

O Universo se expande sobre o nada, pois o nada já está lá onde o Universo, ou a borda dele, irá se expandir.

O fato de não existir nada na borda do Universo faz com que o Universo se expanda, criando-se assim, o vácuo. Conforme o Universo se expande o vácuo é criado sobre o nada e neste vácuo há energia free para o homem utilizá-la.

2) Existe apenas uma única substância, a Energia Essencial (termo keppeano para a energia escalar de Tesla), que é transcendente (não-material, não-temporal e não-espacial) e que produz a matéria através do fenômeno da ressonância.

Para Keppe, matéria é uma ressonância da Energia Essential aprisionada no tempo e no espaço.

Análise: O nada permite a criação do vácuo que contém energia, mas o nada é muito maior do que a energia "aprisionada" no espaço-tempo.

Não há uma junção energética mas sim uma decorrência da própria criação do vácuo, pois conforme o Universo se expande sobre o nada, o vácuo é criado com a sua respectiva energia e posteriormente, a matéria é criada. Por este motivo é que nós temos mais vácuo do que matéria, ou seja, o vácuo não preenche o espaço entre a matéria do Universo e sim a matéria que ocupa o vácuo previamente criado, e cria-se assim, os espaços entre as estrelas, planetas, galáxias etc.

3) Para Keppe, as energias sensíveis ao ser humano e detectáveis por instrumentos não são essenciais, correspondendo todas elas a subprodutos da energia primária (Energia Essencial). Isto implica que a tecnologia baseada na obtenção de movimento através da diferença de potenciais de energias secundárias (gravidade, eletromagnéticas etc) pode ser substituída pela tecnologia de

captação direta de energia primária (energia essencial) através do fenômeno da ressonância (da) de uma energia secundária, eletromagnética, por exemplo.

4) A energia essencial tem duas componentes, ação e complementação, que correspondem aos dois sentidos que compõem a ressonância.

Keppe usa o conceito de "Potencial Puro", correspondendo à idéia de que a diferença de potenciais da física causa entropia acelerada do sistema pelo uso da energia apenas em um sentido. Quando o sistema está em ressonância, a entropia é minimizada e a eficiência maximizada, justamente porque o sistema passa a se beneficiar dos duas componentes complementares de ação e complementação.

O potencial puro pode ser visto como um vórtice causado pela ressonância do sistema e por onde passa a energia essencial.

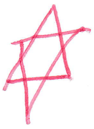
Pág. 73(80) → Leibniz →

Leibniz still saw the sphere as a surface embedded in three-dimensional Euclidean space. It happens, then, that a parallel in an embedded sphere is (itself) itself (if not a great circle), and Leibniz was able to think that the equidistant line to a circle is itself a circle, even on a spherical surface (a regular figure, in his terminology).

... Leibniz missed the most promising



example of a non-Euclidean geometry on the spherical surface, and did not properly grasp the full meaning of a geodesic.

Leibniz-on-the-Parallel-Postulate-and-the-Foundations-of-Geometry..pdf

Pág. 73(80) — [39] → rodapé

Since the above-mentioned marginal notes to Clavius' edition were probably written by Leibniz in 1679,

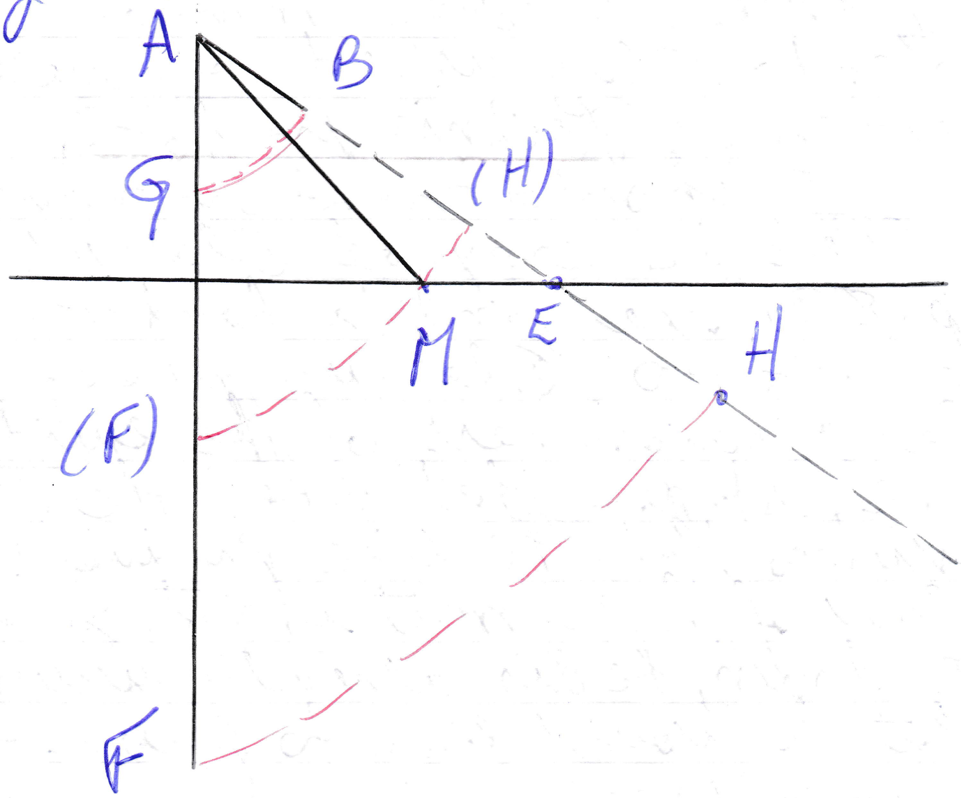
I should mention now that on Leibniz' copy of Clavius' Euclidis (p. 89), we find a handwritten remark to Clavius' proof about the straightness of the equidistant line, stating that when the Jesuit assumes that the line produced by the flow of the segment is not going up or down, he is already assuming what he would like to prove — straightness

("illud sursum vel deorsum supponit jam rectam").

Return: TEXT Pág. 73(80) →

Leibniz' short discussion on the topic only restates that the straightness of the equidistant line should be proved (what Clavius just assumes, Leibniz says),[39] and he puts forward (apresenta) an argument by symmetry.

Pag. 74(81)-



Leibniz discusses the case of two lines, AB and CD, that are intersected by a transversal AF as to form a right and an acute angle. The Parallel Postulate states that, if extended far enough, the two lines will meet.

Leibniz imagines the rotation around A of the transversal AF toward (em direção a) the position of the inclined line AB, and considers that the point F will be under the line AC when (at some point of the rotation movement) the line AF reaches the position of AB.

Since F is below CD and A is above it by a continuity assumption, the extended AB (that is, the rotated AF) meets CD at some point proving the Postulate.

If the length AF is such that when AF reaches the position of AB the point F is already above the line CD (as in the case of A(F) in the diagram) nothing can be concluded. But then, we can take a point F on AF that is far enough from A to do the job.

The same will be true for any finite length of AF.

In the case in which AB and CD are parallel, however the same reasoning cannot apply, since the intersection would occur at infinity, and AF would be a rotating unbounded line meeting the unbounded line CD at their extreme (which is impossible, since AF and CD have no ends).

Leibniz takes this as a further proof that lines cannot be moved (see text 3 above). Thus, Leibniz concludes, the present proof by rotation shows that AB and CD intersect, except in the case in which the intersection should occur at infinity; and this is the case in which AB and CD are

parallel

or form equal angles with a transversal.

Even if we accept the whole reasoning on the immovability of an infinite line

(and Leibniz himself observes that it would require more work), the last passage is unwarranted.

In hyperbolic geometry the transversal line AF, rotating, first intersects CD, than it becomes

asymptotic

with it,

and finally it reaches the line AB (assuming, I mean, that AB is parallel to CD in the hyperbolic plane, and thus the Parallel Postulate is false in this instance).

That is to say, Leibniz doesn't prove the central statement needed to establish the Parallel Postulate that the intersection of the rotating AF with CD only occurs at infinity when the angular sum with the transversal is two right angles.

Leibniz himself realized that this part of the proof was missing, and abandoned it. [43]

[43] → Leibniz' attempt was envisaged by a Medieval Hebrew mathematician (Moïse Ha-Lévi)

Obs: T. Lévy (1992) →

Gersonide, le Pseudo-Tūsī, et le postulat des parallèles.

Pág. 73(80) - ... equidistant line to a circle is itself a circle ...

an example speaking in favor of the claim that the equidistant to a straight line is itself straight (no one mentioned the conic sections)[37].

[37] →

[37] → Clavius' Lemma 1 —
to his proof of the Parallel Postulate has a long discussion about the fact that the line equidistant to a circle is itself a circle.

Leibniz himself commented on Clavius' circle argument with a marginal note to his copy of Euclidis, stating:

> "non semper lineae aequidistantes ejusdem sunt naturae; aequidistans parabolae parabola non est" (p. 90)

Interessante:
Leibniz – the great circles are the shortest and the most determined lines between two points on the sphere, and (moreover) they are 'uniforme' lines.38

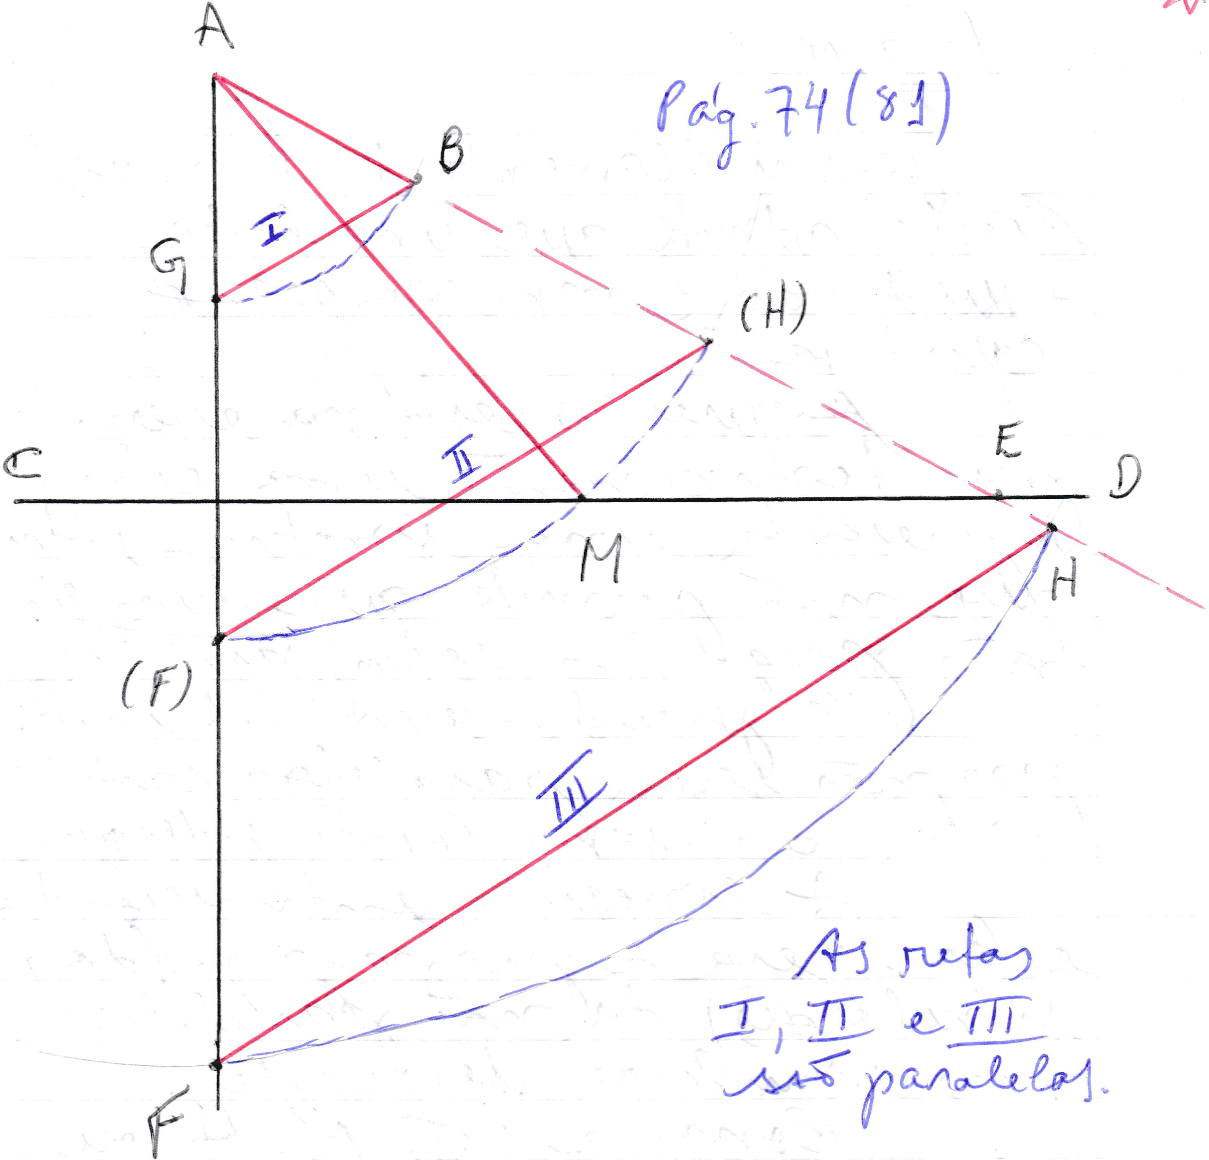
Pág. 74 (81)



As retas I, II e III são paralelas.

Vejamos:
a) AG = AB
b) A(F) = A(H)
c) AF = AH.

Obs. Não precisa o uso de compasso.

Através da Geometria Musichiana (Hiperelíptica ou Musdesic, baseado na hipótese de ângulo hiperelíptico projetivo, AB ≠ AF (não são paralelos) no plano euclidiano, são paralelos na G.M.H ou Musdesic.

Vejamos:

Leibniz comentando Clavius' Circle admite que uma linha equidistante nem sempre é equidistante.

A questão está na esfericidade, pois teoricamente uma esfera apresenta uma simetria intrínseca que não permite que duas linhas não paralelas sejam paralelas.

O "pseudo-erro" "ab initio" por não serem paralelos contamina todas as simulações subsequentes.

A simetria intrínseca da esfera gera a propagação (das simulações) do não paralelismo nas simulações decorrentes.

Com a G.M.H ou Mundesic a hipótese do ângulo hiperelíptico projectivo no qual a dupla elipse curva permite uma real simulação da realidade demonstrando novas nuances de uma nova geometria permitindo que linhas não paralelas no plano euclidiano sejam paralelas, possibilitando a criação de novos paradigmas no mundo físico, criando novos Universos que seriam impossíveis com a

Matemática atual.

Musdesic é uma nova Matemática e consequentemente, uma nova geometria.

O ângulo hipereclíptico projetivo é um novo meio de representar a realidade, adequando o que existe ao formalismo atual matemático.

Aprofundando:

Return Pág. 74(81)

a) AG = AB

b) A(F) = A(H)

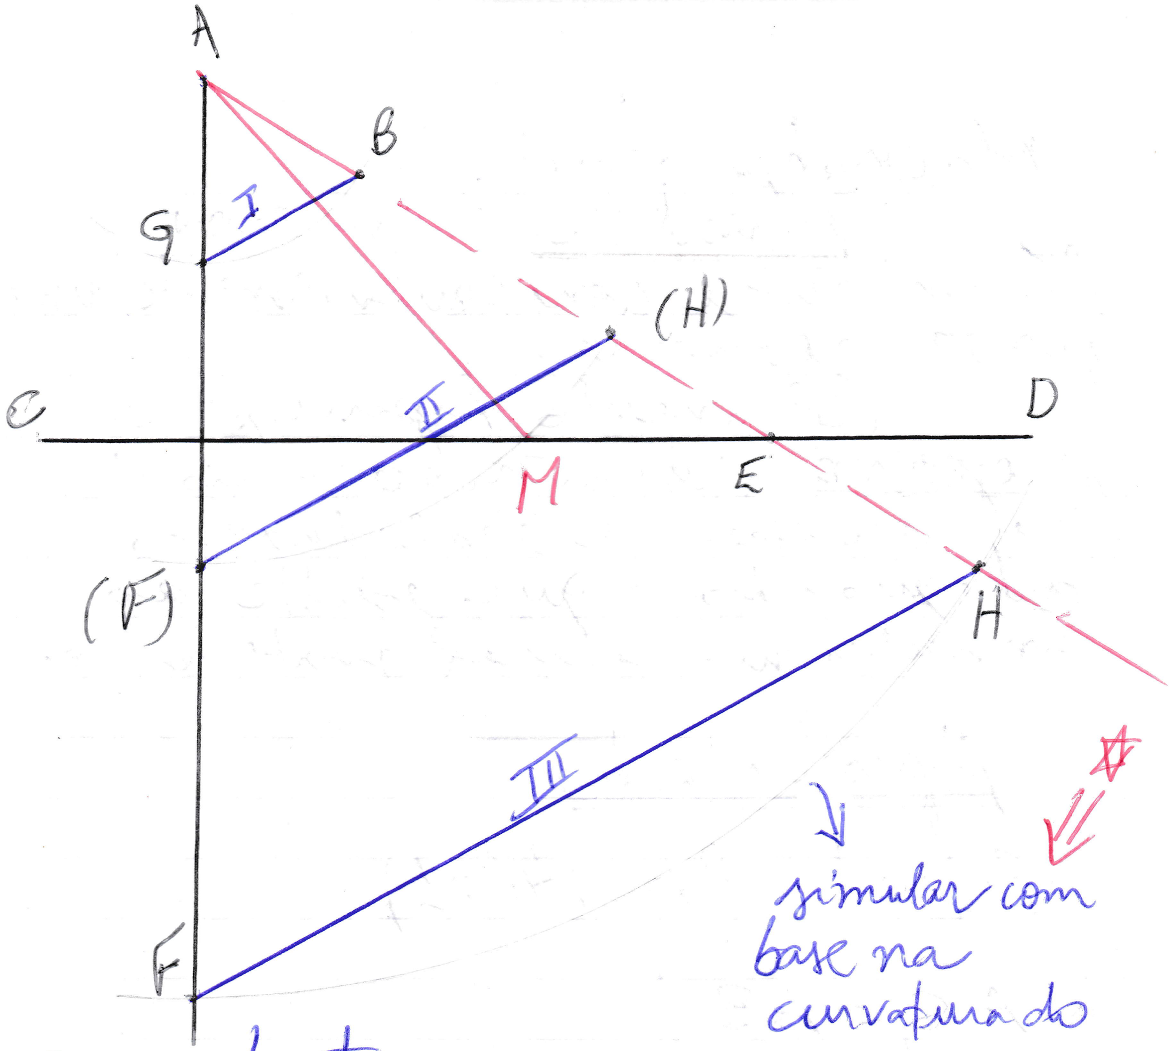
c) AF = AH

IMPORTANT:

Neste exemplo não há a necessidade da utilização de compasso para se obter o paralelismo entre as três retas.

O importante é o comprimento igual de cada segmento em ambas as retas.

AB não é paralelo ao segmento AF. (de reta).



simular com base na curvatura do espaço (bending light)

Important:

Fazendo um estudo mais aprofundado, nós podemos inferir mas sem provar ainda, que AB é paralelo a AF, pois caso haja a igualdade dos comprimentos dos segmentos de retas entre as duas retas AB e AF, gerando as três retas paralelas I, II e III, nós podemos inferir que há um paralelismo intrínseco oculto entre essas duas retas.

Obs: A curvatura entre F e H, criada pelo compasso,

poderá representar em uma simulação
a curvatura da luz (bending light)
e a reta entre F H° o plano
projectivo no qual será projetado
o sistema de dupla elipse curva.

Interessante:

Este paralelismo não se pode
obter em uma esfera pois a
simetria intrínseca interna ou
externa impede que haja este
paralelismo.

Como duas retas, que a princípio,
não são paralelas no plano
cartesiano geram três retas
I, II e III paralelas.

A dupla elipse curva
permite o paralelismo que será
representado no plano no qual
será projetado.

obs: Fazer as simulações e os
cálculos.

Leibniz-on-the-Parallel-Postulate-and-the-Foundations-of-Geometry...pdf
Pag. 57(64)- Chapter 4 -
Leibniz' Attempts to Prove the Parallel Postulate.

Pag. 58(65)- Consider, for instance, that the main feature of a NON-EUCLIDEAN THEORY OF PARALLELISM (in hyperbolic geometry) is the existence of approaching straight lines that do not meet (asymptotic parallels);

if one could disprove this possibility, the Parallel Postulate would be established;

but an asymptótic behavior of lines seems (parece) to depend on their curved and convex "shape" (as the usual Euclidean asymptotic lines are, obviously, not straight); a good definition of straightness (one might hope) would have dispelled (dissipado) the possibility of asymptotic straight lines, thus opening the way to a full-fledged (completo) demonstration of the Postulate.

Leibniz definitions are very numerous →

Definitions:

1) Straight line as the shortest line between two points.
(Borelli, Giordano, Fabri and Hobbes).

obj: Aristotle's statement (Phys. B 9, 200 22-4) that from the 'essence' of the straight line it follows that the sum of the angles of a triangle is equal to two right-angles.

The notion of "straightness" seems not to be captured by "shortness", and the original intent of a definition of a straight line is that of expressing the clearly intuitive idea of a LACK OF CONVEXITY OR CONCAVITY (to use Clavius' words).

Leibniz explicitly mentions the fact that the property of shortness is never used in any proof of the Elements and it is not useful to solve any foundational question.

Leibniz had a discussion with Giordano on this point, in which he appreciated that Giordano had been able to employ the definition of a straight line as the shortest line to implement his proof of the Parallel Postulate; which, being concerned with the notion of equidistance, might rely (depender) as well on the idea of the shortest distance between two lines.

2) This was an improvement, in Leibniz's eyes, on Borelli's treatment of the Postulate.

Interessante:

In the end, however, Leibniz would have preferred that Giordano had employed in his foundational efforts a definition of a straight line that Leibniz showed he knew elsewhere: that of a rotational axis.4

Pag. 60(67) – Leibniz analysis situs.

The definition of the straight line as the locus of points which remain fixed in the motion of a body with two fixed points, i.e.

the axis of rotation,

is in fact the second and most important definition of a straight line that Leibniz use in his writings on analysis situs.

Its clearest mathematical characterization is that the straight line is the only line between two points that is unique under isometries (that is, any other line connecting those two points has at least another isometric realization – imagine the reflection of that line in a plane). It is also connected with Leibniz' notion of UNIFORMITY, as the straight line so defined has the property that every segment of it is congruent to any other segment of the same length by a spatial isometry (its curvature being null).

Its importance for Leibniz is enormous, as it is by far his preferred definition ...

including those aimed at proving the Parallel Postulate.

3) The third definition of a straight line that Leibniz uses is that of a self-similar curve.

Pág. 60(67) → each segment of a line is congruent with any other of equal length, this definition says that the straight line is the only line any segment of which is similar (in the proper geometrical sense) to any other segment (of any length) of the same line.[9]

[9] → Any homothety of a factor λ applied to a curve transforms the curvature of it by a factor 1/λ. If we want a similarity (that is, a homothety and a rigid motion) to bring a segment of a curve to coincide with the whole given curve (also bounded or closed), we have λ > 1, and thus the curvature lessening at every point.

The maximal curvature of the given curve, thus, may only be reached by the transformed segment if it is zero, that is, if the curve is a straight line.

Pág. 170(179)- Euclid's postulates

5. If two straight lines emanating from the endpoints of a given line segment have interior angles on one given side of the line segment summing to less than two right angles,

then the two lines, if extended, meet to from a triangle on that side of the line segment.

Obs: Pág. 171 (180) - In 1795, Scottish mathematician and physicist John Playfair (1748-1819) proposed an alternative formulation of the famous fifth postulate (today known as Playfair's Axiom).

This version of the axiom is considerably easier to handle, and its negation is easier to envision.

Nicolai Ivanovich Lobachevsky (1792-1856) e
János Bolyai (1802-1860), independently came to the same surprising conclusion:

the first four of Euclid's postulates together with the negation of Playfair's version of the fifth postulate will not lead to a contradiction.

Euclid: the parallel postulate cannot be proved a consequence of the remaining postulates of Euclid.

IMPORTANT:

Bolyai's system of

✡

of hyperbolic geometry it is always the case that, for any point P in the plane, there are an infinite number of distinct lines through that point all PARALLEL to any given line not through P.

(In ordinary geometry, where the parallel postulate holds, there is only one, and only one, line through a given point P parallel to a given direction. This is PLAYFAIR'S AXIOM.)

In his new geometry angles in triangles sum to less than 180°, and the ratio of the

Pág. 227(236) - The German mathematician Bernhard Riemann (1826-66) discovered an alternative of non-Euclidean geometry in which Euclid's fifth postulate fails in a different way.

In a system of SPHERICAL GEOMETRY it is never possible to draw a line through a given point parallel to a given line.

Riemann in his famous 1854 lecture "über die Hypothesen welche der Geometrie zu Grunde liegen" (On the hypotheses that lie at the foundation of Geometry), Riemann put foward (coloca para frente) the view that geometry can be the study of any kind of space of any number of dimensions and later developed the mathematics needed to properly describe the shape of space.

Obs: Albert Einstein (1879-1955) later used this work to develop his theory of relativity.

ATENTION:

Cuidado!!! Atenção!!!

Nós devemos prestar atenção na seguinte diferença:

Bolyai → the ratio of the circumference of a circle to its diameter is greater than π.

Na página 255 (264):

In hyperbolic geometry all angles in triangles sum to less than 180°, and the ratio of the circumference of any circle to its diameter is less than π.

(Lobachevskian geometry).

Hyperbolic geometry

(Lobachevskian geometry)

is a non-Euclidean geometry in which the famous PARALLEL POSTULATE fails in the following manner:

Through a given point not on a given line, there is more than one line parallel to that given line.

→

Jules Henri Poincaré (1854-1912) later provided a simple model for this geometry and the means to easily visualize geometric results in this theory.

The "Poincaré disk" consists of all the points in the interior of the UNIT CIRCLE.

A "point" in geometry is any point inside this circle and a "line" is to be interpreted as a circular arc within the circle with endpoints perpendicular to the boundary of the circle.

Any diameter of the boundary circle is also considered a line.

Distances are not measured with a traditional ruler: points on the boundary circle are considered to be infinitely far from the center of the circle.

Bolyai and Lobachevsky showed that all but the FIFTH OF EUCLID'S POSTULATES hold in the hyperbolic geometry and, moreover, that this model of geometry is consistent (that is, free of CONTRADICTIONS).

This establishes that the parallel postulate cannot be logically deduced as a consequence of the remaining axioms proposed by Euclid.

In hyperbolic geometry, all angles in triangles sum to less than 180° and the ratio of the circumference of any circle to its diameter is less than π. (Moreover, the value of this ratio is not the same for all circles). Also, it is possible for two perpendicular lines to be parallel to the same line.

Physicists, following the work of Albert Einstein, suggest that the geometry of our universe is hyperbolic: that it appears to us as Euclidean is a result of the fact that we occupy such a small portion of it. (This is analogous to the fact that it is difficult to recognize the Earth as around when living on it).

Pág. 355 (364) – non-Euclidean geometry.

non-Euclidean geometry :

1795 - John Playfair (1748-1819) presented an alternative, but equivalent, formulation of the parallel postulate:

through any point in the plane, there is precisely one line through that point parallel to any prescribed direction.

Recasting the postulate this way makes it apparent that negation of the famous fifth postulate has two parts. Either:

1. There are no lines through a given point parallel to a given direction.
2. There is more than one line through a given point parallel to a given direction.

From 1826 to 1829, Nicolai Ivanovich Lobachevsky (1792-1856) developed a consistent theory of geometry in which Euclid's fifth postulate fails in the manner described in point 2. → Hyperbolic Geometry.

In the 1850s, Georg Friedrich Bernhard Riemann (1826-1866) presented an alternative form of geometry in which Euclid's fifth postulate fails in the manner describe in point 1 above.

In this theory, today called Riemannian geometry or Spherical Geometry, "lines" are great circles drawn on the surface of a sphere. Consequently, it is impossible to draw a pair of lines that never intersect.

Euclid's second postulate seems to state that straight lines should be of infinite length.

Riemann had the insight to note that "extended indefinitely" does not imply "infinitely long", thus allowing him to consider a geometry in which straight lines loop back on themselves.

In hyperbolic geometry, all angles in a triangle sum to less than 180°, and the ratio of the circumference of a circle to its diameter is greater than π.

In spherical geometry, all angles in a triangle sum to more than 180°, and the ratio of the circumference of a circle to its diameter is less than π.

Euclidean Geometry, in which angles in a triangle always sum exactly to 180°, and the ratio of the circumference to diameter of any circle is precisely π (wrong!!!!) M.U.S., can thus be regarded as an intermediate between the two.

Resume:

a) Encyclopedia of Mathematics-Tanton.pdf
Pág. 377(386)-
Parallel Postulate (Euclid's fifth postulate)

His fifth postulate states:

If two lines L and M subtended from a common line segment have interior angles summing to less than 180°, then those lines, if extended, will meet to form a TRIANGLE.

One can consequently conclude that if those angles sum to more than 180° then the lines, if extended on the other side of the given line segment, will form a triangle on that side.

(The sum of the supplementary interior angles will be less than 180°.)

Furthermore, if the lines never meet, that is, if they are PARALLEL, then the sum of the two angles x and y shown cannot be less than nor greater than 180°, and so must equal 180°. We have:

For a pair of parallel lines with a TRANSVERSAL, as shown in the diagram below right, the angles labeled x and y must sum exactly to 180°. Consequently, the alternate interior angles of transversal are equal.

This is often taken as the statement of Euclid's fifth postulate. For this reason, it is (offen) often called the parallel postulate.

As the parallel postulate is intimately connected with the formation of triangles, it is not surprising that one can use it to prove:

The sum of the interior angles of any triangle equel 180°.

1795 – "Elements of Geometry"
→ John Playfair offered a third, logically equivalent version of the parallel postulate:

Given a line L in the plane and a point P not on that line, then there exists one and only one line through P parallel to L.

This alternative version of the postulate is today called PLAYFAIR'S AXIOM.

1829 → Nikolai Ivanovich
Lobachevsky
(1792 – 1856)
→ discover a consistent theory

of a Non-Euclidean Geometry.

We now have three assertions:

1. Euclid's parallel postulate;
2. Angles in a triangle sum to 180°;
3. Playfair's axiom.

These three statements are logically equivalent, that is, any one implies the other two. To see this, it suffices to show that (3) implies (2), (2) implies (1), and that (1) implies (3).

We will need to make use of the converse of Euclid's parallel postulate:

If a transversal across a pair of lines yields equal alternate interior angles, then the lines are parallel.

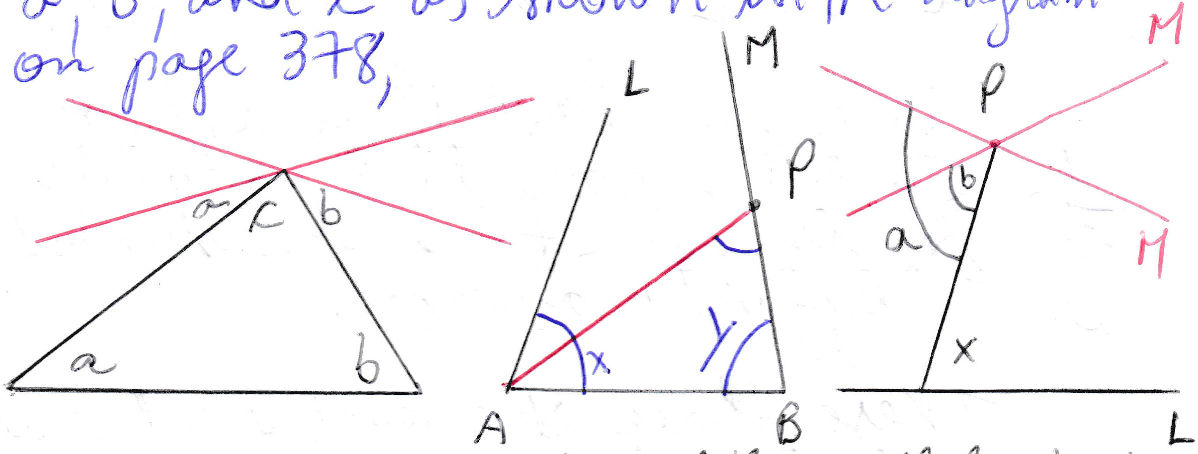
As the EXTERIOR-ANGLE THEOREM, this statement can be proved without making use of any of the three statements above.

Consider now the three implications:

(3) implies (2):

Given a triangle with angles

a, b, and c as shown in the diagram on page 378,



Equivalent versions of the parallel postulate.

... 378, draw two lines at the apex that copy angles a and b. Given that both yield equal alternate interior angles across a transversal, both lines are parallel to the base of the triangle. By Playfair's axiom there is only one such ~~lime~~ (line). Thus angles a, b, and c all lie on the same straight line and so sum to 180°.

(2) implies (1):

In the middle diagram on page 378, suppose that lines L and M are parallel, and so never meet. Could it be that angles x and y sum to less that 180°? Draw a point P on line M, and slide it along M sufficiently far so that the angle of the triangle APB at P is less than 180 - x - y.

Clearly the angle in this triangle at A is less than x.

We now have a triangle with three angles that sum to something less than $x-(180-x-y)+y=180°$.

This is impossible by our assumption that (2) is true. It cannot be the case that L and M are parallel after all.

(1) implies (3):

Discussion on the exterior-angle theorem shows that there certainly exists at least one line through a point P parallel to a given line L.

Suppose there are two such lines. Call them (them) M and M' as shown in the diagram above.

Draw any line from P to L.

Since, by (1), we are assuming that alternate interior angles are equal for parallel lines, both angles a and b show are equal to x.

Consequently M and M' must be the same line.

Pág. 473 (482) → Spherical Geometry

Spherical Geometry (elliptic geometry, Riemannian geometry)

Discovered in 1856 by Georg Friedrich Bernhard Riemann (1826-66), and later slightly modified modified by Felix Klein (1849-1925), spherical geometry is a non-euclidean geometry in which the famous

PARALLEL POSTULATE

fails in the following manner:

Through a given point not on a given line there are no lines parallel to that given line.

Riemann used the surface of a SPHERE as a model of this geometry by interpreting the word line to mean a great circle on the sphere. Given that in a theory of geometry two lines are meant to intersect at just one point (yet any two great circles intersect at two ANTIPODAL POINTS), it is appropriate then to interpret the word point in spherical geometry as an antipodal pair of points on the surface. In this setting, it is now also true that

any two distinct points determine a unique line.

Riemann and Klein proved that all but the fifth of EUCLID'S POSTULATES hold in this model and, moreover, that this model is consistent (that is, free of CONTRADICTIONS).

This establishes that the parallel postulate cannot be logically deduced as a consequence of the remaining axioms proposed by Euclid.

In spherical geometry all angles in triangles sum to more than 180°, and the ratio of the circumference of any circle to its diameter is greater than π (and this value varies from circle to circle).

Obs: Checar!!! ... greater than π.

$\Delta > 180^\circ$ and $\frac{C}{D} > \pi$ (?)

(atenção!!!)

IMPORTANT:

Pág. 46(55) – Bolyai, János (1802 – 1860) is remembered for his 1823 discovery of Non-Euclidean geometry.

...

In Bolyai's system of HYPERBOLIC GEOMETRY it is always the case that, for any point P in the plane, there are an infinite number of distinct lines through that point all PARALLEL to any given line not through P.

(In ordinary geometry where the parallel postulate holds, there is only one, and only one, line through a given point P, parallel to a given direction. This is PLAYFAIR'S AXIOM)

In his new geometry, angles in triangles sum to less than 180° and the ratio of the circumference of a circle its diameter is greater than π.

Pág. 170 - Chapter XIV
Areas and Volumes

The subjects area and volume offer some of the most striking points of disparity between Euclidean and non-Euclidean geometry.

Pág. 174 - In Chapter III we defined as the discrepancy of a triangle, the absolute value of the difference between the sum of the measures of the angles and π. Let us now define as the excess of our triangle the expression

$$\boxed{e = A + B + C - \pi}.$$

This will have the same sign as $\frac{1}{k^2}$, the measure of curvature of space.

We have

$$\sin\frac{e}{2} = -\cos\sigma = \frac{\sin(ABC)}{4\cos\frac{1}{2}\frac{a}{k}\cos\frac{1}{2}\frac{b}{k}\cos\frac{1}{2}\frac{c}{k}}$$

(14)

$= 4$

$$\lim e = \frac{1}{2} \lim (ABC)$$
$$= \frac{1}{2k^2} \lim bc \sin A$$
$$= \frac{1}{2k^2} \lim a \overline{AA'}.$$

Pag. 178 – theorem 5.

The area of a convex polygon is the quotient of the excess of the sum of its angles over $(n-2)\pi$ divided by the measure of curvature of space.

Let the reader show that the area of a proper circle is

$$2\pi k^2 \left(1 - \cos \frac{r}{k}\right) \quad (17)$$

The total areas of the elliptic and the spherical planes will be

$$2\pi k^2, \; 4\pi k^2.$$

In the hyperbolic plane regions may be found having any desired area.

Pág. 175 → Theorem 3

The area of a region of a plane is the sum of the areas of any two regions into which it may be divided provided that these two have no common area.

Pág. 177 – Area = $k^2(A+B+C-\pi)$ (16)

Euclidean Geometry and Non-Euclidean Geometry

Pág.03(15)-Fig.1.1.
On the axiom of parallelism of straight lines.

Pág.02(14)-1.1. Euclidean Geometry
the basis of Euclid's geometry is five postulates (axioms that do not require proof):

5. If a straight line meets two other straight lines in such a way that on one-sided they form two internal one-sided corners, in total less than two right angles, then these straight lines, if continued

indefinitely, will intersect on the side from which the one-sided corners are less than two right angles.

From the fifth postulate it follows that if there are two parallel lines, i.e., the straight line intersecting them forms two inner one-sided angles to the sum of two straight lines, then these parallel straight lines will not intersect no matter how much they continue.

Euclidean geometry, according to which space is infinite, homogeneous, isotropic and three-dimensional, became the basis of classical physics.

However, the fifth postulate of parallel straight lines has been in doubt since the 19th century. It is easy to make such a construction (Figure 1.1). We will draw two parallel lines, and also in the plane of these lines we will draw a circle C of an arbitrary radius centered at point A between these lines so that the circle does not intersect straight lines.

→

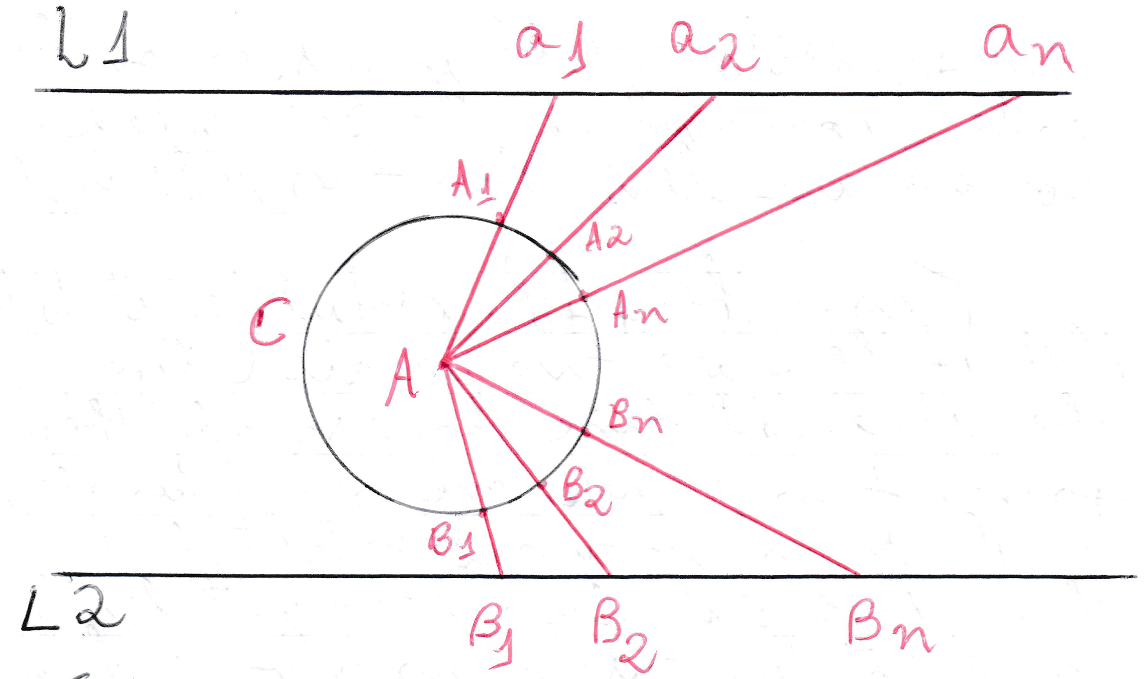

Figure 1.1 On the axiom of parallelism of straight lines.

We will successively decrease the angles of inclination of the rays to zero in both sets of rays. In this case, the points α_n and β_n will move along straight lines L_1 and L_2 right to infinity.

The images of these points A_n and B_n on the circle C will approach each other as closely as you like. At a zero angle of inclination of the rays, the point A_n will coincide with the point B_n. Since there is a one-to-one correspondence between the points α_n and A_n, as well as between the points β_n and B_n, the alignment of the points A_n and

β_n will mean the alignment of the points α_n and β_n, that is parallel lines L_1 and L_2 intersect at infinity.

The inconclusiveness of the postulate of parallel lines led to the construction of geometries as a whole on the basis of concepts and axioms that relate only to the immediate vicinity of each point. So, the possibility arose of creating geometries based on differential geometry (Hilbert, Cohn-Vossen, 1932).

20231122-Non-Euclidean Geometry in Materials of Living and Non-Living Matter-2022.pdf

Pág. 04(16)- 1.2.

Non-Euclidean Hyperbolic Geometry.

In non-Euclidean geometry postulate 5 of the Euclidean system of postulates is replaced by the axiom:

Through a point that does not lie on a given straight line there are at least two straight lines that lie with this straight line in one plane and do not intersect it. this is Lobachevsky's axiom (Lobachevsky, 1829, 1835).

According to this axiom, on the plane through the point P, which lies outside the straight-line A' A, more than one straight line (Figure 1.2) does not intersect the straight-line A'A.

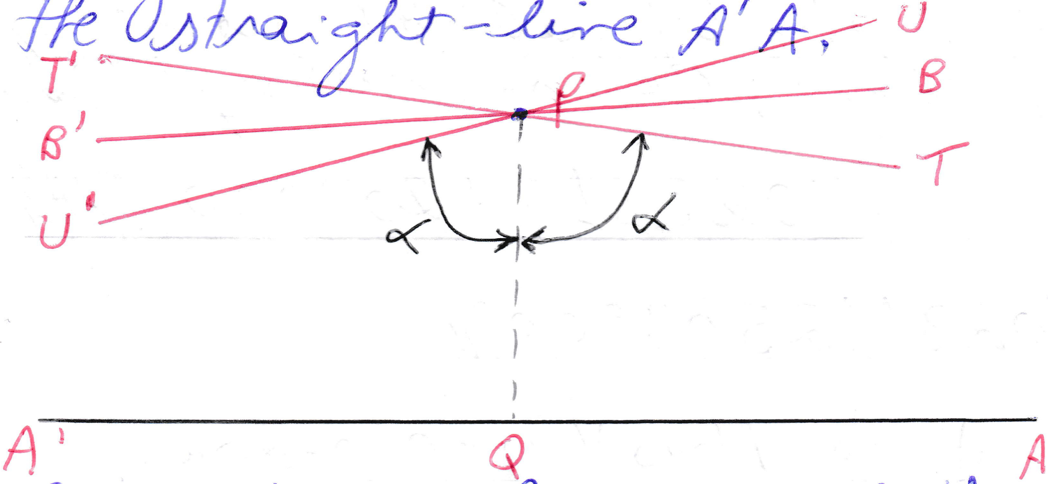

Figure 1.2. – Lines passing through a point in non-Euclidean geometry.

Non-intersecting straight lines fill the part of the beam with apex P lying inside the vertical angles TPU and U'PT' located symmetrically relative to the perpendicular PQ!

The straight lines forming the sides of the vertical corners separate the intersecting straight lines from the non-intersecting straight lines and are themselves intersecting straight lines. These boundary lines are called parallel at point P to line A'A, respectively, in its two directions: T'T parallel to A'A in the direction of A'A and U'U parallel to A'A in the direction of A'A. The rest of the non-intersecting lines are called lines diverging from A'A.

The angle α $(0 < \alpha < \pi/2)$, that the parallel to the point P forms with the perpendicular PQ,

$$\boxed{\measuredangle QPT = \angle QPU' = \alpha}$$

is called the angle of parallelism of the segment $PQ = a$ and is denote by $\alpha = \Pi(a)$. When $a=0$ the angle $\alpha = \pi/2$; with increasing a angle α decreases so that for each given α there is a certain value of a. This dependence is called the Lobachevsky function

$$\Pi(a) = 2 \operatorname{arctg}(e^{-a/K}), \quad (1.1)$$

where K is some constant that determines a segment fixed in magnitude. It is called the radius of curvature of the Lobachevsky space.

There is an infinite number of Lobachevsky spaces, differing in the size of JK.

The model of the Lobachevsky plane can be a surface with constant negative curvature.

The simplest example of such a surface would be the pseudosphere (Figure 1.3) (Beltrami, 1868).

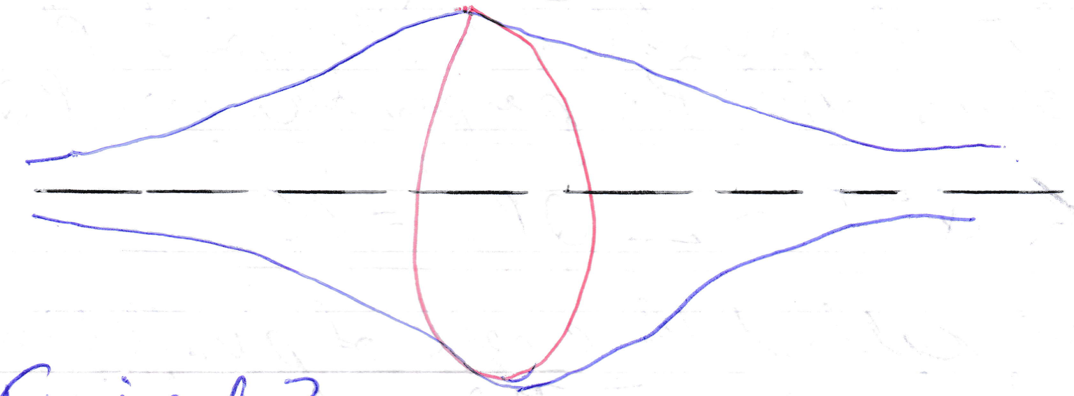

Figure 1.3. Pseudosphere.

There are also other models of Lobachevsky geometry (Klein, 1928).

Pág. 05 (17) — 1.3

Non-Euclidean Eleptical Geometry.

The fact that the sphere is the

spatial form of elliptic geometry is seen directly, since the curvature of a sphere of Radius R in all such cases is equal to $1/R^2$, that is, it is positive and constant.

It can be shown that a metric of constant curvature $K > 0$ can also be introduced on the projective plane. Consider some plane α of Euclidean space and some sphere C. Let the plane of Euclidean space be located horizontally, and the sphere is above the plane.

Let O be the center of the sphere. Obviously, each point of the sphere, if it does not lie on the equator, is projected from the center O to a certain point of the plane α. Diametrically opposite points of the sphere are projected at the same point. The points lying on the equator have no projections. Supplement the plane α with infinitely distant points and introduce a system of neighborhoods into the set of all points of the extended plane. Then we get a projective plane, which we will denote by $\bar{\alpha}$.

Let us agree to say that the horizontal line a passing through the point O intersects the projective plane $\bar{\alpha}$ at an infinitely distant point lying on any of the straight lines in the Euclidean plane α parallel to the line a. Under this condition, each point of the sphere is projected from the center O to a certain point of the projective plane $\bar{\alpha}$, and each point on $\bar{\alpha}$ is the projection of two diametrically opposite points of the sphere.

Let us now introduce geographic coordinates on sphere $\odot$. On the projective plane, the coordinates of some point M will be considered numbers equal to the geographical coordinates of that point of the sphere, which has its projection point M. Since each point of the projective plane is the projection of two opposite points of the sphere, then each point of the projective plane, along with coordinates, also has coordinates. Now, in each neighborhood of a point on the projective plane, we introduce the metric form

$$dS^2 = R^2(\cos^2\psi\, d\varphi^2 + d\psi). \quad (1.2)$$

In this case, the matrix shape of the sphere is written in the form (Efimov, 1945).

$$dS^2 = \cos^2(K^{1/2} v)\, d^2 u + d^2 v \quad (1.3)$$

→

To reduce expression (1.2) to expression (1.3), it is sufficient to set

$$\varphi = K^{1/2} u, \psi^{1/2} v$$

and take into account the relationship between the curvature and the radius of the sphere

$$K = 1/R^2.$$

The geometric system of the metrized projective plane α is called Riemannian non-Euclidean geometry.

In the (the) geometric system of the metrized projective plane α (elliptic plane), any two points define one and only one geodesic line passing through them.

Every two lines have a common point. An elliptical plane has no parallel lines. In an elliptical plane (Riemann geometry), every line intersects another.

The well-known objects of two-dimensional differential geometry can be generalized into multidimensional geometry (Efimov, 1945; Cartan, 2009).

Riemann introduced the concept of an n-extended quantity and defined a measure definition that is possible on an n-dimensional manifold

$$dS^2 = \sum g_{ik}\, dx_i \cdot dx_k,$$ where

the coefficients in front of the product of the differentials of the variables are functions of coordinates.

Pág. 07(19)- 1.4.

Non-Euclidean Geometry of the Higher Dimension Polytopes!

Riemann pointed out the contours of geometric figures as one of the examples of the n-extended value.

The space of these figures, therefore, has dimension n and is limited, i.e., certainly.

The condition for space to be finite is one of the basic conditions in Riemann geometry.

However, the curvature of space will be zero if the planar (two-dimensional) elements of the figure have zero curvature. Thus, there is no need to use the apparatus of differential geometry. Due to the finiteness of the higher-dimensional polytope and the presence of the polytope contour (i.e., the boundary), the higher-dimensional polytope space is closed. Therefore, the system of axioms of n-dimensional Euclidean space, extended from the system of axioms of three-dimensional Euclidean space, cannot be applied to the polytope space of higher dimension. In particular, line segments located inside the higher-dimensional polytope cannot be extended outside the higher-dimensional polytope. The space of a polytope of the highest dimension has a special structure that determines the conditions for the belonging of elements of different dimensions to each other, as will be shown in the next chapter. Therefore, the conditions for membership of elements of different dimensions adopted in the system of axioms of n-dimensional Euclidean geometry, are not fulfilled in the polytope of the highest dimension.

In this regard, it should be recognized that the geometry of the space of polytopes of the highest dimension is not Euclidean.

Conclusion:

This non-Euclidean geometry is not related to the curvature of space and therefore cannot be attributed to either hyperbolic or elliptical non-Euclidean geometries.

$$\frac{2\pi}{\pi-\gamma} = \frac{2\pi R}{l},$$

R is radius of the circle, and l is length of the segment centers of tetrahedrons.

From the last equality can find the radius of the circle

$$R = \frac{l}{\pi-\gamma}.$$

From Figure 8.22 and Figure 8.24 it follows that $l = 3a + 2d$. Subject to the accepted values a and d can get

$$R = \frac{0.81}{\pi-\gamma} \text{ nm}.$$

For example, in case $\gamma = 140°$ is $R = 1.6$ nm.

Obs. This radius value is close to the experimental helix radius of nucleic acid measured by Watson and Crick.

b) 20231122 - Sochi - General Relativity Simplified - (2020).pdf

Pag. 22 (23) -

A space (ust) is flat if it is possible to find a coordinate system for the space with a diagonal metric tensor whose all diagonal elements are ±1; otherwise the space is curved.

More formally, an nD space is flat if it is possible to find a coordinate system in which the quadratic form $(ds)^2$ is given by:

$$(ds)^2 = \sum_{i=1}^{n} \varepsilon_i (dx^i)^2 \qquad (2).$$

where the indexed ε are ±1 while the indexed x are the coordinates of the space.

Geodesic curve is the most "straight" or most "direct" route connecting two points in a given space.

Geodesic curves are normally, but not necessarily, the curves of shortest length.

Interessante : NULL GEODESIC.

Null geodesic is the geodesic path that is followed by a light signal (or any massless object to be more general) in the spacetime (assuming the signal is not under non-gravitational influence). The line element $d\sigma$ (and hence the spacetime interval σ) vanishes identically along null geodesic and that is why it is "null".

Pág. 290(291) – Figure 7.

A simple graphical illustration of the precession of perihelion PP where P_1, P_2, P_3 represent successive perihelia. We note that the indicated precession can have various causes (and hence we use PP instead of $\delta\phi$).

8.2 Light Bending by Gravity.

Light bending (or light deflection) by the gravitational field of a gravitating body like the Sun, is one of the major predictions of general relativity because according to this theory the bending of spacetime by matter and energy should result in bending the geodesic paths of the spacetime and hence the physical objects, whether (se) massive like material particles or massless like photons, which follow these geodesic paths in their free fall (i.e. in the absence of forces other than gravity) should move along curved trajectories.

Analizar.

The bending of light in gravitational fields may also be justified qualitatively by the equivalence principle since light bends in accelerating frames and hence it should also bend in gravitational frames. (frames).

In fact, light bending by gravity can be derived even (mesmo) from the Newtonian theory and hence it is not an effect that is specific to general relativity.

However, the Newtonian prediction is quantitatively different from the prediction of general relativity.[368]

[368] ⇒ commonly recognized Newton prediction which is based on derivation. However, some theories based on the Newtonian gravity seem

to have diffent predictions;

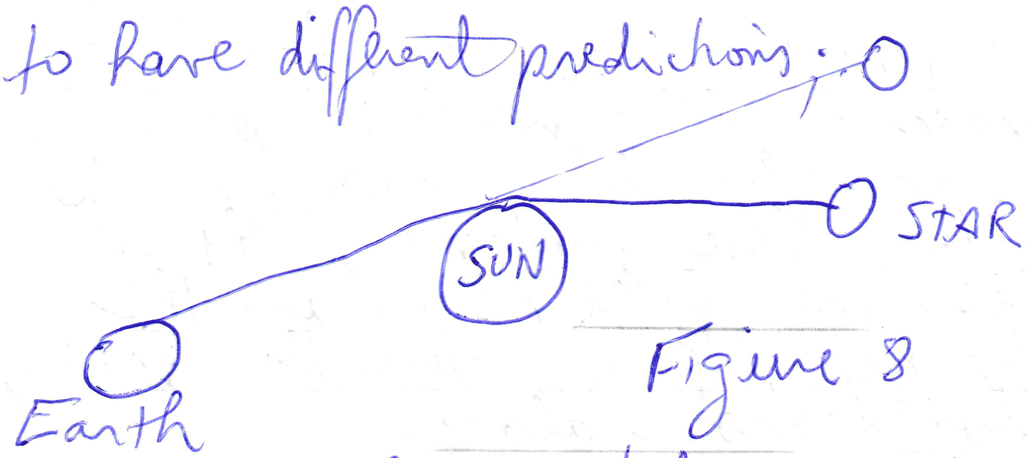

Figure 8

A simple sketch depicting the bending of a light ray from a star as it passes by the Sun toward (in direction) to the Earth and hence it is deflected by the gravity of the Sun.

Using the geodesic equations of null geodesic in the Schwarzschild metric, it can be shown that the deflection of light by the gravity of a static and spherically symmetric gravitating body is a given

$$\delta \phi = \frac{4GM}{c^2 d} \qquad (323)$$

where $\delta\phi$ is the angle of deflection in radians,
G is the gravitational constant,
M is the mass of the gravitating body,
c is the characteristic speed of light and

d is the distance of closest approach of light to the center of the gravitating body.

Pág. 291(292) - Problems

1. The problem of light bending is a problem of motion along geodesic trajectories in spacetime because the light is in free fall (?) under the influence of gravity alone.

Therefore, this problem should be investigated as a geodesic problem in the Schwarzschild metric and hence we can use the results that we obtained in § 4.1.2.

Obs: § 4.1.2. Pág 215(216) →

Geodesic Equation in Schwarzschild Metric.

→ using the Christoffel symbols (§ 4.1.1).

Obs: Pág. 212 (213) - Schwarzschild radius?

Schwarzschild radius (which may also be called gravitational radius and is usually associated with black holes although (embora) it is not specific to them) is the distance from the center of the gravitating object to the points of space where the escape speed is equal to the characteristic speed of light c (assuming that the mass of the object is confined to the region within the Schwarzschild radius).

We should note that this definition is essentially classical. In fact, the general relativistic definition of the Schwarzschild radius is obtained from the Schwarzschild metric and the singularity at

$r = \frac{2GM}{c^2}$ (or by comparing the classical and general relativistic formulations in the classical limit, as will be discussed in §5.1). Anyway, the classical and relativistic definitions are equivalent although the interpretation of r may differ (see §6.2).

The Linearized Field Equation

We investigate the linearized form of the Field Equation which is used as a good approximation to the full (non-linear) Field Equation in the case of weak gravitational fields where the spacetime is pseudo- or quasi-Minkowskian and hence it deviates slightly form the flat geometry of the authentic Minkowskian spacetime.[241]

[241] → In fact, gravity in the weak field regime can be seen as a minor curvature in spacetime and as a Lorentzian field in a flat Minkowskian spacetime.

From the latter perpective, it is like electromagnetism in special relativity.

Important:

A linearização desta equação não é desejável em virtude da própria realidade das forças fundamentais da física que regem o Universo e a utilização "flat Minkowskian spacetime" gera erros que se propagam em todos os cálculos matemáticos envolvidos no perfeito entendimento dos mecanismos que regem o sistema em questão.

obs: Pág. 164(165) ->

11. What is the significance of the fact the divergence of the energy-momentum tensor is zero?

Also link this to the vanishing of the divergence of the Einstein tensor!

Answer:

Let first see what is the significance of the divergence of a rank-1 tensor (i.e. vector) field in 3D space. The divergence of a vector field is a measure for the spatial rate at which a certain quantity (e.g. mass) "diverges" or "converges" in the space.

So if we have a source or sink for that quantity in the concerned region of space then the divergence is non-vanishing because the quantity diverges or converges due to the positive or negative supply by the source or sink. Otherwise, the divergence should vanish because there is no supply. So, at the root of the divergence (or rather divergence-free) is the concept of conservation or the denial of creation and annihilation since each diverging quantity from a certain location in space should come from a source and each converging quantity to a certain location in space should go to some sink.

On generalizing this idea and applying it to energy-momentum tensor in 4D spacetime, we can see that the vanishing of the divergence of the energy-momentum tensor originates from the conservation of energy and momentum, as we concluded in a rather different way earlier.

Pág. 165(166) - the link of this to the vanishing of the divergence of the Einstein tensor should be obvious because the divergence-free nature of the Einstein tensor

(see §. 2.13)

~~off~~ : IMPORTANT:

Pág. 72(73) - 2.1 Space, Coordinate System and Transformation

A space is descri as Euclidean when it can be coordinated by a Cartesian coordinate system[100] and

see (?)

[100] - this is equivalent to the condition that there is a permissible coordinate transformation that takes the general quadratic form

$$(ds)^2 = g_{ij}\, dx^i\, dx^j$$

of the space to the Cartesian quadratic form

$$(ds)^2 = \sum_{i=1}^{n} (dx^i)^2 .$$

In other words, there is a permissible coordinate transformation that takes the metric tensor g_{ij} to the Kronecker delta tensor δ_{ij}.

Return: Pág. 72(73)

[100] ...and described as flat when it can be coordinated by a Cartesian or quasi-Cartesian system.

If the space cannot be coordinated by a Cartesian or quasi-Cartesian system it is described as curved.

A Riemannian space is a space characterized by having a symmetric rank-2 tensor called the metric tensor that represents the geometry of the space.

Riemannian space may ~~also~~ may also be characterized (and hence restricted) by the condition that it is possible to construct a locally Cartesian coordinate system at any of its points, i.e. it is locally Euclidean or flat! [101]

[101] → We note that there are some abstract metric spaces which are not Euclidean or flat

even locally and accordingly they are not Riemannian.

Riemannian space may similarly be characterized by having a line element ds whose square is defined by the quadratic form

$(ds)^2 = g_{ij} dx^i dx^j$ where

g_{ij} is the metric tensor,

dx^i and dx^j are coordinate differentials and

i and j range over the space dimensions.[102]

[102] ⇒ To be more clear, $(ds)^2$ is the square of the line element ds while $g_{ij} dx^i dx^j$ is the quadratic from (since it is quadratic in dx) althrough (embora) it is common to call $(ds)^2$ the quadratic form (referring to its mathematical expression $g_{ij} dx^i dx^j$).

Conventionally, the quadratic form (which is based on the metric tensor) of Riemannian space is positive definite. Hence, a space whose characteristics are similar to the characteristics of Riemannian space but its quadratic form is not positive definite (i.e. it is Riemannian apart (from) from this mathematical nicety) is commonly known as pseudo- or quasi- Riemannian.

As indicated earlier physicists generally do not discriminate between Riemannian and pseudo-Riemannian and hence both might be described as Riemannian.

Return: Pág. 165(166) →

see (§ 2.13) →

The divergence-free nature of the Einstein tensor (see § 2.13) means that the curvature of spacetime is "conserved" in some sense and hence it can only be generated from a source of "energy-momentum".

In fact, this link between the curvature of spacetime (as represented by the Einstein tensor) and the energy-momentum (as represented by the energy-momentum tensor) is embedded in the Field Equation which correlates the Einstein tensor to the energy-momentum tensor (and hence it correlates the divergence-free nature of the curvature to the divergence-free nature of the energy-momentum, as we will see in § 3).[221]

[221] → In fact, this is the essence of the general relativistic paradigm that the energy-momentum is the physical source of the geometric curvature which represents the gravity.

Pag. 165 (166) – 12.

Make a comparison between the Einstein tensor G and the energy-momentum tensor T.

→ We note the following:

a) Both G and T are rank-2 symmetric tensors in 4D spacetime and hence each has 16 components 10 of which are independent;

b) the divergence of both tensors is zero;

c) G and T are proportional to each other according to the Field Equations (see § 3.2);

d) G is geometric while T is physical and

e) the physical dimensions of G are reciprocal area while the physical dimensions of T are energy density.

Return : Pag. 292(293)

In fact, all we need from that system is Eq. 182 because the essence of light bending is represented by a correlation between

$r = 1/u$ and ϕ (i.e. how ϕ changes r changes) and that is what Eq. 182 is about. So, our investigation here starts from Eq. 182, that is:

$$\frac{d^2u}{d\phi^2} + u = \frac{3GMu^2}{c^2} \qquad (324)$$

In brief, what we need for finding a formula for light bending by gravity is to solve Eq. 324 and hence infer the angular deflection in the path of light that is caused by the gravitational field of the star. Now if we consider a light ray grazing a typical star that represents a gravitating object then we have

$u \gg \frac{3GMu^2}{c^2}$. This can be

verified by taking the ratio of $\frac{3GMu^2}{c^2}$ to u and using the Sun to represent the typical star, that is:

$$\frac{3GMu^2}{c^2 u} = \frac{3GMu}{c^2} = \frac{3GM}{c^2 r} \simeq$$

$$\frac{3 \times 6.674 \times 10^{-11} \times 1.989 \times 10^{30}}{(3 \times 10^8)^2 \times 6.9551 \times 10^8} \simeq$$

$$6.362 \times 10^{-6}$$

where r represents the radius of the Sun since the ray is grazing (in fact r should be radial coordinate).

Therefore, as a first approximation the term

$\frac{3GMu^2}{c^2}$ can be ignored in solving Eq. 324 and hence we solve the equation

$$\frac{d^2u}{d\phi} + u = 0 \text{ instead.}$$

The solution of the latter equation is

$$\mu = \frac{1}{r} = \frac{\cos\phi}{d} \quad \left(-\frac{\pi}{2} < \phi < \frac{\pi}{2}\right) \quad (325)$$

Where d is a constant.

As we will see, d represents the distance of closest approach of the light ray to the center of gravitating object and hence in the case of grazing ray it represents the radius (or radial coordinate) of the gravitating star.

We should note that the solution can also be given as $\boxed{\mu = \frac{\sin\phi}{d}}$ with $0 < \phi < \pi$.

In fact, for a polar coordinate system in a standard form (i.e. where ϕ is the angle that r or makes with the positive x axis of the corresponding Cartesian system) $\boxed{\mu = \frac{\cos\phi}{d}}$ ✡ represents a straight line parallel to the y-axis and intercepting the x axis at d (see Figure 9) while

$\boxed{\mu = \frac{\sin\phi}{d}}$ ✡ represents a straight line parallel to the x-axis and intercepting the y axis at d.

Linear transformations of Euclidean Space

Pág. 338(339) - §10 - the curvature and torsion of a space curve.

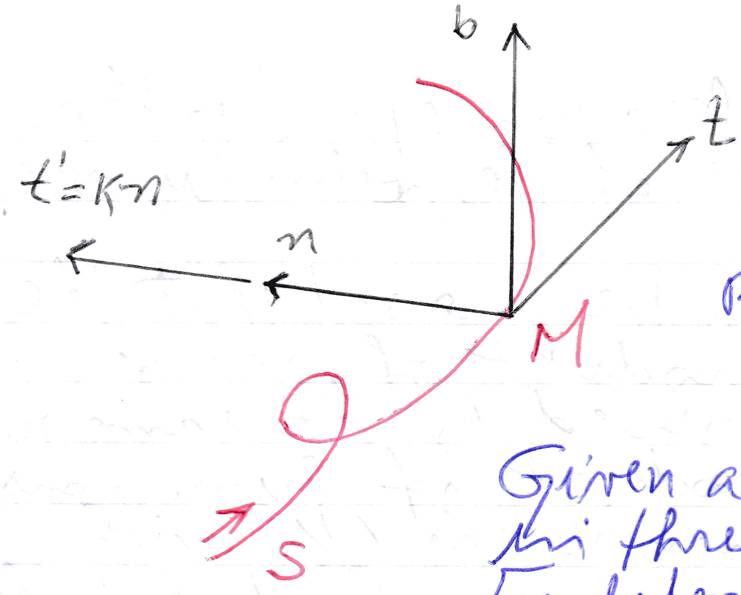

Fig. 63

Given a curve S in three-dimensional Euclidean space.

We assume that S is the path of a point M moving with unit velocity, that is to say, during unit time it traverses an arc of S whose length is equal to unity.

Under this condition, the time spent is numerically to the length of the path traversed.

Denote the length by s and view it as an independent argument.

Denote by t the vector of instantaneous velocity of M.

We can consider it to be a unit vector:

$$(t, t) = 1 \quad (1)$$

It lies along a tangent to the curve S in the direction of motion and is called the tangent vector.

If the line is not straight, then t changes its direction in space. Therefore, the point M experiences an acceleration equal to the derivative of the velocity vector, or t'_s.

It can be proved that the scalar product of vectors is differentiated by the same rule as a product of functions.

Differentiating (1) with respect to s, we find that the acceleration is orthogonal to the velocity:

$$(t, t)'_s = 2(t, t'_s) = 0$$

Putting $\kappa(s) = |t'_s|$ and assuming that $\kappa(s) \neq 0$ we introduce the unit vector n which is coincident in direction with t'_s (Fig. 63). Then

$$t'_s = \kappa n \qquad (2)$$

κ is called the curvature of the curve at the given point M.

By definition, $\kappa \geqslant 0$.

Vector n is called the principal normal vector, while the plane passing through M parallel to vector t and n is termed the osculating plane of the space curve S at the point M.

Let us construct the unit vector

$$b = [t \times n].$$

It is perpendicular to the osculating plane and is called the binormal vector at the point M (Fig. 63).

Cálculo de la distancia entre dos puntos en el plano de Lobachevski

Pág. 438(439) - Fig. 159.

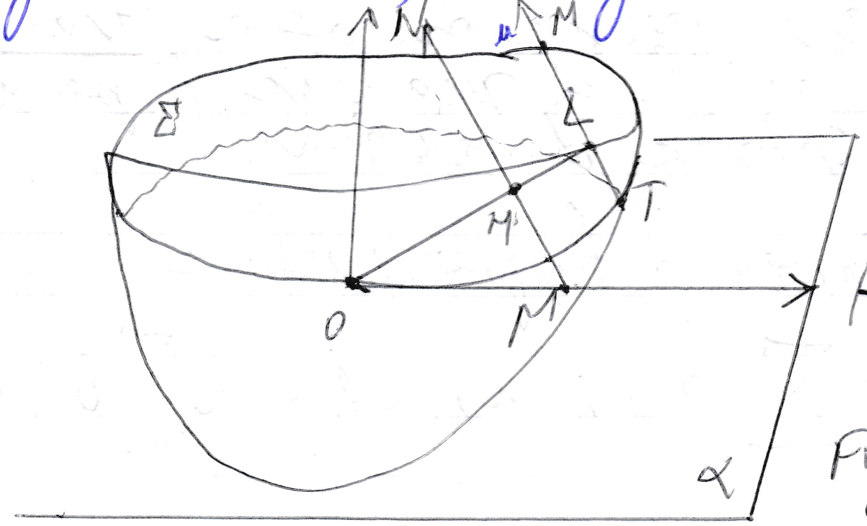

Fig. 159

orisfera Σ' (es la geometria de Euclides (947).

Un punto arbitrario M del plano α te corresponda ~~a~~ un punto M' de la oriesfera Σ', en el cual ésta se interseca con la recta que pasa por M paralelamente a la perpendicular trazada a α en el punto O (fig. 159; la dirección de paralelismo se supone establecida hacia el mismo sentido desde el plano α en que está situada la orisfera Σ').

Fácilmente se comprende que las imágenes de todos os puntos del plano α no llenan la orisfera Σ por completo.

(llenan - preencher)

En el plano α consideremos alguna recta OA que pase por el punto O; sea ON la perpendicular al plano α en el punto O (el punto N se encuentra en el mismo lado respecto a α que la orisfera Σ').

En la bisectriz del ángulo AON, tracemos un segmento l de modo que le corresponde un ángulo de paralelismo

$\Pi(l) = \frac{\pi}{4}$; denotemos con la letra L el extremo de dicho segmento.

Debido a la elección de la magnitud de l, la recta u perpendicular al segmento OL en su extremo L y perteneciente al plano del ángulo AON, será paralela con respecto al rayo OA hacia un lado, y lo será con respecto al ON hacia el otro (fig. 159). Como la recta u es paralela a ON, es el eje de la oriesfera Σ y, por consiguiente, interseca Σ en cierto punto T.

Ahora, en el rayo OA tomemos un punto arbitrario M (distinto al O), trazando a través de él un rayo paralelo con respecto a ON. Este rayo pasa por el plano AON entre las rectas paralelas TL y ON. Por consiguiente, el punto M', en el cual el mismo atraviesa el oriciclo OT, se halla entre los puntos O y T. Por otro lado, si tomamos un punto cualquiera P' en el oriciclo OT entre O y T, trazando a través del mismo una recta paralela a la ON desde O hacia N, aquélla será paralela a la recta u en la misma dirección; en la otra dirección, esta recta se desviará de la recta u hacia el rayo OA, intersecándolo en un punto P. Esto significa que cada punto del oricirclo OT que se encuentre entre O y T es la imagen de un cierto punto perteneciente al rayo OA.

Por fin, queda claro que el punto O corresponde a sí mismo.

Así pues, las imágenes de todos los puntos del rayo OA llenam el arco del oricirclo OT con un extremo excluido T.

De aquí concluimos directamente que las imágenes de todos los puntos del plano Λ llenan sobre la orisfera Σ un dominio "cubierto" por el arco OT (con el extremo T excluido) al girar éste alrededor de la recta ON.

Desde el punto de vista de la geometría sobre la orisfera este dominio constituye nada más que el recinto interior del círculo K, cuyo centro es el punto O y cuyo radio es el arco del oricirclo OT. El arco OT se llama radio de curvatura del espacio de

Lobachevski. Si elegimos algún arco del oriciclo por concepto de la unidad de medida de las longitudes sobre la orisfera Σ, entonces la longitud del arco OT se expresará por un cierto número R. El número R (con la escala elegida) lo llamaremos también radio de curvatura.

Pág. 439(440)- si x es cualquier segmento que se halla dentro de E, el ángulo del paralelismo $\Pi(x)$ tiende uniformemente a $\frac{\pi}{2}$ para $R \to \infty$ (véase el § 230) (Pág. 476(477)).

En el caso límite de $R=\infty$ el círculo K se extiende sobre toda la orisfera Σ, pero entonces la orisfera Σ coincide con el plano α, resultando euclidiano el espacio.

... $x'^2 + y'^2 = R$.

Sistema de coordenadas sobre el plano de Lobachevski α. Esto es, con cada punto M del plano α compararemos, por concepto de coordenadas, dos números

$\Longrightarrow$

$$x = \frac{x'}{R}, \quad y = \frac{y'}{R},$$

donde x' y' son las coordenadas cartesianas de la imagen M' del referido punto sobre la esfera Σ.

De lo antecedente se deduce que las coordenadas de cualquier punto del plano α satisfacen la desigualdad

$$x^2+y^2<1;$$

recíprocamente, si dos números x, y dados con anterioridad satisfacen tal desigualdad, entonces sobre el plano α existe un punto (exactamente uno), cuyas coordenadas son los mismos números x, y dados.

Los números x, y se llaman coordenadas beltramianas del punto M.

Hoje é o dia do aniversário da minha querida Mãe Leda. Estou com muita saudades de você e um dia nos encontraremos no reino celeste junto de Deus Todo-Poderoso, Misericordioso, Piedoso e infinitos ósos. Amém!!!

Pág. 292 (293) – However, we can seek a better solution by substituting this approximate solution into the u^2 term of Eq. 324, that is

$$\frac{d^2u}{d\phi^2}+u=\frac{3GM\cos^2\phi}{c^2d^2}$$

It can be easily verified that a solution of the last equation is:

$$u=\frac{\cos\phi}{d}+\frac{GM(2-\cos^2\phi)}{c^2d^2}$$

Now, to find the total deflection of the light ray during its journey from infinity (i.e. $r\rightarrow\infty$) on one end (to) (de um lado) to infinity on the other end (i.e. from $u=0$ at the source of light to $u=0$ at the detector of light), we set $u=0$ in the last equation and

find the difference between ϕ at one end and ϕ at the other end, that is:

$$\frac{\cos\phi}{d} + \frac{GM(2-\cos^2\phi)}{c^2d^2} = 0$$

$$\frac{\cos\phi}{d} + \frac{2GM}{c^2d^2} - \frac{GM\cos^2\phi}{c^2d^2} = 0$$

$$\frac{GM}{c^2d}\cos^2\phi - \cos\phi - \frac{2GM}{c^2d} = 0 \qquad (326)$$

Pag. 293(294) →

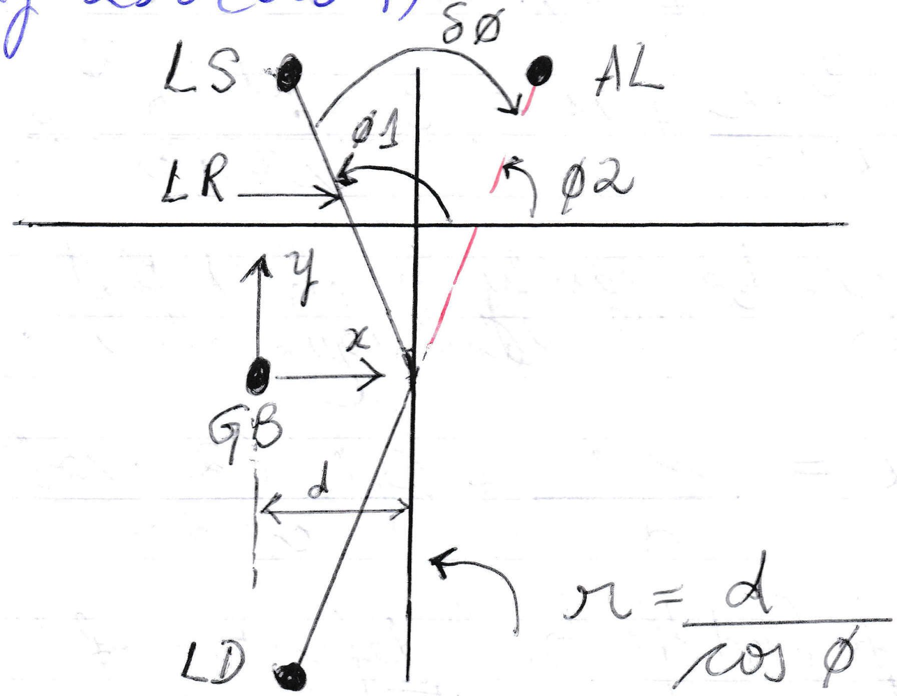

Figure 9: A simple sketch depicting the deflection of a light ray emitted from a light source LS as the ray passes by a gravitating body GB (which is at the origin of

coordinates) toward a light detector LD and hence the light ray is deflected by an angle $\delta\phi$ causing the image of LS to be visually displaced and thus it is seen at an apparent location AL. The other symbols in the sketch are explained in the text.

Now, if we note that $\frac{GM}{c^2 d}\cos^2\phi$ is very small for a light ray grazing a typical star then we can ignore this term ✡

Obs: Wrong!!!

Aqui está o problema, nós devemos observar que este "pequeno" ajuste ou um certo tipo de arredondamento ou cancelamento prejudica todo o cálculo pois esta ação gera um efeito em cadeia nos cálculos. O mais grave, é que este falso ajuste gera um erro de cálculo na obtenção do valor do Pi, agora com o meu ajuste, nós obtemos M.U.S. (Mathematical Uniforme Space)

Nós não podemos admitir qualquer ajuste ou omissão de qualquer valor no cálculo desta equação.

Return:

We can...

$\frac{GM}{c^2 d} \cos^2\phi$ is very small for a light ray.

$G = 6.674 \times 10^{-11}$

$M = 1.989 \times 10^{30}$

$c = 3 \times 10^{8}$

$r = 6.9551 \times 10^{8}$

obs:

$$u = \frac{1}{r} = \frac{\cos\phi}{d} \quad \left(-\frac{\pi}{2} < \phi < \frac{\pi}{2}\right)$$

off:

$d = 6.9551 \times 10^{8}$

IMPORTANT:

Calcular o valor correto

$$\frac{GM}{c^2 d} \cos\phi$$

Obs: Utilizar no M.U.S.

Return: We can ignore this term (Wrong !!!) ?
↙
and hence we get an approximate equation:

$$-\cos\phi - \frac{2GM}{c^2 d} \simeq 0$$

whose solution is:

$$\cos\phi \simeq -\frac{2GM}{c^2 d} \qquad (327)$$

and hence:

$$\phi_1 \simeq \frac{\pi}{2} + \frac{2GM}{c^2 d} \quad \text{and} \quad \phi_2 \simeq \frac{\pi}{2} - \frac{2GM}{c^2 d} \qquad (328)$$

These two possible values of ϕ correspond to the two ends of the light ray (i.e. source of light at infinity on one end and detector of light at infinity on the other end). In fact, the value

$$\phi_2 \simeq \frac{\pi}{2} - \frac{2GM}{c^2 d}$$ corresponds to

$$\phi \simeq -\frac{\pi}{2} - \frac{2GM}{c^2 d}$$ or similarly to

$$\phi \simeq \frac{3\pi}{2} - \frac{2GM}{c^2 d}$$ (see Figure 9)

and that is why it does not give the correct sign.

More justification is given in the upcoming note 2 in the end of this answer. # (see)

Now, if we take the difference between ϕ at infinity on one end where the light source is located and ϕ at infinity on the other end where the light detector is located (see Figure 9) then we get the total deflection, that is:

$$\delta\phi = \phi_1 - \phi_2$$

$$\simeq \frac{\pi}{2} + \frac{2GM}{c^2 d} - \left(\frac{\pi}{2} - \frac{2GM}{c^2 d}\right) = \frac{4GM}{c^2 d}$$

which is the general relativistic formula that is given in the text (see Eq. 323).

Note 1 : the reader may feel uncomfortable about the last approximation where we discarded the term

$$\frac{GM}{c^2 d}\cos^2\phi .$$

So, we show in this note

that this approximation is very good. Eq. 326 (which can be written as

$$GM\cos^2\phi - c^2 d\cos\phi - 2GM = 0)$$

is a quadratic equation in $\cos\phi$ and hence from the quadratic formula we get:

$$\cos\phi = \frac{c^2 d \pm \sqrt{c^4 d^2 + 8G^2M^2}}{2GM} \qquad (329)$$

It is obvious that the root with plus sign is unacceptable because it is too large hence it should be rejected since

$$-1 \le \cos\phi \le +1.$$

Now, if we consider a grazing light ray and use the Sun as a typical star then from the approximate root (i.e. Eq. 327) we get:

$$\cos\phi \simeq -\frac{2GM}{c^2 d} \simeq$$

$$\frac{2 \times 6.674 \times 10^{-11} \times 1.989 \times 10^{30}}{(3\times10^8)^2 \times 6.9551 \times 10^8} \simeq$$

→

$$\simeq -4.2413596 \times 10^{-6}$$

while from the exact root (i.e. Eq. 329 with the minus sign), we get:

$$\cos\phi = \frac{c^2 d - \sqrt{c^4 d^2 + 8G^2 M^2}}{2GM} \simeq$$

$$\simeq 4.2413599 \times 10^{-6}$$

As we see, the approximate root is virtually identical to the exact root.

Note 2: the transition from Eq. 327 to Eq. 328 may not be obvious.

However, we should note first that we have two different solutions because the original equation is quadratic and although (embora) we already rejected one root on mathematical basis we should admit the existence of two physical roots. In fact, we can demonstrate formally that ϕ_1 and ϕ_2 of Eq. 328 are the principal solutions, but instead we can follow a simpler approach by using the trigonometric identity $\cos(\alpha \pm \beta) =$

trigonometric identity

$$\cos(\alpha \pm \beta) = \cos\alpha \cos\beta \pm \sin\alpha \sin\beta$$

With the sine approximation of small angle (i.e. $\sin\beta \simeq \beta$) to conclude that ϕ_1 and ϕ_2 in Eq. 328 produce Eq. 327 (and hence ϕ_1 and ϕ_2 are solutions to Eq. 327), that is:

$$\boxed{\cos\phi_1} = \cos\left(\frac{\pi}{2} + \frac{2GM}{c^2 d}\right) =$$

$$\cos\frac{\pi}{2}\cos\frac{2GM}{c^2 d} - \sin\frac{\pi}{2}\sin\frac{2GM}{c^2 d}$$

$$\simeq -\frac{2GM}{c^2 d}$$

$$\boxed{\cos\phi_2} = \cos\left(\frac{3\pi}{2} - \frac{2GM}{c^2 d}\right) =$$

$$\cos\frac{3\pi}{2}\cos\frac{2GM}{c^2 d} + \sin\frac{3\pi}{2}\sin\frac{2GM}{c^2 d}$$

$$\simeq \frac{2GM}{c^2 d}$$

where we used the aforementioned alternative expression for ϕ_2 (to obtain the correct sign) and where the smallness of $\frac{GM}{c^2 d}$

(and hence $\frac{2GM}{c^2 d}$ is justified in exercise 7.

Note 3 : the provision

$$\boxed{u \gg \frac{3GMu^2}{c^2}}$$

can be justified more generally by the following:

$$\frac{3GMu^2}{c^2 u} = \frac{3GMu}{c^2} = \frac{3GM}{c^2 r} =$$

$$= \frac{3}{2}\frac{2GM}{c^2 r} = \frac{3}{2}\frac{R_S}{r}$$

where R_S is the Schwarzschild radius and r represents the star radius (or radial coordinate) or larger.

Now, for ordinary stars $R_S \ll r$ and hence the provision is justified.

The reader should note that the "grazing" condition that associates this provision (and its alike) in the above derivation represents the worst case and hence the provision becomes stronger in the non-grazing case.

Note 4: The validity of the above derivation should be restricted to the weak gravitational field case where the spacetime is approximately flat. This may be suggested by a number of indications such as (tal como) defining d as "distance", using polar coordinates (also see exercise 5) and accepting straight line solution as a first approximation (which is based on

$$\boxed{u \gg \frac{3GMu^2}{c^2}}$$

and the smallness of

$$\boxed{\frac{GM}{c^2 d}}$$

). In fact, this restriction should be suggested by the question itself since "stars" usually generate weak gravitational fields (if we exclude neutron stars). This is also suggested by the use of terms like "typical star" and "ordinary star" (as well as other indications in the solutions of the upcoming Exercises).

Note 5: The above derivation

is based on a number of approximations and compromising assumptions (e.g. classical gravitational systems of weak gravity). Accordingly, the derived formula should have limited validity from these perspectives (at least as far as this derivation is concerned).

Note 6: We defined d as the distance of closest approach, But considering the initial straight-line solution it should be more appropriate to define it as the distance of impact (or impact parameter) where the supposed straight line is defined by the initial direction of the ray. However, we adopted as possible ease of comparison to the upcoming classical derivation; see exercise 8). Anyway, for the considered weak gravitational field case (where the deflection of light is very tiny) the difference between the two definitions should be practically negligible.
(insignificante)

→

Pág. 295(296) – Exercises

2. Accordingly, accelerating frames are considered as composition of series of inertial frames (i.e. instantaneous rest frames) where the deflection of light increases gradually as the speed of the frame increases.370

[370] → However, we should note that it is not true in general that the observations in an accelerating frame are the same as the observations in the instantaneous (inertial) rest frame (see for example § 10.1.1).

3. What is the significance of light bending by gravity?
Since we have no gravitated mass then we should also have no gravitating mass (as such) and therefore gravity is an effect of the spacetime geometry (which is the result of the mass-energy distribution) rather than (em vez de) a force in a technical sense.
∴ the bending of light by gravity can be derived in classical physics

(although it is quantitatively different to that of general relativity) and hence it is consistent with the theoretical framework of Newtonian gravity and its paradigms (such (to/ terms) as force and gravitational field) despite potential reservations on some derivation methods.

4. Show that $u = \frac{\cos\phi}{d}$ is a solution to the equation

$$\frac{d^2u}{d\phi} + u = 0$$

Answer:

This can be easily shown by inserting $u = \frac{\cos\phi}{d}$ into the equation $\frac{d^2u}{d\phi} + u = 0$, that is:

$$\frac{d^2u}{d\phi^2} + u = -\frac{\cos\phi}{d} + \frac{\cos\phi}{d} = 0$$

5. Verify that (a) the polar equation

$$\frac{1}{r} = \frac{\cos\phi}{d} \quad \left(\text{with } -\frac{\pi}{2} < \phi < \frac{\pi}{2}\right)$$

is an

equation of a straight line parallel to the y axis,

(b) the polar equation $\frac{1}{r} = \frac{\sin\phi}{d}$ (with $0 < \phi < \pi$) is an equation of a straight line parallel to the x axis.

Answer:

The transformation equations between polar coordinates (i.e. r and ϕ) and Cartesian coordinates (i.e. x and y) are:

$$r = \sqrt{x^2+y^2} \quad \cos\phi = \frac{x}{\sqrt{x^2+y^2}}$$

$$\sin\phi = \frac{y}{\sqrt{x^2+y^2}}$$

a) Transforming from polar coordinates to Cartesian coordinates we get:

$$\frac{1}{r} = \frac{\cos\phi}{d}$$

$$\frac{1}{\sqrt{x^2+y^2}} = \frac{x}{d\sqrt{x^2+y^2}}$$

$$x = d$$

which is the Cartesian equation of a straight line parallel to the y axis and intercepting the x axis at d.

b) Transforming again from polar to Cartesian we get:

$$\frac{1}{r} = \frac{\sin\phi}{d}$$

$$\frac{1}{\sqrt{x^2+y^2}} = \frac{y}{d\sqrt{x^2+y^2}}$$

$$y = d$$

which is the Cartesian equation of a straight line parallel to the x axis and intercepting the y axis at d.

6. Verify that:

$$u = \frac{\cos\phi}{d} + \frac{GM(2-\cos^2\phi)}{c^2d^2} \quad (330)$$

is a solution to the following equation:

$$\frac{d^2u}{d\phi^2} + u = \frac{3GM\cos^2\phi}{c^2d^2} \quad (331)$$

Answer:

We have

(equations) →

$$\frac{du}{d\phi} = -\frac{\sin\phi}{d} + \frac{2GM\cos\phi\sin\phi}{c^2d^2}$$

$$\frac{d^2u}{d\phi^2} = -\frac{\cos\phi}{d} - \frac{2GM\sin^2\phi}{c^2d^2} + \frac{2GM\cos^2\phi}{c^2d^2}$$

(332)

Pág. 297

On substituting from Eqs. 332 and 330 into the left hand side of Eq. 331, we get:

$$\frac{d^2u}{d\phi^2} + u = -\frac{\cos\phi}{d} - \frac{2GM\sin^2\phi}{c^2d^2} + $$

$$+ \frac{2GM\cos^2\phi}{c^2d^2} + \frac{\cos\phi}{d} +$$

$$+ \frac{GM(2-\cos^2\phi)}{c^2d^2}$$

$$= -\frac{2GM\sin^2\phi}{c^2d^2} + \frac{2GM\cos^2\phi}{c^2d^2} + \frac{2GM}{c^2d^2} -$$

$$\frac{GM\cos^2\phi}{c^2d^2}$$

$$= -\frac{2GM(1-\cos^2\phi)}{c^2d^2} + \frac{2GM\cos^2\phi}{c^2d^2} + \frac{2GM}{c^2d^2} -$$

$$\frac{GM\cos^2\phi}{c^2d^2}$$

$$= -\frac{2GM}{c^2d^2} + \frac{2GM\cos^2\phi}{c^2d^2} + \frac{2GM\cos^2\phi}{c^2d^2} +$$

$$\frac{2GM}{c^2d^2} - \frac{GM\cos^2\phi}{c^2d^2}$$

$$= \frac{3GM\cos^2\phi}{c^2d^2}$$

which is the right hand side of Eq. 331 and hence Eq. 330 is a solution to Eq. 331.

7. Show that for a light ray grazing a typical star,

$$\boxed{\frac{GM}{c^2d}\cos^2\phi}$$ is very small (i.e. close to zero).

Answer:

Let use the Sun as a typical star. So, for a light ray grazing the Sun, we have:

$$\frac{GM}{c^2d} \simeq \frac{6.674\times10^{-11}\times1.989\times10^{30}}{(3\times10^8)^2\times6.9551\times10^8}$$

$$\boxed{\simeq 2.121\times10^{-6}}$$

Moreover, according to our setting

(i.e. the light ray follows a path oriented along the y-axis orientation with very small deflection)

$\phi \simeq \frac{\pi}{2}$ and hence $\cos^2\phi \simeq 0$.

Accordingly, $\frac{GM}{c^2 d} \cos^2\phi$ is very small.

Note: the smallness of $\frac{GM}{c^2 d}$ can be verified more generally as follows:

$$\frac{GM}{c^2 d} = \frac{1}{2} \frac{2GM}{c^2 d} = \frac{1}{2} \frac{R_S}{d}$$

where R_S is the Schwarzschild radius. Now, for ordinary stars $R_S \ll d$ and hence $\frac{GM}{c^2 d}$ is very small.

✡

---

8. Derive a classical for light bending by stars (e.g. Sun) and hence show that the classical deflection is half the general relativistic deflection.

Answer: Let have a corpuscule of light whose mass is m and whose speed at infinity (i.e. very far away from the gravitating body) is c and hence its classical total energy (i.e. kinetic plus potential) is

$$E = \frac{1}{2} mc^2 > 0.$$

Now according to classical mechanics the orbit of this corpuscle in the gravitational field of a gravitating body is a hyperbola with the gravitating body being at one of its foci.[372]

[372] → In classical mechanics, the shape of the orbit of a gravitated body is

elliptic if $E < 0$,

parabolic if $E = 0$ and

hyperbolic if $E > 0$.

Due to the conservation of total energy (i.e. kinetic plus potential) in the conservative gravitational field the total energy of this corpuscle along its orbital path remains constant, i.e. $E = \frac{1}{2} mc^2$! Moreover, in classical mechanics the relation between the total energy E of a gravitated object of mass m that follows a hyperbolic path in the gravitational field of a gravitating object of mass M and the transverse semi-axis a of its hyperbolic path is given by:

$$E = \frac{GMm}{2a} \quad \text{that is} \quad a = \frac{GMm}{2E} \qquad (333)$$

Referring to Figure 10, we have

$$\tan\left(\frac{\delta\phi}{2}\right) = \frac{a}{b} = \frac{GMm}{2Eb} = \frac{GMm}{mc^2 b} = \frac{GM}{c^2 b}$$

where b is the conjugate semi-axis of the hyperbolic path and where in step 2 we substituted from Eq. 333 while in step 3, we used $E = \frac{1}{2} mc^2$. Now, if we consider that the deflection of light by gravity in classical systems is very tiny (i.e. $\delta\phi$ is very small) then we can use the tangent approximation for small angles in the last equation, that is:

$$\tan\left(\frac{\delta\phi}{2}\right) \simeq \frac{\delta\phi}{2} = \frac{GM}{c^2 b} \quad \text{that is}$$

$$\delta\phi \simeq \frac{2GM}{c^2 b}$$

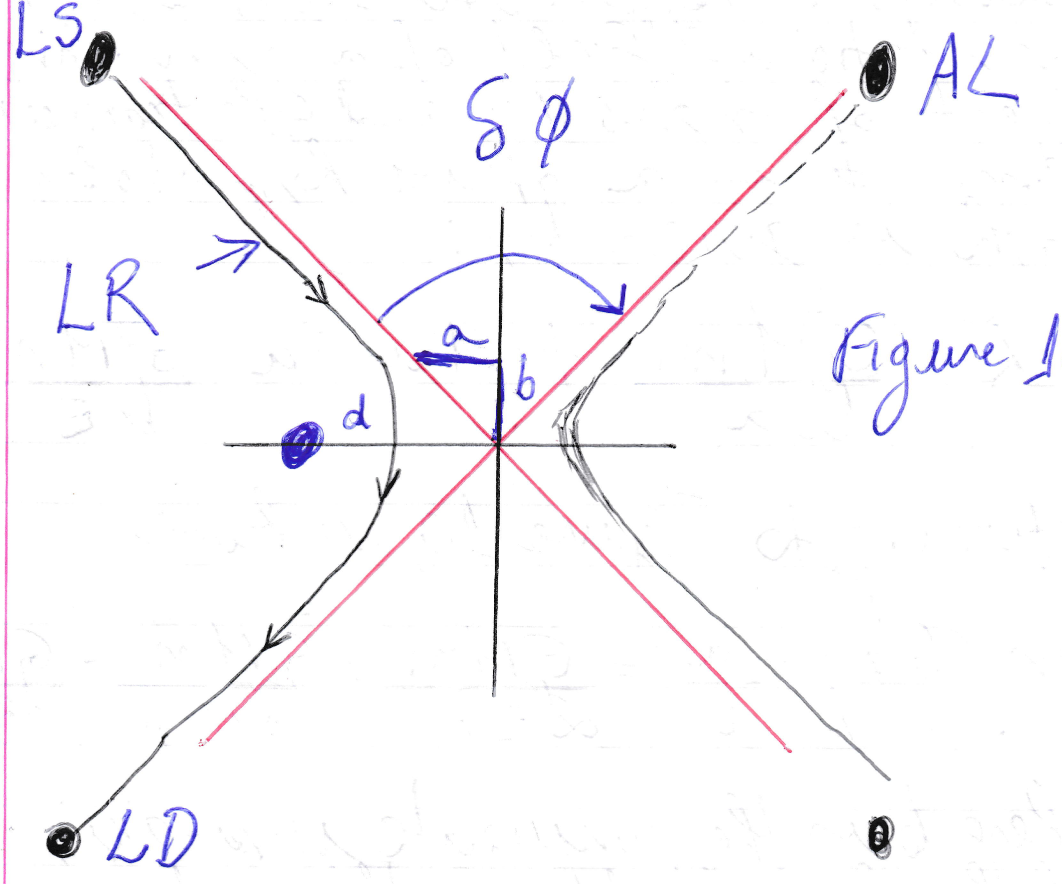

Figure 10: A simple sketch depicting the deflection of a light ray LR emitted from a light source LS as the ray passes by a gravitating body GB toward a light detector LD and hence the ray is deflected by an angle δφ causing the image of LS to be visually displaced and thus it is seen at an apparent location AL. The other symbol in the sketch are explained in the text.

Pag. 298 (299) –

To compare this classical formula with the general relativistic formula (i.e. $\delta\phi \simeq \frac{4GM}{c^2 d}$) we need to find the relation between b and d. Now, d in the general relativistic setting is the distance of closest approach and hence it corresponds in the classical setting to the distance the focus (where the gravitating body is located) and the vertex of the hyperbolic branch that represents the path (see Figure 10). Accordingly, we should have:

$$d = \sqrt{a^2+b^2} - a \qquad (334)$$

$$d + a = \sqrt{a^2+b^2}$$

$$(d+a)^2 = a^2 + b^2$$

$$d^2 + 2da + a^2 = a^2 + b^2$$

$$d^2 + 2da = b^2$$

$$b = \sqrt{d^2 + 2da}$$

$$b = d\sqrt{1 + 2(a/d)}$$

where we used standard relations from

the geometry of hyperbola (the unfamiliar reader should refer to the literature of conic sections).

Now, since the deflection is very tiny (and hence the hyperbola is highly eccentric) then from the properties of hyperbola we should have

$a \ll d$ and hence $(a/d) \simeq 0$

and $b \simeq d$, that is

$$\delta\phi \simeq \frac{2GM}{c^2 d}$$

As we see, this classical deflection is half the general relativistic deflection, i.e. $\delta\phi \simeq \frac{4GM}{c^2 d}$.

Note: The implicit assumption of the variation of the speed of light over its path in the gravitational field (because the conservation of the variation of the speed of light over its path in the gravitational field (because the conservation of kinetic-plus-potential energy requires the speed of light to vary along its path as the potential varies along this path). ... We should also note that the approximation $b \simeq d$ may also be obtained (possibly more directly) from Eq. 334 because the tininess of the deflection means that $a \ll b$ and hence from Eq. 334, we can conclude that $d \simeq b$. 20231128200000

20231129 083000///
Pág. 299 (300) →

10. Calculate the deflection of a light ray grazing the Sun.

Since the ray is grazing, then d in the formula of light deflection represents the Sun radius (or radial coordinate ~~nott~~ noting that the difference between the two is negligible in theses classical systems) which is about 6.9551×10^{8} m. Accordingly:

$$\delta\phi = \frac{4GM}{c^2 d} \simeq \frac{4 \times 6.674\times 10^{-11} \times 1.989\times 10^{30}}{(3\times 10^{8})^2 \times 6.9551 \times 10^{8}}$$

$$\simeq 8.483 \times 10^{-6}\ \text{rad} \simeq 1.7497\ \text{arcsec}.$$

This, of course, is the general relativistic value. the classical value is half this.

14. light deflection formula $\delta\phi$

$\frac{2GM}{c^2 d}$ in classical physics and

$\frac{4GM}{c^2 d}$ in general relativity.

15. Show formally that the deflection of a gravitational lens decreases with the

increase of the distance of closest approach of the deflected ray.

From the light bending formulae (i.e. $\delta\phi = \frac{4GM}{c^2 d}$ in general relativity and $\delta\phi = \frac{2GM}{c^2 d}$ in classical gravity).

we see that the angle of deflection $\delta\phi$ is inversely proportional to the distance of closest approach d (i.e. the farthest rays are least deflected).

This is unlike the bending of (convex) optical lenses where the deflection of ray is directly proportional to the distance of the deflected ray from the central axis (and this is behind the focusing nature of optical lenses).

16. Show that the deflection of light by gravity can be considerable only if the gravitating object is compact (e.g. black hole)

The relativistic and classical light bending formulae can be written (respectively) in terms of the Schwarzschild radius R_S of the gravitating object as:

$$\delta\phi = \frac{2R_S}{d} \quad \text{and} \quad \delta\phi = \frac{R_S}{d}$$

Now, since $R_S \ll d$ unless the gravitating object is compact (where d can be comparable to R_S) then the deflection can be considerable only if the gravitating object is compact.

17. Show that in gravitational lensing the lensed object cannot be observed when the distance of the observer from the lens is less than a certain amount, and give an estimate of this amount.

Because the distance of closest approach d has a minimum limit (which is the radius R of the lens) the lensed object cannot be observed when the distance D of the observer from the lens is less than a certain amount. In fact, we can make a rough estimation of this amount using the tangent approximation of small angle, i.e. $\delta\phi \simeq \tan(\delta\phi) \simeq d/D$ and hence:

$$D_m \simeq \frac{d_m}{\delta\phi_x} = \frac{c^2 R^2}{4GM} \quad \text{where}$$

D_m is the minimum distance between the observer an the lens (for successful observation), d_m is the minimum limit of d and $\delta\phi_x$ is the maximum possible deflection, and where in the second step we used the general relativistic formula $\delta\phi = \frac{4GM}{c^2 d}$

with $\delta\phi \equiv \delta\phi_x$ and

$$d \equiv d_m = R.$$

In fact, this estimation is based on other approximations and hence it should represent an order of magnitude estimation. However, all these approximations do not affect the main point which is the requirement of a minimum limit on the distance between the observer and the lens
(for successfull observation).

Cassirer and Klein on the Geometrical Foundations of Relativistic Physics.

Abstract: Several studies have emphasized the limits of invariance-based approaches such as Klein's and Cassirer's when it comes to account for the shift (para a mudança) from the spacetimes of classical mechanics and of special relativity to those of general relativity.

... derived from Riemann rather than Klein.

Pág. 91 (99) → Norton's suggestion is that Einstein's theory of gravitation shows a combination of these strategies: While following Riemann in the determination of metrical properties, he relied on Klein, ~~info~~ insofar (enquanto) as he deprived his coordinate system of all but topological properties.

Pág. 92 (100) - 4.2.
Felix Klein's Argument from Projective Geometry.

In Norton's reconstruction, Klein's subtractive (-) approach was modeled on projective geometry and the geometries of metrical space of zero or constant curvature.

In 1871, he presented a model of non-Euclidean geometry based on the analytic treatment of projective geometry by means of the algebraic theory of invariants.

Klein used a projective metric first studied by Arthur Cayley to derive the three principal cases of geometries of metrical space of constant curvature, that is parabolic, elliptic, and hyperbolic (corresponding to a manifold of null, more or less than zero, respectively).[3]

[3] - Cayley in his "Sixth Memoir up Quantics" (1859) had limited himself to show that his projective system included (Euclidean) metrical. Klein was the first to derive the non-Euclidean cases (i.e. elliptic and hyperbolic geometries).

Pág. 102 (119) —

We can introduce a bigger spacetime: the spacetime of everything, and embed the spacetime of mathematics into the spacetime of everything as a subspace.

Now imagine a surface S such as the sphere S^2 embedded in the space $\mathbb{R}^3$.
There are two kinds of geometry of S. The extrinsic (or rather external?) geometry of the surface

S is concerned with the geometry and shape of S such as the bending or curvature with respect to the ambient space $\mathbb{R}^3$, and has probably been studied since antiquity (think of conic sections in the Greek mathematics).

It was Gauss who initiated the intrinsic geometry (or should we say "internal geometry"?) of the surface S.

Then Riemann vastly generalized the intrinsic geometry to higher dimensional abstract manifolds in his famous lecture

"On the hypotheses which lie at the foundations of geometry"

4) Probably to a lesser degree, Poincaré's use of the hyperbolic geometry in his works on Fuchsian functions, which put hyperbolic geometry into the main stream of mathematics,[32]
before that the main interest was more philosophical, as Poincaré explained in his extensive self-analysis of his scientific works (Poincaré 1921, § II)[33],
and his works in topology which have changed the landscape of mathematics in the twentieth century.

[32] → This use of the hyperbolic plane by Poincaré was a starting point of many great theories and major results in mathematics. For example, the hyperbolic plane is a special case of symmetric spaces introduced by É. Cartan, which are Riemannian manifolds whose curvature tensor has zero covariant derivative and include and are more general than

Riemannian manifolds with constant curvature.

... and the uniformization of Riemann surfaces through surfaces of constant curvature, in particular hyperbolic surfaces, has also led to Thurston's geometrization program in geometry and topology, which was proved by Grigori Perelman in 2002-2003.

[33] - Here we are mainly (principalmente) talking about the specific non-Euclidean geometry given by the hyperbolic geometry but not the general non-Euclidean geometries. Otherwise, as José Ferreirós pointed out, it will be necessary to enter into extensive discussions related to philosophical issues and applications of non-Euclidean geometries in mathematical physics.

... the geometrical methods employed by Newton in Section 2 and 3, Book 1, of the second edition of his Principia in which he resorted (recorreu) to the

radius of curvature[1]

(Nauenberg, 1994; Brackenridge, 1995, pp. 79-85)

[1] → These methods are based on the fact that the normal component of force is

proportional to the speed squared and inversely proportional to the radius of curvature.

Pag. 132(147) → 5.2

Propositions 39-41, Book 1.

They deal with the motion of a point mass in a spherically symmetric potential $V(r)$. The corresponding central force is

$$F = \frac{dV}{dr}\hat{r} \qquad (5.1)$$

Where $\hat{r}$ is the unit vector pointing away from the centre of force. Without loss of generality we can assume that the mass is $m = 1$. Indeed, this is a one-body problem (a body attracted by a centre of force) and no use is made of the third law of motion.

5.2.1. Proposition 39

In Proposition 39, Newton considers a "body" moving in a straight line ADE under the action of a centripetal force (see Fig. 5.1)

He shows that the square of the speed is proportional to the area subtended under the curve that represents the variation of the force's intensity as a function of distance.

In Fig. 5.1 a body is falling from rest in A towards the center of force C.

Klein and Lie on the Differential Geometry of Kummer Surfaces

Kummer surfaces, which arise naturally in line geometry, and quartics with a double conic curve. A special case of the latter had been studied by Gaston Darboux and Théodore Moutard in the context

of sphere geometry.
When the double conic is the imaginary sphere-circle that lies on all spheres, Darboux showed that the lines of curvature of this quartic are algebraic curves of the 8th degree.
Using his mapping, Lie realized these curves must go over into asymptotic curves of degree 16 on the corresponding Kummer surface.

Pág. 181 (195) →
Asymptotic curves are only visible in regions of negative curvature as they are otherwise imaginary curves.

Pág. 328 (338) – 13.7

Bernhard Riemann

Thus, as for Gauss and Lobachevsky, "space" for Riemann means physical space and geometry describes the metric relations of this space.
And like Gauss and Lobachevsky, Riemann was willing (estava disposto) to entertain the possibility that Euclidean geometry does not give the best description

of physical space. Indeed (de fato) compared to Gauss and Lobachevsky, Riemann extended the a priori possible manifolds to manifolds with other dimensions than three and to manifolds that are described by a Riemannian metric that has varying curvature.

Pag. 329 (339) - 13.8

Beltrami's Real Substrate:

Beltrami is often given the honor of having proved the consistency of non-Euclidean geometry and thus the impossibility of proving the parallel postulate.

This is true in the following sense:

On the basis of Gauss' intrinsic theory of surfaces, Beltrami showed in 1868 that the geometry on a surface with constant negative Gauss curvature is the same as Lobachevskian non-Euclidean geometry.

Schwab and his critics

(1743–1821)

In a 1791 issue of the journal, Schwab published a paper against Schultz, and offered an analytic proof of the fact that

one side of a triangle is shorter than the sum of the other two.

Pág. 528 (533) – Schwab →

He set himself no less an aim (also) than to resuscitate

Leibniz' "analysis situs"

and prove the PARALLEL POSTULATE.

Schwab's first work on the topic is a "Tentamen novae parallelarum theoriae", published in 1801, in which he presented his epistemological view and a new theory of parallel.

This was later supplemented by a longer essay in French, the "Essai sur la situation" from 1808, which expounded Schwab's more general views about Leibniz's project of an analysis situs.

And finally by a Commentatio on the First Book of the Elements (1814), in which Schwab attempted to reform elementary geometry and prove all the axiom in Euclid.[46]

[46] → ... in a few of them he restated his geometrical examples and the theory of parallels.

Nonetheless (no entanto) he did not not write those eight volumes on the theory of parallel that De Morgan found somewhere attributed to him:

"Eight volumes on the theory of parallels? If there be such a work, I trust I and it never meet, though ~~neve~~ ever so far produced" (De Morgan, 1915, vol. 1, p. 230)

Book: De Morgan, A Budget of Paradoxes" → 1915.

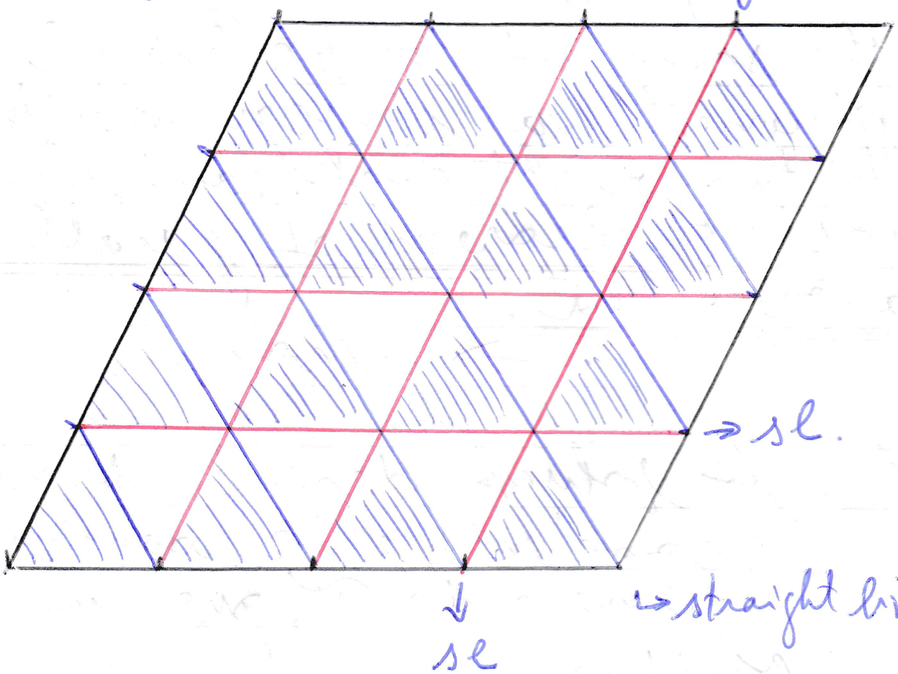
In the Light of Physiological,
Psychological and Physical Inquiry-
2007.pdf
→151 pages (1943)-Pág.59(62)



Equal and similar triangles placed in paving alongside one another with their bases in one and the same straight line.

If a triangle be displaced in a plane along a straight line (without rotation), all its points, including those of its bounding lines, will describe equal paths.

The same bounding line will furnish, therefore, in any two different portions, a system of two straight lines equal distant from one another at all points and the operation coincidently vouches (garantir) for the equality of the angles made by the line of displacement on corresponding sides of the two straight lines.

The sum of the interior angles on the same side of the line of displacement was consequently determined to be two right angles and thus EUCLID'S theorem of parallel was reached.

⟹ wrong!!!

Obs: A solução depende da nova geometria e do novo (valor) número do π, que eu chamo M.U.S.
(Mathematical
Uniforme
Space)

✡ ✡

Neste caso, Fifth Postulate of Euclid or Parallel Postulate poderá haver duas soluções, uma paralela e a outra que (ela) as retas se interceptam dentro do sistema de cálculo.

cont. Pag. 60(63) →

The sliding of a triangle along a ruler has remained to this day the simplest and most natural method of drawing parallel lines.

It is scarcely necessary to remark the theorem of parallel and the theorem of the angle-sum of a triangle are inseparably connected and represent merely different aspects of the same experience.

Pag. 74(77) –

If an oblique-angle triangle having the sides a, b, and c be displaced in the direction of the side b, only a and c will, by the principle above stated, describe equivalent parallelograms, which are alike in an equal pair of parallel sides on the same parallels. If a make with b a right angle, and the triangle be displaced at right angles to c, the distance c, the side c will describe the square c^2 while the two other sides will describe parallelograms the combined areas of which are equal to the area of the square. But the two parallelograms are, by

the observation which just precedes,
equivalent respectively to
$\underline{a^2 \text{ and } b^2}$ —
and with this the Pythagorean theorem
is reached.

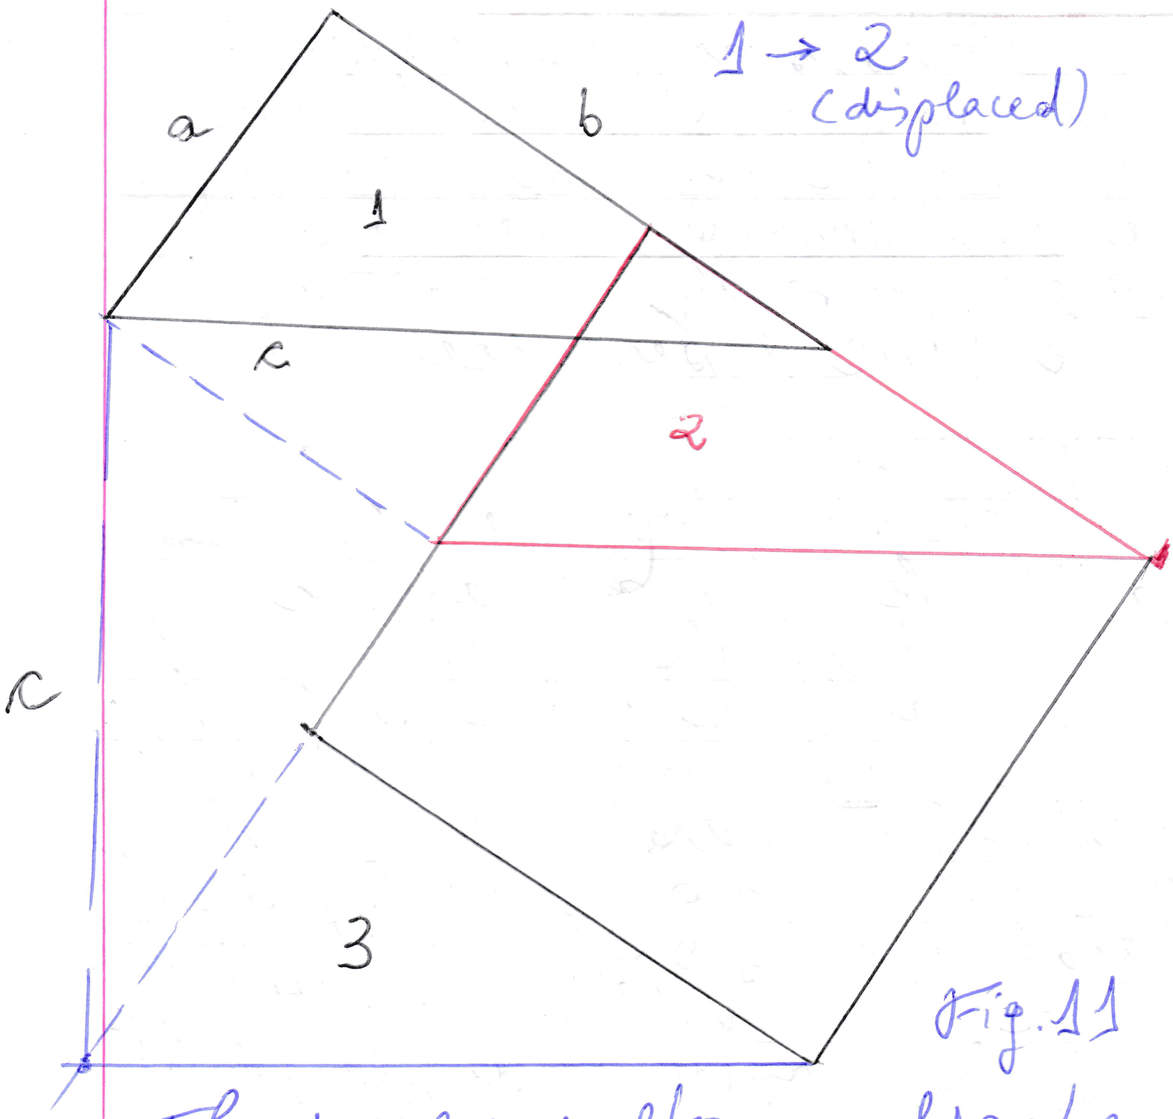


Fig. 11

The same result may also be attained by first sliding the triangle a distance a at right angle to a, and then a distance b at right angles to b, where

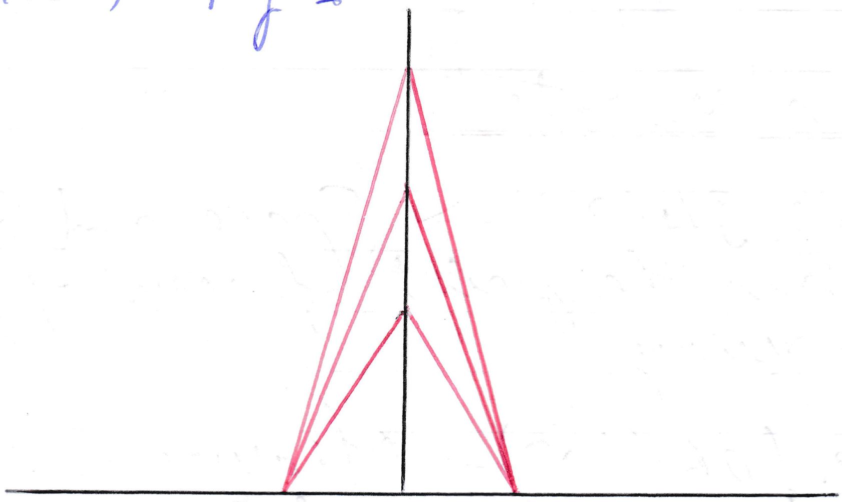
$a^2 + b^2$ will be equal

to the sum of the surfaces swept out by c, which is obviously c^2.

Taking an oblique angle triangle, the same procedure just as easily and obviously gives the more general proposition,

$$c^2 = a^2 + b^2 - 2ab\cos\gamma.$$

Pag. 77(80) - Fig. 12



It is possible without a special angular measure to determine the straight line that cuts another straight line at right angles by making all its points equidistant from two points in the first straight line lying at equal distances from the point of intersection.

The bisector of an angle can be determined in a quite similar manner, and by continued bisection an angular unit can be derived of any smallness we wish.

A straight line parallel to another

straight line can be defined as one, all of whose can be translated by congruent curved or straight paths into points of the first straight line[1].

[1] → If this form had been adopted, the doubts as to the Euclidean theorem of parallel would probably have risen much later.

Interessante!!!

Pág. 94(97) → Space and Geometry from the point of view of physical inquiry

Pág. 106(109) – Measure of Curvature, and Curvature of Space.

Gauss's measure of the curvature of a surface at any point is given by the expression

$$k = \frac{d\sigma}{ds}$$ where

ds is an element of the surface and

dσ is the superficial element of the unit-sphere the limiting radii of which are parallel to the limiting normals of the element ds.

This measure of curvature may also be expressed in the form

$$k = \frac{1}{\rho_1 \rho_2},$$

where ρ_1, ρ_2 are the radii of curvature of the surface at the point in question.

Of special interest are the surfaces whose measure of curvature for all points has the same value, — the surfaces of constant curvature.

Interessante!!!

Conceiving the surfaces as infinitely thin, non-distensible but flexible bodies, it will be found that surfaces of like curvature may be made to coincide by bending, as for example a plane sheet of paper wrapped round a cylinder or cone, but cannot be made to coincide with the surface of a sphere.

During such deformation, nay (no), even on crumpling, the proportional parts of figures drawn in the surface remain invariable as to lengths and angles, provided we do not go out of the two dimensions of the surface in our measurements.

Conversely (por outro lado), likewise (da mesma forma), the curvature of the surface does not depend on its conformation in the third dimension of space, but solely upon its interior proportionalities.

Riemann now conceived the idea of generalizing the notion of measure of curvature and applying it to spaces of three or more dimensions.

Conformably thereto, he assumes that finite unbounded spaces of constant positive curvature are possible, corresponding to the unbounded but finite two-dimensional surface of the sphere, while what we commonly take to be (infinite) infinite space would correspond to the unlimited plane of curvature zero, and similarly a third species of space would correspond to surfaces of negative curvature.

Just as the figures drawn upon a surface of determinate constant curvature can be displaced without distortion upon this surface only (for example, a spherical figure on the surface of its sphere only, or a plane figure in its plane only), so should analogous conditions necessarily hold for spatial figures and rigid bodies.

The latter are capable of free motion only in spaces of constant curvature, as Helmholtz has shown at length.

Just as the shortest lines of a plane are infinite, but on the surface of a sphere occur as great circles of definite finite length, closed and reverting into themselves, so Riemann conceived in the three-dimensional space of positive curvature analogues of the straight lines and the plane as finite but unbounded.

Pág. 114 (117) –

Euclid's Fifth Postulate

→

Fifth Postulate (also called the Eleventh Axiom and by some the Twelfth):

"If a straight line meet two straight lines, so as to make the two interior angles on the same side of it taken together less than two right angles, these straight lines being continually produced, shall at length meet upon that side on which are the angles which are less than two right angles".

IMPORTANT:

Euclid easily proves that if a straight line falling on two other straight lines makes the alternate angles equal to each other, the two straight lines will not meet but are parallel.

㉔ Obs: Com a nova geometria haverá uma prova qual, que estas retas se encontrarão e ainda assim, continuarão paralelas dentro do contexto da nova matemática e do novo número pi, M.U.S. < pi.

But for the proof of the converse (prova do inverso), that parallels make equal alternate angles with every straight line falling on them, he is obligeld to resort to the Fifth Postulate.

This converse is equivalent to the proposition that only one parallel to a straight line can be drawn through a point.

Further, by the fact that with the aid of this converse it can be proved that the sum of the of the angles of a triangle is equal to two right angles and that from this last theorem again the first follows the relationship between the propositions in question is rendered distinct and the fundamental significance of the Fifth Postulate for Euclidean geometry is made plain.

IMPORTANT :

Com a nova geometria hiperelíptico, a soma dos ângulos de um triângulo será diferente do valor de dois ângulos retos.

Pág. 116 - Saccheri's Theory of Parallels.
(119)

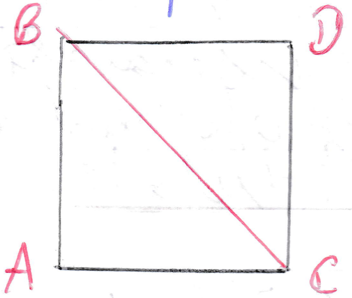


Fig. 16

Let us consider, for example, two congruent isosceles triangles ABC, DBC having right angles at A and D (Fig. 16), and let them be laid together at their hypothenuses BC so as to form the equilateral quadrilateral ABCD.

The first twenty-seven propositions of Euclid do not suffice to determine the character and magnitude of the two equal (right) angles at B and C.

Obs:

✡ Estes ângulos serão diferentes, ou seja, estes ângulos terão um outro número em decorrência da geometria hiperelíptica.

For measure of length and measure of angle are fundamentally different and directly not comparable; hence the first propositions regarding the connection of sides and angles are qualitative only, and hence the imperative necessity of a quantitative theorem regarding angles, (like that of the angle-sum.)

Be it further remarked that theorems analogous to the twenty-seven planimetric propositions of Euclid may be set up for the surface of a sphere and for surfaces of constant negative curvature and that in these cases the analogous construction gives respectively obtuse and acute angles at B and C.

Obs: surface of a sphere → obtuse
surface of constant
negative curvature → acute.   Book

⇙

Saccheri →
Euclides ab omni naevo vindicatus.
Milan, 1733.
German translation in Engel and Staeckel's Die Theorie der Parallelinien. Leipsic, 1895.

Pág. 117(120)- Saccheri

If the Fifth Postulate is involved in the remaining assumption of Euclid,
